Experimental proof of the postulated theory is rather difficult as we have to measure living cells or subcellular structures of micrometer or submicrometer dimensions. Measurement method of electromagnetic emission from individual cells using special microelectronic sensors is described e.g. in Ref. [32]. Each detection structure in a microelectronic sensor has two electrodes 10 μm wide with a small gap between them. The electromagnetic emission of a sedimented cell at the gap is measured. The measurement results are promising. Nonetheless, the microtubular structures organized inside a cell need not be a source of electromagnetic emission from the cell. Two needle electrodes pricked inside a cell may be more convenient for measurement of the oscillating electric field generated by microtubules.

9. Conclusions

Microtubules satisfy conditions for excitation of vibrations and energy condensation. The damping effects of cytosol viscosity are minimized by slip layer at the boundary between the microtubule and cytosol. Formation of the slip layer depends on large deformability of microtubules at low stress and on the ionic layer at their surface. Energy supplied to the microtubule from the hydrolysis of GTP to GDP may be sufficient for excitation.

Extended objects in quantum systems and soliton solutions

H. Matsumoto, P. Sodano, and H. Umezawa
Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1
(Received 28 July 1978; revised manuscript received 23 October 1978)

It is shown that the soliton solutions of the classical Euler equations are closely related to the extended objects created in quantum many-body systems. The general argument is supplemented by a concrete example which shows how the boson transformation applied to a quantum system leads to the static soliton solution in the $(1+1)$-dimensional $\lambda\phi^4$ model.

There has recently been an active interest in the study of extended objects which are described by the soliton solutions of the Euler equations for classical fields (say ϕ).[1] The Ginzburg-Landau equation[2] can also be regarded as a kind of Euler equation in which ϕ is the order parameter. In parallel to the study of soliton solutions of the Euler equations, we have been formulating a systematic method for the construction of extended objects which appear in quantum many-body systems.[3] This method begins with a set of Heisenberg equations for quantized fields (say ψ) and makes use of the so-called boson transformation method[4] to obtain those states in which classically behaving extended objects and quantum modes coexist. This method has been applied to the study of extended objects in various ordered states such as dislocations, grain boundaries, point defects and surface sound waves in crystals[5] and vortices, surface electromagnetic waves, Josephson currents in superconductors, etc.[4,6]

The aim of this paper is to present a brief description of the relation between the above-mentioned two approaches in the study of extended objects. In particular, it will be pointed out that the extended objects constructed by the boson method become the soliton solutions of the Euler equations when the Planck constant, h, is ignored, implying that the soliton solutions can be regarded as the extended objects with quantum origin. We feel that this consideration sheds light on the question about the gap between the classical and quantum physics.

Let us begin with a brief summary of the boson method. Consider a Heisenberg equation

$$\Lambda(\partial)\psi = F[\psi]. \tag{1}$$

To make the essence of the boson method transparent, we first consider a simple case, in which no composite particles appear and the perturbative expansion method is usable. We assume also that ψ is a scalar field. Equation (1) leads to the Yang-Feldman equation

$$\psi = \varphi^{\text{in}} + [\Lambda(\partial)]^{-1}F[\psi], \tag{2}$$

where φ^{in} is a free boson field satisfying

$$\Lambda(\partial)\varphi^{\text{in}} = 0. \tag{3}$$

It is important to note here that the mass in the $\Lambda(\partial)$ is the physical mass and, therefore, that φ^{in} is renormalized (or physical) free field. To understand this, we rewrite (2) in the form

$$\langle a|\psi(x)|b\rangle = \langle a|\varphi^{\text{in}}|b\rangle + (-i)\int d^4y\Delta(x-y)\langle a|F_y[\psi]|b\rangle, \tag{4}$$

where the states $|a\rangle$ and $|b\rangle$ are the ones in the Fock space of φ^{in}, and $F_y[\psi]$ means $F[\psi]$ at the space-time position y. The function $\Delta(x)$ in (4) is the Green's function

$$\Lambda(\partial)\Delta(x) = i\delta(x). \tag{5}$$

The second term on the right-hand side of (4) diverges unless $\langle a|F_y[\psi]|b\rangle$ vanishes in a reasonable manner at the limit $t_y \to \pm\infty$. To avoid this divergence we must choose φ^{in} to be the renormalized one. The above argument implies that we regard the Heisenberg equation as an equation among matrix elements (i.e., the weak relation). All the equations for Heisenberg operators in the following should be understood as weak relations.

When we solve (2) by successive iteration, we are led to the usual perturbative expansion. The result is an expression of ψ in terms of φ^{in},

$$\psi(x) = \psi[x:\varphi^{\text{in}}], \tag{6}$$

which is called the dynamical map.[7]

Let us now introduce a c-number function $f(x)$ which satisfies

$$\Lambda(\partial)f = 0. \tag{7}$$

Then we can generalize the Yang-Feldman equation as

$$\psi = \varphi^{\text{in}} + f + [\Lambda(\partial)]^{-1}F[\psi], \tag{8}$$

which obviously satisfies (1). Solving (8) by successive iteration, we obtain a new solution of (1),

 ©1979 The American Physical Society

$$\psi^f(x) = \psi(x:\varphi^{\text{in}} + f). \tag{9}$$

Note that ψ^f is equal to ψ in which φ^{in} is replaced by $\varphi^{\text{in}} + f$ (the boson transformation). The fact that both ψ and ψ^f satisfy the same Heisenberg equation (1) is the content of the boson transformation theorem,

$$\Lambda(\partial)\psi^f = F[\psi^f]. \tag{10}$$

Let us now introduce the c-number field ϕ^f as

$$\phi^f = \langle 0|\psi^f|0\rangle. \tag{11}$$

When we ignore h (the Planck constant), ϕ^f will be denoted by ϕ_0^f,

$$\phi_0^f = \lim_{h\to 0}\phi^f. \tag{12}$$

Note that now the difference between the vacuum expectation value of the product of ψ^f and the product of the vacuum expectation value of ψ^f is due to the contraction of in-fields, which creates the loop diagrams in the course of successive iteration applied to (2). Since the contraction of in-fields creates terms which vanish at $h=0$, we can write

$$\langle 0|F[\psi^f]|0\rangle = F[\phi^f] + O(h), \tag{13}$$

where $O(h)$ stands for those terms which vanish at $h=0$. Thus (8) leads to

$$\phi_0^f = f + [\Lambda(\partial)]^{-1}F[\phi_0^f], \tag{14}$$

which gives the classical Euler equation

$$\Lambda(\partial)\,\phi_0^f = F[\phi_0^f]. \tag{15}$$

The above argument shows that ϕ_0^f is given by tree diagrams only.

Summarizing, when we calculate $\psi(x:\varphi^{\text{in}})$ by means of the tree approximation, the vacuum expectation value of the boson-transformed one (i.e., $\langle 0|\psi^f|0\rangle$) gives ϕ_0^f which satisfies the classical Euler equation.

Let us now illustrate the construction of the soliton solution ϕ_0^f from the boson transformation by using the following model of (1+1) dimensions:

$$(-\partial^2 - \mu^2)\psi(x) = \lambda\psi^3(x). \tag{16}$$

Here $x=(x_0, x_1)$ and $\psi(x)$ is a scalar Heisenberg field. We are particularly interested in finding what choice of the boson transformation function $f(x)$ leads to the static soliton solution.

Using the notation

$$v \equiv \langle 0|\psi(x)|0\rangle, \tag{17}$$

we define the Heisenberg operator $\rho(x)$ by the relation

$$\psi(x) = v + \rho(x). \tag{18}$$

Equation (16) then leads to

$$(-\partial^2 - m^2)\rho(x) = \tfrac{3}{2}mg\rho^2(x) + \tfrac{1}{2}g^2\rho^3(x), \tag{19}$$

and also to $\lambda v^2 = -\mu^2$. Here $g=\sqrt{2\lambda}$ and $m^2 = 2\lambda v^2$. Let ρ^{in} denote the in field which is the asymptotic limit of ρ. We have

$$(-\partial^2 - m^2)\rho^{\text{in}}(x) = 0. \tag{20}$$

In the following we consider the extended objects created by the condensation of ρ^{in}. The tree approximation leads to the following dynamical map for ρ:

$$\rho(x) = \rho^{\text{in}}(x) + \tfrac{3}{2}mg(-i)\int d^2y\Delta(x-y):[\rho^{\text{in}}(y)]^2: + \left\{\tfrac{1}{2}g^2(-i)\int d^2y\Delta(x-y):[\rho^{\text{in}}(y)]^3: + \tfrac{9}{2}m^2g^2(-i)^2\int d^2yd^2z\Delta(x-y)\Delta(y-z):\rho^{\text{in}}(y)[\rho^{\text{in}}(z)]^2:\right\} + \cdots. \tag{21}$$

Here $\Delta(x-y)$ is the Green's function satisfying

$$(-\partial^2 - m^2)\Delta(x-y) = i\delta^{(2)}(x-y). \tag{22}$$

We put (21) in the form

$$\rho(x) = \sum_{n=1}^{\infty}\rho^{(n)}(x), \tag{23}$$

where n denotes the order of the normal products. Then the following relation holds in the tree approximation:

$$\rho^{(n)}(x) = \tfrac{3}{2}mg(-i)\int d^2y\,\Delta(x-y):\sum_{i+j=n}\rho^{(i)}(y)\rho^{(j)}(y): + \tfrac{1}{2}g^2(-i)\int d^2y\,\Delta(x-y):\sum_{i+j+k=n}\rho^{(i)}(y)\rho^{(j)}(y)\rho^{(k)}(y):. \tag{24}$$

We now perform the boson transformation

$$\rho^{\mathrm{in}}(x) \to \rho^{\mathrm{in}}(x) + f(x), \tag{25}$$

where the c-number function f satisfies

$$(-\partial^2 - m^2) f(x) = 0. \tag{26}$$

Denoting the boson-transformed ρ-field operator by ρ^f, we have

$$\phi_0^f(x) = v + \langle 0 | \rho^f(x) | 0 \rangle. \tag{27}$$

We consider the static case. The space coordinates $x_1, y_1, \ldots$ will be simply denoted by $x, y, \ldots$. Then (26) and (27) read

$$\frac{d^2}{dx^2} f(x) = m^2 f(x) \tag{28}$$

and

$$\phi_0^f(x) = v + f(x) + \tfrac{3}{2} mg \int dy\, K(x-y) f^2(y) + \left[\tfrac{1}{2} g^2 \int dy\, K(x-y) f^3(y) + \tfrac{9}{2} m^2 g^2 \int dy\, K(x-y) f(y) \int dz\, K(y-z) f^2(z) \right] + \cdots, \tag{29}$$

where the Green's function $K(x-y)$ is defined by

$$\left(\frac{d^2}{dx^2} - m^2 \right) K(x-y) = \delta(x-y). \tag{30}$$

The recurrence relation (24) becomes

$$\rho_f^{(n)}(x) = \tfrac{3}{2} mg \int dy\, K(x-y) : \sum_{i+j=n} \rho_f^{(i)}(y) \rho_f^{(j)}(y) : + \tfrac{1}{2} g^2 \int dy\, K(x-y) : \sum_{i+j+k=n} \rho_f^{(i)}(y) \rho_f^{(j)}(y) \rho_f^{(k)}(y) :. \tag{31}$$

As a solution of (28), we choose $f(x)$ which diverges at $x = -\infty$ and regular at $x = \infty$; $f(x) = A \exp[-mx]$. Since $f(x)$ diverges at $x = -\infty$, we choose the Green's function K in such a way that $K(x-y) = 0$ for $x > y$:

$$K(x) = -\theta(-x) \frac{1}{m} \sinh mx. \tag{32}$$

Noticing that $\rho_f^{(1)}(x) = f(x)$, we can easily see from (31) that

$$\rho_f^{(n)}(x) = C_n (e^{-mx})^n, \tag{33}$$

and C_n satisfy the recurrence formula

$$C_n = \frac{1}{m^2(n^2-1)} \left(\tfrac{3}{2} mg \sum_{i+j=n} C_i C_j + \tfrac{1}{2} g^2 \sum_{i+j+k=n} C_i C_j C_k \right), \quad (n \geq 2), \tag{34}$$

$C_1 = A$.

Solving (34), together with the relation $v = m/g$, we have

$$C_n = 2v \left(\frac{A}{2v} \right)^n, \tag{35}$$

which leads to

$$\phi_0^f(x) = v + 2v \sum_{n=1}^{\infty} \left(\frac{A}{2v} e^{-mx} \right)^n = v \frac{1 + (A/2v) e^{-mx}}{1 - (A/2v) e^{-mx}}. \tag{36}$$

When A is chosen as

$$A = -2ve^{ma}, \tag{37}$$

the $\phi_0^f(x)$ is obtained as

$$\phi_0^f(x) = v \tanh[(m/2)(x-a)], \tag{38}$$

which is the well-known static solution of the Euler equation

$$(-\partial - \mu^2) \phi_0^f(x) = \lambda [\phi_0^f(x)]^3. \tag{39}$$

When $A = 2ve^{ma}$, $\phi_0^f(x)$ is given by

$$\phi_0^f(x) = v \coth[(m/2)(x-a)], \tag{40}$$

which is another solution of (39).

For the static case, (38) and (40) are the only solutions which satisfy (39) with the condition $\phi_0^f(x) \to v (x \to \infty)$. The choice of $f(x)$ and the Green's function $K(x)$ is restricted from the well-defined property of the integration in the right-hand side

of (29). If $f(x)$ is extended to be time dependent, there are many varieties for the choice of $f(x)$. The relation between the choice of $f(x)$ and the N-soliton solution will be a future problem.

The situation becomes involved when there appear certain bound states which prohibit us from using the successive iteration. Such a situation arises in many practical cases, in which the extended objects are created by condensation of composite Goldstone bosons (such as crystal phonons, magnons, etc.). When we cannot use the successive iteration, proof of the boson transformation theorem becomes very complicated. Since this has been discussed in Ref. 4, it will not be repeated here. In the following we present a sketch of the general structure of the boson method for derivation of the soliton solutions.

Suppose that the Heisenberg equation (1) gives rise to the set of in fields $(\varphi_1^{\text{in}}\,\varphi_2^{\text{in}}\cdots\varphi_n^{\text{in}}\cdots)$. Here $\varphi_\alpha^{\text{in}}$ $(\alpha=1,\ldots,n)$ are the boson in fields and other in fields are fermions. The free field equation for the boson in fields are

$$(-\partial^2-m_\alpha^2)\varphi_\alpha^{\text{in}}=0. \tag{41}$$

Since we require that ψ is realized in the Fock space of the in fields, all the matrix elements of ψ among the vectors in this Fock space should be well defined. This means that ψ can be expressed by a linear combination of normal products of the in fields:

$$\psi(x)=\psi(x;\varphi_\alpha^{\text{in}},\ldots). \tag{42}$$

This is the dynamical map and should be understood as a weak relation. To calculate $F[\psi]$ in the right-hand side of the Heisenberg equation (1), we need to define the products of ψ. The products are defined by the rule which states that one first calculates the products of normal products of the in fields and rearranges them into a linear combination of normal products. The space-time integration should be performed only after the products of normal products are well taken care of. We assume that when certain divergences appear through the course of calculation, they can be eliminated by some regularization procedures in a reasonable manner. Once the products of ψ are determined, all the matrix elements of both sides of the Heisenberg equation (1) can be calculated. A well-known expression for the dynamical map is the Lehmann-Symanzik-Zimmermann (LSZ) formula.

Now perform the substitution called the boson transformation

$$\varphi_\alpha^{\text{in}}(x)\to\varphi_\alpha^{\text{in}}(x)+f_\alpha(x), \tag{43}$$

in which $f_\alpha(x)$ $(\alpha=1,\ldots,n)$ are c-number functions which satisfy the equations for $\varphi_\alpha^{\text{in}}$,

$$(-\partial^2-m_\alpha^2)f_\alpha=0. \tag{44}$$

Then, the boson transformation theorem states that the boson-transformed Heisenberg field

$$\psi^f(x)=\psi(x;\varphi_\alpha^{\text{in}}+f_\alpha,\ldots) \tag{45}$$

also satisfies the Heisenberg equation (1), thus leading to (10). Note that the boson $\varphi_\alpha^{\text{in}}$ in (43) can be either elementary or composite.

The expression (43) for the boson transformation indicates that $f_\alpha(x)$ are created by the condensation of the bosons $\varphi_\alpha^{\text{in}}$. The result of this condensation is the appearance of certain extended objects. Since $f_\alpha(x)$ are c numbers, these extended objects behave classically: Intuitively speaking, the quantum fluctuation becomes much smaller than the macroscopic effect of the condensed bosons. The c-number field ϕ^f is defined by (11). Note that $\phi^f(x)$ describes a classically behaving extended object even when $h\neq 0$. When we ignore h, $\phi^f(x)$ becomes $\phi_0^f(x)$, i.e., Eq. (12). Following the argument which led to (13), we can prove that ϕ_0^f satisfies the classical Euler equation (15).

When the boson which makes the boson transformation happens to be composite, we should formulate the tree approximation in such a way that the internal lines of the tree diagrams include the propagation function of the composite boson. Such a formulation of the tree approximation can be made by means of the Ward-Takahashi relations. Since this kind of tree approximation has been formulated in Ref. 8 in which the itinerant electron ferromagnetism was studied, it will not be repeated here.

Equation (44) for f_α admits various propagating wave solutions. A well-known example of wavelike extended objects in solid state physics is the ultrasonic waves in crystals.

When we consider a static extended object, (44) becomes

$$(\nabla^2-m^2)f_\alpha=0. \tag{46}$$

When $m=0$, this equation has a trivial solution, i.e., $f_\alpha(x)=$constant. When we disregard this trivial solution, Eq. (46) with $m^2\geq 0$ does not admit any solution which is Fourier transformable. We thus conclude that the static objects created by the condensation of bosons carry certain singularities which prohibit the Fourier transform of f_α.

Since $f_\alpha(x)$ for static objects should carry certain singularities which prohibit its Fourier transform, $f_\alpha(x)$ has either a divergent singularity or a topological singularity. Here the divergent singularity means that $f_\alpha(x)$ diverges at $|\vec{x}|=\infty$ at least in certain directions of $\vec{x}$. The topological singularity means that $f_\alpha(x)$ is not single valued.

Since $f_\alpha(x)$ is path dependent when it is not single valued, the topological singularity can be mathematically expressed by the relation

$$G^{\alpha\dagger}_{\mu\nu}(x)\neq 0 \quad \text{for certain } x,\ \mu,\ \nu,\ \text{and } \alpha, \tag{47}$$

where $G^{\alpha\dagger}_{\mu\nu}$ is defined by

$$G^{\alpha\dagger}_{\mu\nu}(x)\equiv[\partial_\mu,\partial_\nu]f_\alpha(x). \tag{48}$$

Furthermore, existence of the path-dependent $f_\alpha(x)$ requires that $\partial_\rho f_\alpha(x)$ should be single valued,

$$[\partial_\mu,\partial_\nu]\partial_\rho f_\alpha(x)=0. \tag{49}$$

Equation (44) together with (48) and (49) leads to

$$\partial_\nu f_\alpha(x)=\frac{1}{\partial^2+m_\alpha^2}\,\partial^\mu G^{\alpha\dagger}_{\mu\nu}(x), \tag{50}$$

where the derivative operator $(1/\partial^2+m_\alpha^2)$ is defined in terms of the Fourier representation as follows:

$$\frac{1}{\partial^2+m_\alpha^2}\,e^{ipx}=-\frac{1}{p^2+m_\alpha^2}\,e^{ipx}. \tag{51}$$

Thus $(1/\partial^2+m_\alpha^2)$ is the Green's function of the Klein-Gordon equation with the mass m_α. Note that $G^{\alpha\dagger}_{\mu\nu}$ is Fourier transformable. Equation (50) leads to $\partial^2 f_\alpha=0$, implying that $m_\alpha=0$. We thus conclude that the extended objects associated with the topological singularity (47) can be created only by the condensation of *massless* bosons. A systematic study of extended objects with topological singularities has been presented in Ref. 3.

We need a special remark when the Heisenberg field ψ is a fermion field, because $\langle 0|\psi^f|0\rangle$ vanishes. In this case we can still construct various bosonlike operators by means of products of an even number of ψ's. When we find a set of bosonlike operators [say $\varphi_a(\psi)$; $a=1,\ldots,l$] which satisfy a closed set of Heisenberg equations, we can write down the classical equations of the same form. Latter classical equations are regarded as the Euler equations, and our consideration in this paper can be applied to these Euler equations. However, it frequently happens that the Heisenberg equations are not closed by a finite number of bosonlike operators; to obtain a closed set of Heisenberg equations for bosonlike operators, we usually need certain approximations. The Gor'kov equation[9] for the order parameter $\Delta(x)$ in the theory of superconductivity is a well-known example of this kind of Euler equation. There the Goldstone boson is a bound state of two electrons. When we denote the boson-transformed electron Heisenberg field by ψ^f, the order parameter $\Delta(x)$ is equal to $\langle 0|\psi^f_\downarrow\psi^f_\uparrow|0\rangle$. When $\Delta(x)$ is very small, the Gor'kov equation becomes the Ginzburg-Landau equation. When $\Delta(x)$ is not small, its Euler equation (i.e., the Gor'kov equation) has an extremely complicated structure. However, we can derive also a classical equation for physical quantities such as the electromagnetic field and current by applying the boson transformation to the dynamical maps of the electromagnetic Heisenberg field and electron Heisenberg field.[4,10] This equation can be used for the study of extended objects in superconductors. The same situation is true in the relativistic superconductorlike models (e.g., the Nambu model).

Let us close this paper with two comments on the boson method. In this paper we considered mostly $\phi^f(x)$ which is the vacuum expectation value of the boson-transformed Heisenberg field $\psi^f(x)$. When we calculate other matrix elements of ψ^f and the boson-transformed S matrix, we can study the reactions among extended objects and quantum particles. Another comment is the following: Since ϕ^f contains $\hbar$, it has quantum effects in it, although it describes a classical object. In other words, ϕ^f is the soliton solution with quantum correction; the quantum correction is given by the loop diagrams.

Cytoskeletal microtubules structurally organize interiors of living eukaryotic cells. As polymers of subunit proteins ("tubulin"), which are each dipoles, microtubules are thus lattices of oriented dipoles. In general, three types of arrangements of dipoles in lattices may occur: (i) random, (ii) ferroelectric (parallel-aligned) and (iii) an intermediate weakly ferroelectric phase, which is length-dependent. Because of involvement in dynamical cell activities (movement, growth, mitosis, differentiation, etc.), models of microtubule signaling and information processing have been proposed. In these, tubulin units are assumed to represent informational "bit states" and to be coupled to intra-tubulin dipoles. In the present paper, we consider microtubules as lattice arrays of coupled local dipole states that interact with their immediate neighbors. Depending on the values of assumed model parameters, the system may exhibit "frustration": conflict in satisfying all dipole couplings. Such systems have properties suitable for efficient information processing and computation. By slightly altering temperature and external field (both within physiological conditions), microtubule dipole lattices may assume a ferroelectric phase with long-range order and alignment with capabilities to propagate kink-like excitations. The ferroelectric phase appears to be optimal for microtubule signaling and assembly/disassembly. Microtubules may organize cell activities by operating in different modes suitable for information processing and computation (intermediate phase) or signaling and assembly/disassembly (ferroelectric phase).

1. Introduction

Interiors of living cells are structurally and dynamically organized by networks of protein polymers called the cytoskeleton. Of these filamentous structures which include actin and intermediate filaments, microtubules (MTs) are the best characterized and appear to be the most fundamental (Dustin, 1984). MTs are hollow cylinders 25 nanometers (nm) in diameter whose lengths may span macroscopic dimensions. MTs are assemblies of 13 longitudinal protofilaments, each of which is a series of subunit proteins known as tubulin (Fig. 1). Each tubulin subunit is a polar, 8 nm-long dimer which consists of two slightly different 4 nm-long monomers, each with a molecular weight of 55 kDa. These two constituent parts are referred to as α and β tubulin. Each dimer has a net mobile electronegative charge due to an abundance of acidic amino acids, and binds 18 calcium ions. The net negative mobile charge is localized predominantly towards the α monomer so that each tubulin dimer bears an oriented dipole. Thus, MTs are an example of an electret substance, i.e. an assembly of oriented dipoles. In this paper we investigate the types of spatial arrangements of these dipoles in detail and their implications on MT behavior.

Conformational states of tubulin dimers present within MTs have been suggested to be coupled to charge or dipolar states, thereby allowing for cooperative interactions with neighboring tubulin dimer sites (Hameroff & Watt, 1982; Hameroff, 1987;

0022–5193/95/120371 + 10 $08.00/0

© 1995 Academic Press Limited

Rasmussen *et al*., 1990). This coupling would also lead to the presence of piezoelectric properties which are very common in ferroelectrics which, in turn, could prove very important in MT signaling, communication and assembly/disassembly behavior (Athenstaedt, 1974; Margulis *et al*., 1978).

MT associated proteins (MAPs) which may be structural, contractile or enzymatic are attached to MTs at specific tubulin dimer sites and can link MTs with other MTs, other parallel arrayed cytoskeletal elements, membranes and organelles to form networks and scaffolding within living cells. MAP attachment sites may be irregular, or can describe various helical patterns on MT surface lattices (Burns, 1978; Kim *et al*., 1986). The focal point of the cytoskeleton is the centriole, a pair of cylindrical assemblies of nine MT triplets oriented perpendicular to each other. Centrioles organize the array of cytoplasmic MTs during interphase, duplicate at mitosis to nucleate the two poles of the mitotic spindle and establish orientation and architecture for the next generation of cells.

Genes for α and β tubulin are complex, multi-gene families that give rise to varying tubulin isozymes. During evolution, some tubulins have been highly conserved for basic cell functions; however, extensive MT heterogeneity exists in complex cells due to genetic diversity, expression, post-translational modifications, MAPs and assembly patterns. For example, two-dimensional gel electrophoresis has shown 17 different varieties of β tubulin exist in mammalian brain MTs, whereas fewer exist in other tissues (Lee *et al*., 1986). Tubulin structure may also be altered by "post-translational" modification: enzymatic alteration (usually addition or removal of amino acids such as glycosylation or detyrosination) triggered by intracellular events including second messenger activities.

MT self-assembly and disassembly are dynamic, complex processes whose states depend on various factors including temperature and calcium ion concentration. Oriented by centrioles, MT polymerization determines the architecture and form of cells which can quickly change by MT depolymerization and reassembly in another direction. GTP, an energy-providing analog of ATP, binds to free, unpolymerized tubulin; GTP-tubulins then self assemble to form MTs in an entropy driven process. Within assembled MTs, GTP hydrolyzes to GDP, imparting energy into the MT lattice via tubulin conformational changes. MTs whose ends are comprised of GTP-tubulin are stable and will continue to grow. MTs whose ends are comprised of GDP-tubulin are unstable and will depolymerize rapidly. As GTP is hydrolyzed to GDP within MT, GDP-tubulin is exposed at MT ends and, unless stabilized by MAPs, centrioles or other structures, MTs rapidly disassemble. Free GDP-tubulin is reconverted to GTP-tubulin which becomes available for reassembly. *In vitro*, this "dynamic instability" (Kirschner & Michison, 1986; Hotani *et al*., 1992) results in erratic alterations between growing and shrinking phases; *in vivo* "selectionist" activity occurs in which MT networks can adaptively probe or retreat in cellular appendages including axonal and dendritic growth cones and developing synapses (e.g. Reinsch *et al*., 1991; Sabry *et al*., 1991). Recent works have shown that MT spatial structures or patterns may form under the maintenance of a sustained energy source (GTP hydrolysis), suggesting that MTs may be dissipative structures (Tabony & Job, 1990, 1992).

to be mentioned in report

similar to fractal nature of entropy

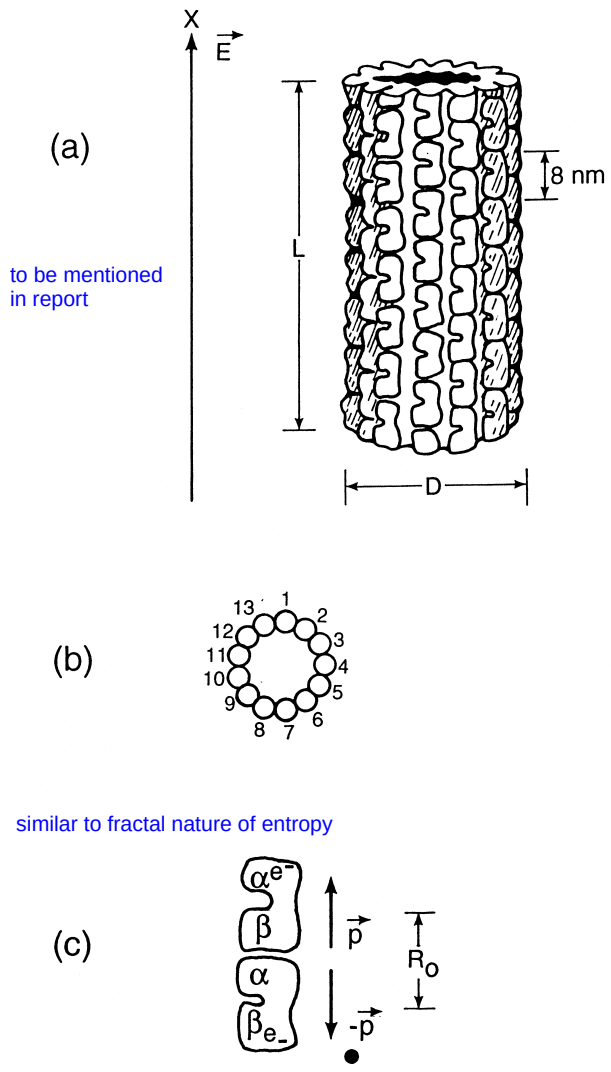

FIG. 1. An illustration of the microtubular arrangement.

Some evidence links the cytoskeleton with information processing and cognitive function. For example, Mileusnic *et al*. (1980) correlated production of MT subunit protein (''tubulin'') and MT activities with peak learning, memory and experience in baby chick brains. Cronley-Dillon *et al*. (1974) showed that when baby rats begin their critical learning phase for the visual system (when they first open their eyes), neurons in the visual cortex begin producing vast quantities of tubulin. Tubulin production is drastically reduced when the critical learning phase is over (when the rats are 35 days old). Moshkov *et al*. (1992) showed structural and chemical changes in goldfish brain neuronal cytoskeleton following sensory stimulation. In gerbils exposed to cerebral ischemia, Kudo *et al*. (1990) correlated the amount of reduction in dendritic MAP-2 with the degree of cognitive impairment. Bensimon & Chernat (1991) found that selective destruction of brain MTs by the drug colchicine caused cognitive defects in learning and memory which mimic the clinical symptoms of Alzheimer's disease, in which the cytoskeleton becomes entangled. Geerts *et al*. (1992) showed that sabeluzole, a memory-enhancing drug, increases fast axoplasmic transport. Matsuyama & Jarvik (1989) have proposed that Alzheimer's is a disease of MTs and MAPs. In specific hippocampal regions of the brains of schizophrenic patients, Arnold *et al*. (1991) found distorted neuronal architecture due to a lack of two MAPs (MAP-2 and MAP-5).

Models of learning in mammalian NMDA (n-methyl-d-aspartate) hippocampal neurons (i.e. long-term potentiation—LTP) involve pre- and post-synaptic enhancement of synaptic function. Silva *et al*. (1992) have shown calcium-calmodulin kinase to be essential for LTP. Aszodi *et al*. (1991) have demonstrated protein kinase A to be involved in learning. Halpain & Greengard (1990) have shown that post-synaptic activation of NMDA receptors induces rapid dephosphorylation of dendrite-specific MAP-2. Aoki & Siekevitz (1988) linked learning to protein kinase C mediated MAP-2 phosphorylation/ dephosphorylation, and Theurkauf & Vallee (1983) demonstrated that MAP-2 phosphorylation/ dephosphorylation consumed a huge proportion of brain biochemical energy. Bigot & Hunt (1990) showed that NMDA and other excitatory amino acid neurotransmitters caused redistribution of intraneuronal MAPs, and Wang & Rasenick (1991) have shown that G proteins directly link with MTs. Surridge & Burns (1992) demonstrated that the lipid second messenger phosphatidylinositol binds specifically to MAP-2, a coupling which may ''constitute a link by which extracellular factors influence the microtubule cytoskeleton''. Kwak & Matus (1988) showed that denervation caused long-lasting changes in MAP distribution, and Desmond & Levy (1988) showed that LTP involved cytoskeletal-mediated shape changes in dendritic spines. Lynch & Baudry (1987) have proposed that proteolytic digestion of the sub-synaptic cytoskeleton, followed by its structural reorganization, correlate with learning, and Friedrich (1990) has formalized a learning model of synaptic cytoskeletal restructuring. Synaptic regulation, both in learning and steady state, also depends on material (enzymes, receptors, neurotransmitters, etc.) synthesized in the cell body and transported along axons and dendrites by contractile MAPs attached to MT (''axoplasmic transport''). Similar mechanisms involving actin, synapsin and other cytoskeletal polymers are involved in neurotransmitter release.

Further suggestion for cytoskeletal computation and/or information storage stems from the spatial distribution of discrete sites (or states) in the cytoskeleton. For example, tubulin subunits in closely arrayed MTs have a density of about 10^{17} cm^{-3}, which is very close to the theoretical limit for charge separation (Gutmann, 1986). Thus cytoskeletal polymers have maximal density for information representation by charge, and the capacity for dynamically coupling that information to mechanical and chemical events via cooperative dipole states.

Previous papers have modeled signaling and information processing in MTs based on coherent phonons, solitons and cellular automata based on dipole coupled conformational states of tubulin.

In this paper we address the question of how some functions of MTs (i.e. assembly/disassembly and proposed signaling and information processing) may be related to the ground state properties of the lattice of dipoles. In general, three kinds of geometrical arrangements of dipoles are found: (i) random where no order in the dipole arrangements exists, (ii) ferroelectric (long-range parallel-aligned order) and (iii) intermediate, weakly ferroelectric where short range order is present. Each of these arrangements may exist under different conditions of temperature, electric field and MT length, and a single MT may switch among the different arrangements. The long-range ordered ferroelectric state appears most suitable for assembly/disassembly and signaling processes while the short-range ordered weakly ferroelectric state is well suited for information processing. In the next two sections we discuss these properties in detail.

2. The Dipolar Lattice and its Phases

Our basic premise physically views the entire MT as a regular array of coupled local dipole states

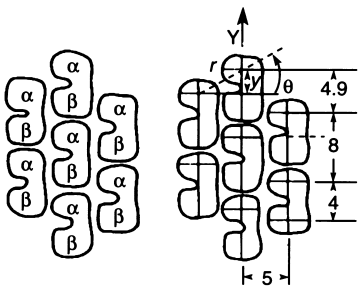

FIG. 2. A tubulin dimer and its nearest neighbors.

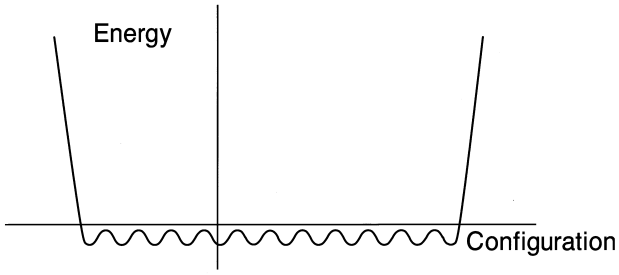

FIG. 4. A schematic representation of the energy dependence on conformational states.

which interact with their immediate neighbors. Although tubulin undergoes conformational changes (e.g. Melki *et al*., 1989), we adopt a simplified view in which elastic degrees of freedom are not explicitly included in the description. We will return to this question in the Discussion.

The starting point in the analysis is to adopt a hexagonal lattice structure with the dimensions and orientations observed by X-ray diffraction of MTs and shown in Fig. 2. Each lattice site is assumed to possess a dipole moment $p = Q \cdot d$ where $Q = 2e$ and $d \cong 4$ nm whose projections on the vertical axis can only be $+p$ or $-p$. The interaction energy between two neighboring lattice sites is

$$H_{ij} = \frac{1}{4\pi\epsilon\epsilon_0} \frac{3\cos^2\theta - 1}{r_{ij}^3} p^2, \tag{1}$$

where ϵ_0 is the vacuum permittivity and r_{ij} is the distance between sites i and j. The angle θ is between the dipole axis and the direction between the two dipoles. Figure 3 illustrates the situation resulting from our calculations.

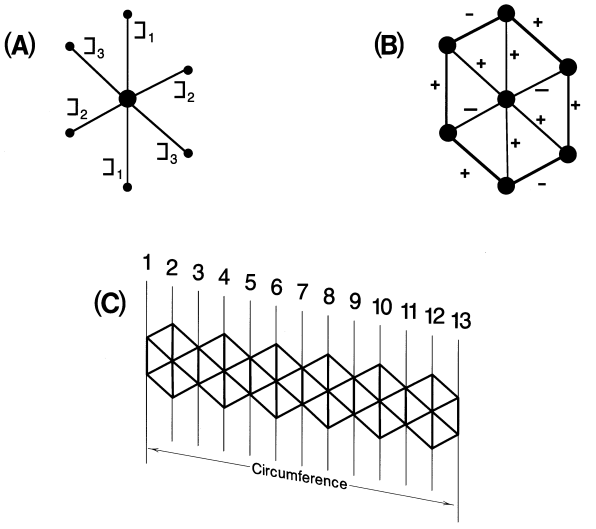

FIG. 3. Exchange constants (a) and their signs (b) within a unit hexagonal cell. (c) A band of hexagons spanning the circumference of a microtubule.

In Fig. 3(b) the signs "+" and "−" refer to dipole–dipole interactions that prefer either a parallel or antiparallel arrangements of dipole moments, respectively. Below, we present the numerical results for the constants J_1, J_2, J_3 and the corresponding angles.

$$J_1 = 5.77 \times 10^{-21}\ \text{J} \quad \theta_1 = 0^\circ$$

$$J_2 = -0.71 \times 10^{-21}\ \text{J} \quad \theta_2 = 58.2^\circ$$

$$J_3 = 3.40 \times 10^{-21}\ \text{J} \quad \theta_3 = 45.6^\circ$$

We can, therefore, map this situation as an anisotropic two-dimensional Ising model on a triangular lattice so that the effective Hamiltonian is

$$H = \underset{\langle nn \rangle}{-\Sigma} J_{ij} S_i^z S_j^z, \tag{2}$$

and the effective spin variable $S_i^z = \pm 1$ denotes the dipole's projection on the vertical axis. The exchange constants J_{ij} take the values J_1, J_2, J_3 depending on the choice of dipole pairs.

What, therefore, appears in Fig. 3(b) is that the system exhibits a certain amount of *frustration* (Suzuki, 1977) in its ground state. This means that for a closed path around the 13 protofilaments of the microtubule, it is impossible to satisfy all bond requirements since there is an odd number of antiparallel bonds. Note that no frustration exists in the direction along the MT axis giving the overall ferroelectric character to the lattice. It will also be seen how this is manifested through size dependence of net polarization.

Small potential barriers separating the various equivalent arrangements of spins (see Fig. 4) play another useful role. Relaxation times are very long for the various accessible states giving them long-term stability. Some other properties of this intermediate, weakly ferroelectric phase are: (i) absence of long-range order between spin sites and (ii) the presence of short-range correlations. This means that the system is very "soft" energetically, permitting a number of spin arrangements which are relatively

stable. However, there is no tendency towards the formation of large correlated spin clusters. This intermediate phase also allows easy formation of local ordered states, each of which carries an information content and is long-lived, i.e. relatively stable over time. On the other hand, it is not difficult to switch from one local state to another through various physical means by overcoming local potential barriers. Furthermore, a complete phase transformation can be achieved by:

(i) an application of an electric field along the axis. We estimate that intracellular fields on the order of $10^4\ \mathrm{Vm}^{-1}$ are sufficient to switch an MT from an intermediate state to a ferroelectric state (F). (Note that fields up to $10^7\ \mathrm{Vm}^{-1}$ are known to exist across cell membranes).

(ii) Raising the temperature above the ferroelectric transition temperature will drive the system to a disordered (paraelectric) phase.

We mentioned above that another ordered phase is favored when a moderate external field is applied (or indeed when the temperature is lowered further). This phase, called a ferroelectric phase, is characterized by long-range order manifested by an alignment of spin directions along the axis. This is shown in Fig. 5. Obviously, from the point of view of optimal information content, this is *not* a very useful phase. However, the ferroelectric phase can play a major role in signaling and the assembly/disassembly processes. This will be discussed at length in the next Section. Before we discuss this aspect, we investigate its general properties. The ferroelectric phase can also be destabilized by temperature when T exceeds T_c. To obtain a crude estimate of T_c we approximated the MT by an infinite triangular lattice with the exchange constants J_1, J_2 and J_3 given above and used the formula (Domb, 1960).

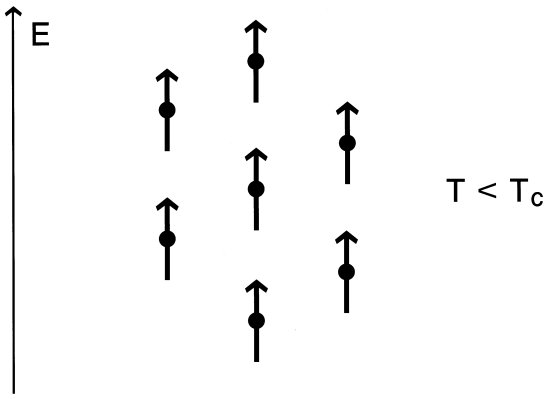

FIG. 5. The dipole orientations in the ferroelectric state.

$$\sinh\left(\frac{2J_1}{K_B T_C}\right)\sinh\left(\frac{2J_2}{K_B T_C}\right) + \sinh\left(\frac{2J_1}{K_B T_C}\right)\sinh\left(\frac{2J_3}{K_B T_C}\right) + \sinh\left(\frac{2J_2}{K_B T_C}\right)\sinh\left(\frac{2J_3}{K_B T_C}\right) = 1. \quad (3)$$

The result we obtained using the above crude estimate for an infinitely long lattice is $T_c \cong 402\ K$ *for the charge of* $q = 2e$, the permittivity $\epsilon = 10$ and the dipole displacement $d = 4$ nm. On the other hand, taking $q = 1e$, $\epsilon = 5$ and $d = 4$ nm yields $T_c = 201$ K. These two very rough estimates of T_c indicate nevertheless that it is feasible to expect an interesting phase behavior in the physiological temperature range around 300 K for a specific choice of model parameters. In addition, it is well known that the size of a lattice affects T_c greatly. In general, for size N, $T_c(N)$ is related to that for an infinite lattice $T_c(\infty)$ through (Binder *et al*., 1985):

$$T_c(N) = T_c(\infty) - \alpha N^{-1/\gamma}, \quad (4)$$

where α is an approximate proportionality coefficient and γ is the correlation length exponent (typically close to 1/2). Thus, for a finite-size lattice, the transition temperature is expected to be less than that for an infinite lattice. In other words, dipole ordering is more likely to occur when a critical size of the MT is achieved. In addition, other important factors may affect the value of T_c and thus provide sensitive control mechanisms. Through a coupling to the elastic degrees of freedom (conformational change), the value of T_c may be shifted. The dielectric constant ϵ may be altered by the presence of water molecules surrounding an MT structure. This would decrease the value of T_c and introduce disorder. Small changes in the angles between the dimer dipoles may remove the frustration mechanism effectively preventing the onset of the intermediate phase. Changes in the opposite direction can enhance frustration favoring the intermediate phase over the F phase and effectively switching from the growth mode of operation to an information processing behavior. Thus symmetry transitions or mechanical forces may effect switching between phases.

Once in the ferroelectric phase, the system is also very sensitive to the frequency of electromagnetic oscillations. It is known that in organic ferroelectric materials a resonant frequency exists W_0 which is inversely proportional to the length, stiffness constant

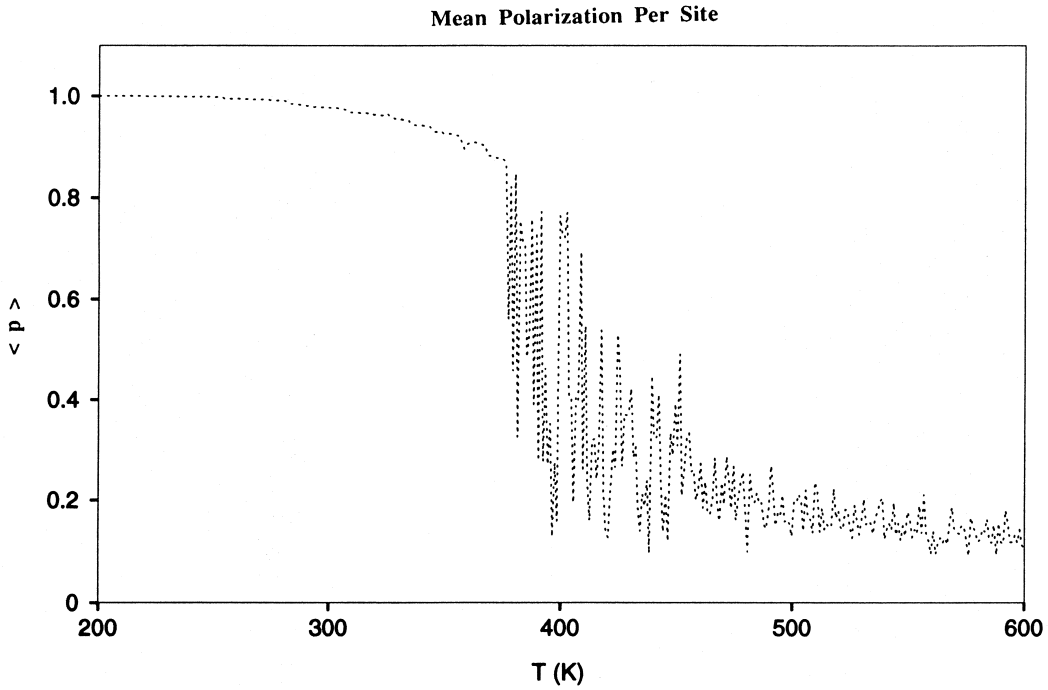

FIG. 6. A plot of the mean polarization per site for a triangular lattice whose size is 13×26.

and the square root of the density (Matthias, 1973). Extrapolating the data given by Matthias (1973), one finds for microtubules a resonant frequency range exceeding 10^8 Hz and thus being rather close to the microwave range predicted by Fröhlich (1980) to play a major role in living cells.

In Figs 6 and 7 we have shown the results of our Monte Carlo computations intended to reveal the size dependence of the phase behavior discussed above. Figure 6 is a plot of the mean polarization per site when the microtubule is composed of only 26 layers (i.e. it is a 13×26 lattice). It is clear that three distinct ranges exist: (i) the low-temperature ferroelectric range, (ii) the intermediate weakly ordered phase range and (iii) the high-temperature paraelectric range. Figure 7 illustrates the same dependence for a microtubule with 5000 layers (i.e. it is a 13×5000 lattice). We conclude that the intermediate weakly ferroelectric phase all but disappeared.

To summarize, in this section we have argued that two ordered phases are likely to govern the behavior of dipole moments in an MT. A ferroelectric phase is characterized by long-range order and has many characteristics useful in energy transfer properties discussed in the next section. An intermediate weakly ordered phase exhibits short-range order but has a multitude of equivalent, long-lived dipolar states. It appears that in the latter phase the system can explore a large subset of the phase space at a low energetical cost unlike in the ferroelectric phase. Having unhindered access to a multitude of conformational states indicates easy transitions from one configuration to another at little or no energy cost. A number of control mechanisms are possible which allow switching from one phase to the other and hence from one mode of operation to the other.

3. Ferroelectricity, Signaling and Assembly/Disassembly

It is well known that ferroelectrics are one of the few types of materials whose description is most adequately provided in terms of mean field models (Kretschmer & Binder, 1979). A typical approach is to postulate a double-well quartic on-site potential $V(S_n)$ that gives the overall effect of the environment on a selected dipole site n. Thus,

$$V(S_n) = -\tfrac{1}{2}AS_n^2 + \tfrac{1}{4}BS_n^4, \tag{5}$$

where S_n is the effective spin variable at site n and the coefficients A and B are model-dependent. It will be subsequently assumed that over long distances the variable S_n changes very gradually and can be treated as a continuous variable.

In the F phase, the MT cylinder taken as a whole represents a giant dipole. When the cross-section of an MT is viewed using electron microscopy, the outer surfaces of an MT are surrounded by a "clear zone" of several nm which apparently represents the oriented molecules of cytoplasmic water and enzymes (Steb-

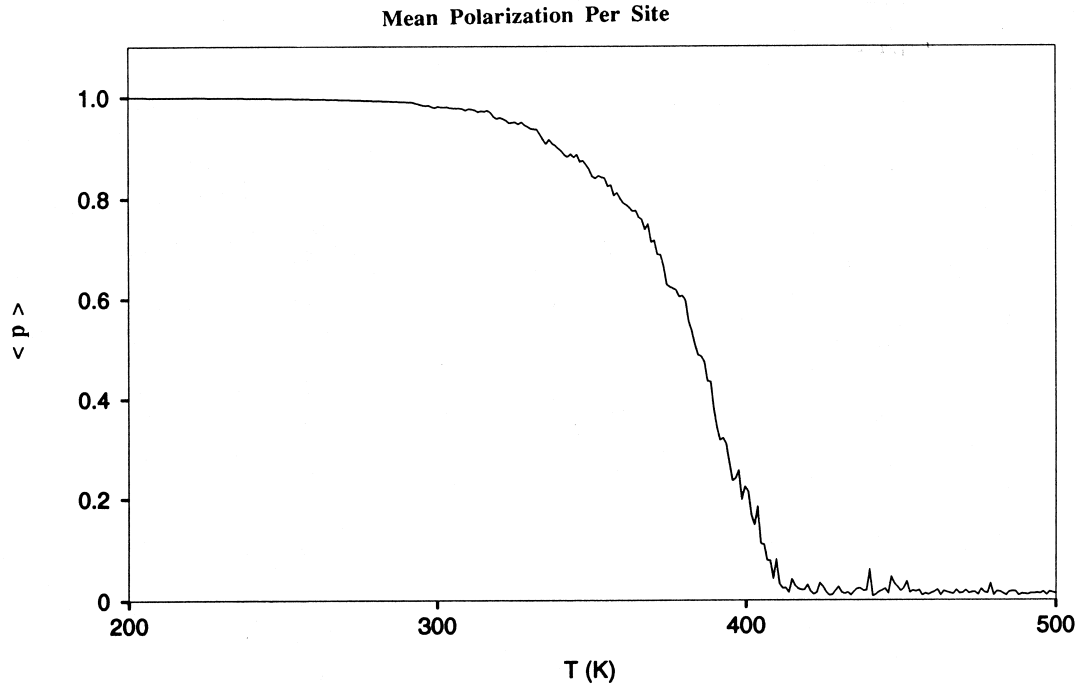

FIG. 7. A plot of the mean polarization per site for a triangular lattice whose size is 13×5000.

bings & Hunt, 1982). This could be explained by the presence of an electric field produced by an MT. Therefore, we assume that together with the polarized water surrounding it, an MT generates a nearly uniform intrinsic electric field parallel to its axis (see Fig. 1). Consequently, the additional potential energy due to this electric field and associated with each dipole is

$$V_{\mathrm{el}} = -CS_n, \quad C = qE, \tag{6}$$

where q denotes the effective charge of a single dimer and E is the magnitude of the intrinsic electric field. Within this picture, the model Hamiltonian for the dipole moments of a microtubule can be written as

$$H = \sum_{i=1}^{n} \left[\frac{1}{2} M \left(\frac{\mathrm{d}S_n}{\mathrm{d}t} \right)^2 + \frac{1}{2} K (S_{n+1} - S_n)^2 - \frac{A}{2} S_n^2 + \frac{B}{4} S_n^4 - CS_n \right]. \tag{7}$$

The first term above represents the kinetic energy associated with the longitudinal displacements of constituent dimers each of which has mass M. The second term arises from the restoring strain forces between adjacent dimers in the protofilament. If the stiffness parameter K is sufficiently large, then it is expected that large-amplitude long-wavelength excitations of the displacement field will be formed manifested by a slowly varying modulation of S_n along the MT axis.

In order to derive a realistic equation of motion for this system, the viscosity of the solvent is indispensable and the associated damping force must be introduced. Assuming for simplicity that the solvent is made up of only water molecules we may infer that water will provide a viscous medium that will damp out vibrations of dimer dipoles. This can be taken into account by adding the viscous force to the equation of motion with

$$F = -\gamma \frac{\mathrm{d}S_n}{\mathrm{d}t},$$

where γ is the damping coefficient.

Based on our assumption that the dipolar oscillations of dimers within an MT form a system that can be classified as displacive ferrodistortive, we can use the continuum approximation to obtain the corresponding equation of motion as

$$M \frac{\mathrm{d}^2 S}{\mathrm{d}t^2} - KR_0^2 \frac{\mathrm{d}^2 S}{\mathrm{d}x^2} - AS + BS^3 + \gamma \frac{\mathrm{d}S}{\mathrm{d}t} - qE = 0. \tag{8}$$

Note that the x-coordinate is along the protofilament axis. Moreover, for longitudinal sound waves the dispersion relation

$$\omega = \sqrt{K/M}$$

can be used to identify the sound velocity with

$$V_0^2 = \omega R_0 = \sqrt{K/M}\, R_0.$$

We now seek solutions of eqn (7) in the traveling-wave form where the moving coordinate ξ is given by

$$\xi = \left[\frac{|A|}{M(V_0^2 - V^2)}\right]^{1/2}(x - Vt) = \alpha(x - Vt), \qquad (9)$$

with V denoting the propagation velocity and the coefficient α is, of course,

$$\alpha = \left[\frac{|A|}{M(V_0^2 - V^2)}\right]^{1/2}$$

Consequently, eqn (8) is reduced to the ordinary differential equation below

$$M\alpha^2(V^2 - V_0^2)S'' - \gamma\alpha V S' - AS + BS^3 - qE = 0, \quad (10)$$

where $S' \equiv \mathrm{d}S/\mathrm{d}\xi$. This is an equation for an anharmonic oscillator with linear friction.

For the sake of convenience we now introduce a normalized displacement field as:

$$\Psi(\xi) = S(\xi)/S_0$$

where the normalizing coefficient

$$S_0 = \sqrt{|A|/B}$$

corresponds to the minimum of the double well potential in eqn (5).

It has been shown by Collins *et al*. (1979) that eqn (10) has a unique bounded solution which is given by the formula (and illustrated graphically in Fig. 8)

$$\Psi(\xi) = a + \frac{b - a}{1 + \exp(\beta\xi)}, \qquad (11)$$

where

$$\beta = (b - a)/\sqrt{2}$$

and the parameters a, b and d satisfy the cubic equation

$$(\Psi - a)(\Psi - b)(\Psi - d) = \Psi^3 - \Psi - \sigma, \qquad (12)$$

where

$$\sigma = q\sqrt{B}|A|^{-3/2}E.$$

Formula (11) describes a kink-like excitation (KLE) which takes the form of a domain wall separating two distinct ferroelectric domains.

It is also important to note that the above kink-like soliton propagates along the protofilament with a fixed velocity

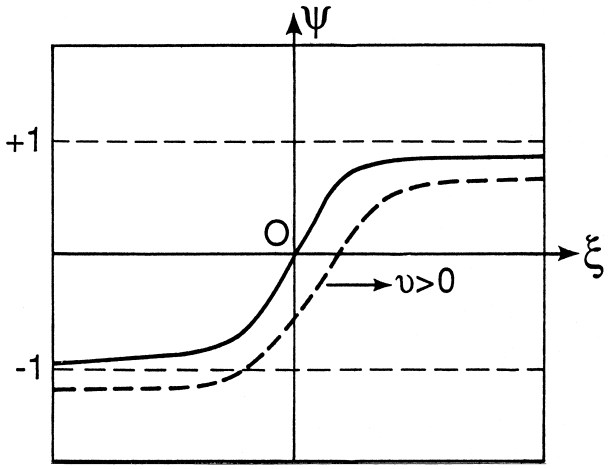

FIG. 8. The kink-like profile to the solution $\Psi(\xi)$ of eqn (11).

$$V = V_0/\left[1 + \frac{2\gamma^2}{9d^2MV_0^2}\right]^{1/2}, \qquad (13)$$

which is *less* than the sound velocity V_0 and decreases with an increase of the friction coefficient γ. It is clear that V depends on the magnitude of the electric field E through the parameter d.

For T well below T_c, V can be approximated by a linear relationship with E

$$V \approx \frac{3V_0}{\gamma|A|}\sqrt{\frac{MB}{2}}\, qE, \qquad (14)$$

where the coefficient of proportionality is called mobility and will be denoted by μ. Using simple arguments from fluid dynamics, μ can be estimated numerically as

$$\mu \approx 2 \times 10^{-5}\ \mathrm{m^2\ V^{-1}\ sec^{-1}}$$

Thus, for $E = 10^5\ \mathrm{V\ m^{-1}}$ we obtain $\mathrm{V} \cong 2\ \mathrm{m\ sec^{-1}}$ which can increase to $10^2\ \mathrm{m\ sec^{-1}}$ close to the MTs ends where E increases dramatically.

Assuming a smooth journey from one end of the protofilament to the other we estimate the average time of propagation $\bar{T}$ for a single KLE to be

$$\bar{T} = \frac{L}{\bar{V}} \approx 5 \times 10^{-7}\ \mathrm{sec}$$

A recent paper (Chou *et al*., 1994) also pointed to the possible role of solitary waves in the dynamics of microtubules.

To summarize, we showed that a unique kink-like excitation exists in the ferroelectric phase which

may propagate along an MT with a velocity that is proportional to the electric field E. KLEs in stable microtubules may constitute signals transducing membrane events via second messengers to other cell regions. Energy for such KLEs may come from GTP hydrolysis or phosphorylation via MAPs. In neurons, KLEs in microtubules may signal error information retrograde (i.e. from axon to dendrite) which would be useful in synaptic regulation and learning as in artificial neural network "back-propagation". In unstable MTs (i.e. whose ends are not stabilized by MAPs or other structures), KLEs can explain the fact that growth rates are different at the two ends of an MT. To this end, we assume that KLE formation is mainly due to the hydrolysis of GTP into GDP so that one act of hydrolysis corresponds to conformational change resulting in the formation of a single KLE. However, a KLE is preferentially oriented towards the direction of the intrinsic electric field. The propagation of a KLE will then distribute the energy of hydrolysis at the preferred end of an MT. This energy may then be used to detach dimers from the MT. This picture is in accordance with a hypothesis put forward by Kirschner & Mitchison (1986) who stated that on-rate (growth) is limited in principle only by the rate of diffusion of the monomer subunits into MT polymers (i.e. by the concentration of the constituent monomers in solution). On the other hand, the off-rate (depolymerization) can be extremely rapid and the net amount of MT polymer formed can be regulated independently by the hydrolysis of GTP.

It is reasonable to expect that at the onset of the MT assembly process, when MTs are very short, the formation of KLEs is very unlikely (or even impossible), since for a short chain the displacement field gradient required would be very high and the associated energy to form it prohibitively large. However, when the length of an MT reaches a threshold value, kink propagation could become a real possibility. Excitation of kinks being related to GTP hydrolysis would become dependent on the GTP concentration. As MTs become longer, KLE propagation accelerates leading to a disassembly at the "-" end. KLE propagation in stable MTs would depend on MAP phosphorylation or cytoplasmic kinase activity triggered by membrane events and second messengers.

4. Summary

We have argued in this paper that the spatial arrangement of dipole moments of a microtubule is crucial to its functioning as a dynamic system. Due to the presence of frustration in the dipole–dipole interactions, an intermediate weakly ferroelectric phase is predicted to arise at low enough temperatures and electric fields as well as for sufficiently short microtubules. Its attractiveness lies in maximal computational capabilities offered by a highly degenerate ground state and by long relaxation times giving relative stability to short-range correlated dipole patterns. Each pattern can be seen as containing binary information. This phase strongly resembles the well-known spin glass phenomenon which has received much attention in frustrated spin systems such as random-anisotropy magnets. Recently, spin-glass models have been applied in connection with biological systems (Stein, 1992).

The other possible ordered state is a ferroelectric phase with an almost perfect alignment of dipole movement along the protofilament axis. It is characterized by long-range order and hence its usefulness for information processing is dubious. However, it eagerly supports the formation of domain walls between the two stable orientations of dipole movements. The application of an external electric field preferentially directs kink-like excitations towards the properly aligned end. These kink-like excitations may be utilized as signaling mechanisms or causing disassembly due to energy release.

We have discussed the various possible control mechanisms (temperature, electric field, mechanical distortion) that could select the MT operating modes among information processing, weakly ordered and signaling and assembly/disassembly (ferroelectric) types.

(*Received on* 26 *May* 1993, *Accepted in revised form on* 3 *January* 1995)

Cytoskeletal microtubules structurally organize interiors of living eukaryotic cells. As polymers of subunit proteins (''tubulin''), which are each dipoles, microtubules are thus lattices of oriented dipoles. In general, three types of arrangements of dipoles in lattices may occur: (i) random, (ii) ferroelectric (parallel-aligned) and (iii) an intermediate weakly ferroelectric phase, which is length-dependent. Because of involvement in dynamical cell activities (movement, growth, mitosis, differentiation, etc.), models of microtubule signaling and information processing have been proposed. In these, tubulin units are assumed to represent informational ''bit states'' and to be coupled to intra-tubulin dipoles. In the present paper, we consider microtubules as lattice arrays of coupled local dipole states that interact with their immediate neighbors. Depending on the values of assumed model parameters, the system may exhibit ''frustration'': conflict in satisfying all dipole couplings. Such systems have properties suitable for efficient information processing and computation. By slightly altering temperature and external field (both within physiological conditions), microtubule dipole lattices may assume a ferroelectric phase with long-range order and alignment with capabilities to propagate kink-like excitations. The ferroelectric phase appears to be optimal for microtubule signaling and assembly/disassembly. Microtubules may organize cell activities by operating in different modes suitable for information processing and computation (intermediate phase) or signaling and assembly/disassembly (ferroelectric phase).

1. Introduction

Interiors of living cells are structurally and dynamically organized by networks of protein polymers called the cytoskeleton. Of these filamentous structures which include actin and intermediate filaments, microtubules (MTs) are the best characterized and appear to be the most fundamental (Dustin, 1984). MTs are hollow cylinders 25 nanometers (nm) in diameter whose lengths may span macroscopic dimensions. MTs are assemblies of 13 longitudinal protofilaments, each of which is a series of subunit proteins known as tubulin (Fig. 1). Each tubulin subunit is a polar, 8 nm-long dimer which consists of two slightly different 4 nm-long monomers, each with a molecular weight of 55 kDa. These two constituent parts are referred to as α and β tubulin. Each dimer has a net mobile electronegative charge due to an abundance of acidic amino acids, and binds 18 calcium ions. The net negative mobile charge is localized predominantly towards the α monomer so that each tubulin dimer bears an oriented dipole. Thus, MTs are an example of an electret substance, i.e. an assembly of oriented dipoles. In this paper we investigate the types of spatial arrangements of these dipoles in detail and their implications on MT behavior.

Conformational states of tubulin dimers present within MTs have been suggested to be coupled to charge or dipolar states, thereby allowing for cooperative interactions with neighboring tubulin dimer sites (Hameroff & Watt, 1982; Hameroff, 1987;

0022–5193/95/120371 + 10 $08.00/0

© 1995 Academic Press Limited

Rasmussen *et al*., 1990). This coupling would also lead to the presence of piezoelectric properties which are very common in ferroelectrics which, in turn, could prove very important in MT signaling, communication and assembly/disassembly behavior (Athenstaedt, 1974; Margulis *et al*., 1978).

MT associated proteins (MAPs) which may be structural, contractile or enzymatic are attached to MTs at specific tubulin dimer sites and can link MTs with other MTs, other parallel arrayed cytoskeletal elements, membranes and organelles to form networks and scaffolding within living cells. MAP attachment sites may be irregular, or can describe various helical patterns on MT surface lattices (Burns, 1978; Kim *et al*., 1986). The focal point of the cytoskeleton is the centriole, a pair of cylindrical assemblies of nine MT triplets oriented perpendicular to each other. Centrioles organize the array of cytoplasmic MTs during interphase, duplicate at mitosis to nucleate the two poles of the mitotic spindle and establish orientation and architecture for the next generation of cells.

Genes for α and β tubulin are complex, multi-gene families that give rise to varying tubulin isozymes. During evolution, some tubulins have been highly conserved for basic cell functions; however, extensive MT heterogeneity exists in complex cells due to genetic diversity, expression, post-translational modifications, MAPs and assembly patterns. For example, two-dimensional gel electrophoresis has shown 17 different varieties of β tubulin exist in mammalian brain MTs, whereas fewer exist in other tissues (Lee *et al*., 1986). Tubulin structure may also be altered by "post-translational" modification: enzymatic alteration (usually addition or removal of amino acids such as glycosylation or detyrosination) triggered by intracellular events including second messenger activities.

MT self-assembly and disassembly are dynamic, complex processes whose states depend on various factors including temperature and calcium ion concentration. Oriented by centrioles, MT polymerization determines the architecture and form of cells which can quickly change by MT depolymerization and reassembly in another direction. GTP, an energy-providing analog of ATP, binds to free, unpolymerized tubulin; GTP-tubulins then self assemble to form MTs in an entropy driven process. Within assembled MTs, GTP hydrolyzes to GDP, imparting energy into the MT lattice via tubulin conformational changes. MTs whose ends are comprised of GTP-tubulin are stable and will continue to grow. MTs whose ends are comprised of GDP-tubulin are unstable and will depolymerize rapidly. As GTP is hydrolyzed to GDP within MT, GDP-tubulin is exposed at MT ends and, unless stabilized by MAPs, centrioles or other structures, MTs rapidly disassemble. Free GDP-tubulin is reconverted to GTP-tubulin which becomes available for reassembly. *In vitro*, this "dynamic instability" (Kirschner & Michison, 1986; Hotani *et al*., 1992) results in erratic alterations between growing and shrinking phases; *in vivo* "selectionist" activity occurs in which MT networks can adaptively probe or retreat in cellular appendages including axonal and dendritic growth cones and developing synapses (e.g. Reinsch *et al*., 1991; Sabry *et al*., 1991). Recent works have shown that MT spatial structures or patterns may form under the maintenance of a sustained energy source (GTP hydrolysis), suggesting that MTs may be dissipative structures (Tabony & Job, 1990, 1992).

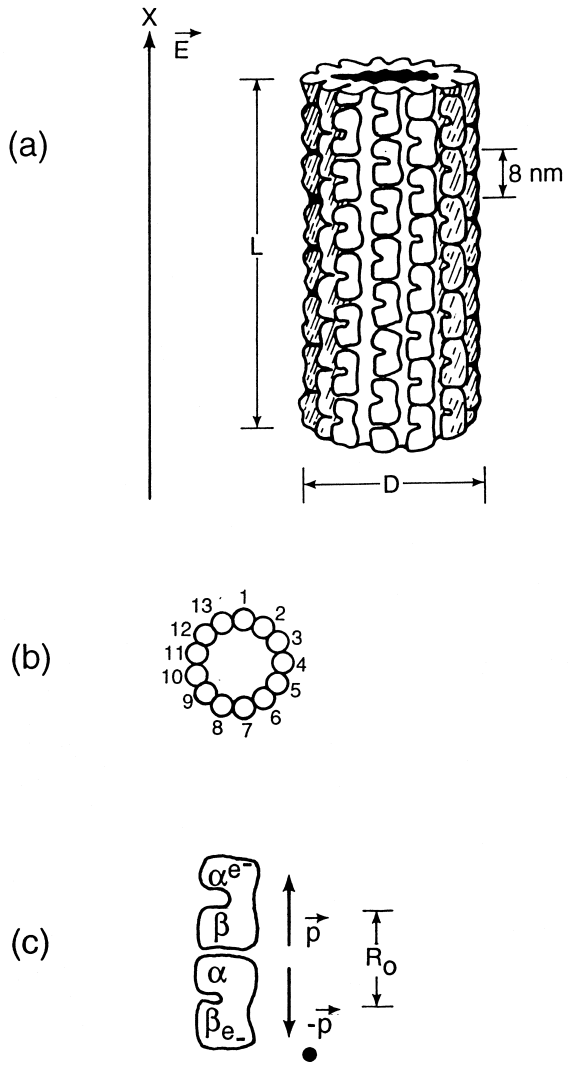

FIG. 1. An illustration of the microtubular arrangement.

Some evidence links the cytoskeleton with information processing and cognitive function. For example, Mileusnic *et al*. (1980) correlated production of MT subunit protein (''tubulin'') and MT activities with peak learning, memory and experience in baby chick brains. Cronley-Dillon *et al*. (1974) showed that when baby rats begin their critical learning phase for the visual system (when they first open their eyes), neurons in the visual cortex begin producing vast quantities of tubulin. Tubulin production is drastically reduced when the critical learning phase is over (when the rats are 35 days old). Moshkov *et al*. (1992) showed structural and chemical changes in goldfish brain neuronal cytoskeleton following sensory stimulation. In gerbils exposed to cerebral ischemia, Kudo *et al*. (1990) correlated the amount of reduction in dendritic MAP-2 with the degree of cognitive impairment. Bensimon & Chernat (1991) found that selective destruction of brain MTs by the drug colchicine caused cognitive defects in learning and memory which mimic the clinical symptoms of Alzheimer's disease, in which the cytoskeleton becomes entangled. Geerts *et al*. (1992) showed that sabeluzole, a memory-enhancing drug, increases fast axoplasmic transport. Matsuyama & Jarvik (1989) have proposed that Alzheimer's is a disease of MTs and MAPs. In specific hippocampal regions of the brains of schizophrenic patients, Arnold *et al*. (1991) found distorted neuronal architecture due to a lack of two MAPs (MAP-2 and MAP-5).

Models of learning in mammalian NMDA (n-methyl-d-aspartate) hippocampal neurons (i.e. long-term potentiation—LTP) involve pre- and post-synaptic enhancement of synaptic function. Silva *et al*. (1992) have shown calcium-calmodulin kinase to be essential for LTP. Aszodi *et al*. (1991) have demonstrated protein kinase A to be involved in learning. Halpain & Greengard (1990) have shown that post-synaptic activation of NMDA receptors induces rapid dephosphorylation of dendrite-specific MAP-2. Aoki & Siekevitz (1988) linked learning to protein kinase C mediated MAP-2 phosphorylation/ dephosphorylation, and Theurkauf & Vallee (1983) demonstrated that MAP-2 phosphorylation/ dephosphorylation consumed a huge proportion of brain biochemical energy. Bigot & Hunt (1990) showed that NMDA and other excitatory amino acid neurotransmitters caused redistribution of intraneuronal MAPs, and Wang & Rasenick (1991) have shown that G proteins directly link with MTs. Surridge & Burns (1992) demonstrated that the lipid second messenger phosphatidylinositol binds specifically to MAP-2, a coupling which may ''constitute a link by which extracellular factors influence the microtubule cytoskeleton''. Kwak & Matus (1988) showed that denervation caused long-lasting changes in MAP distribution, and Desmond & Levy (1988) showed that LTP involved cytoskeletal-mediated shape changes in dendritic spines. Lynch & Baudry (1987) have proposed that proteolytic digestion of the sub-synaptic cytoskeleton, followed by its structural reorganization, correlate with learning, and Friedrich (1990) has formalized a learning model of synaptic cytoskeletal restructuring. Synaptic regulation, both in learning and steady state, also depends on material (enzymes, receptors, neurotransmitters, etc.) synthesized in the cell body and transported along axons and dendrites by contractile MAPs attached to MT (''axoplasmic transport''). Similar mechanisms involving actin, synapsin and other cytoskeletal polymers are involved in neurotransmitter release.

Further suggestion for cytoskeletal computation and/or information storage stems from the spatial distribution of discrete sites (or states) in the cytoskeleton. For example, tubulin subunits in closely arrayed MTs have a density of about 10^{17} cm^{-3}, which is very close to the theoretical limit for charge separation (Gutmann, 1986). Thus cytoskeletal polymers have maximal density for information representation by charge, and the capacity for dynamically coupling that information to mechanical and chemical events via cooperative dipole states.

Previous papers have modeled signaling and information processing in MTs based on coherent phonons, solitons and cellular automata based on dipole coupled conformational states of tubulin.

In this paper we address the question of how some functions of MTs (i.e. assembly/disassembly and proposed signaling and information processing) may be related to the ground state properties of the lattice of dipoles. In general, three kinds of geometrical arrangements of dipoles are found: (i) random where no order in the dipole arrangements exists, (ii) ferroelectric (long-range parallel-aligned order) and (iii) intermediate, weakly ferroelectric where short range order is present. Each of these arrangements may exist under different conditions of temperature, electric field and MT length, and a single MT may switch among the different arrangements. The long-range ordered ferroelectric state appears most suitable for assembly/disassembly and signaling processes while the short-range ordered weakly ferroelectric state is well suited for information processing. In the next two sections we discuss these properties in detail.

2. The Dipolar Lattice and its Phases

Our basic premise physically views the entire MT as a regular array of coupled local dipole states

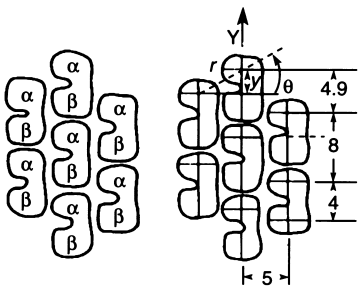

FIG. 2. A tubulin dimer and its nearest neighbors.

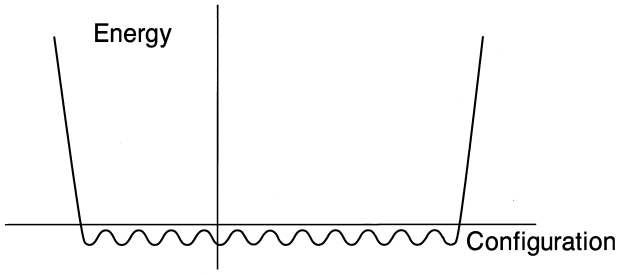

FIG. 4. A schematic representation of the energy dependence on conformational states.

which interact with their immediate neighbors. Although tubulin undergoes conformational changes (e.g. Melki *et al*., 1989), we adopt a simplified view in which elastic degrees of freedom are not explicitly included in the description. We will return to this question in the Discussion.

The starting point in the analysis is to adopt a hexagonal lattice structure with the dimensions and orientations observed by X-ray diffraction of MTs and shown in Fig. 2. Each lattice site is assumed to possess a dipole moment $p = Q \cdot d$ where $Q = 2e$ and $d \cong 4$ nm whose projections on the vertical axis can only be $+p$ or $-p$. The interaction energy between two neighboring lattice sites is

$$H_{ij} = \frac{1}{4\pi\epsilon\epsilon_0} \frac{3\cos^2\theta - 1}{r_{ij}^3} p^2, \tag{1}$$

where ϵ_0 is the vacuum permittivity and r_{ij} is the distance between sites i and j. The angle θ is between the dipole axis and the direction between the two dipoles. Figure 3 illustrates the situation resulting from our calculations.

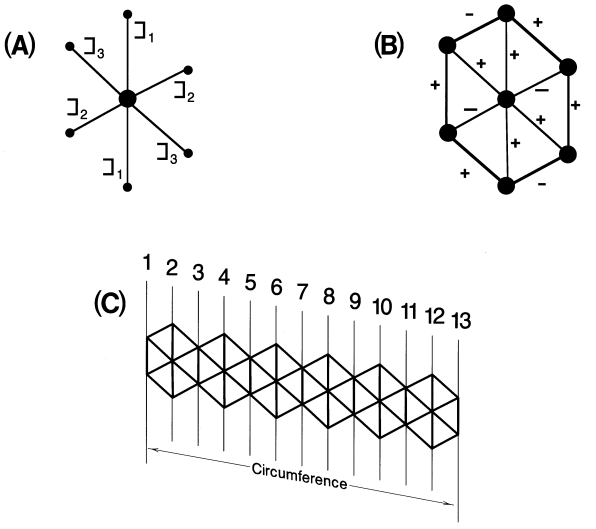

FIG. 3. Exchange constants (a) and their signs (b) within a unit hexagonal cell. (c) A band of hexagons spanning the circumference of a microtubule.

In Fig. 3(b) the signs "+" and "−" refer to dipole–dipole interactions that prefer either a parallel or antiparallel arrangements of dipole moments, respectively. Below, we present the numerical results for the constants J_1, J_2, J_3 and the corresponding angles.

$$J_1 = 5.77 \times 10^{-21}\ \text{J} \quad \theta_1 = 0^\circ$$

$$J_2 = -0.71 \times 10^{-21}\ \text{J} \quad \theta_2 = 58.2^\circ$$

$$J_3 = 3.40 \times 10^{-21}\ \text{J} \quad \theta_3 = 45.6^\circ$$

We can, therefore, map this situation as an anisotropic two-dimensional Ising model on a triangular lattice so that the effective Hamiltonian is

$$H = \underset{\langle nn \rangle}{-\Sigma} J_{ij} S_i^z S_j^z, \tag{2}$$

and the effective spin variable $S_i^z = \pm 1$ denotes the dipole's projection on the vertical axis. The exchange constants J_{ij} take the values J_1, J_2, J_3 depending on the choice of dipole pairs.

What, therefore, appears in Fig. 3(b) is that the system exhibits a certain amount of *frustration* (Suzuki, 1977) in its ground state. This means that for a closed path around the 13 protofilaments of the microtubule, it is impossible to satisfy all bond requirements since there is an odd number of antiparallel bonds. Note that no frustration exists in the direction along the MT axis giving the overall ferroelectric character to the lattice. It will also be seen how this is manifested through size dependence of net polarization.

Small potential barriers separating the various equivalent arrangements of spins (see Fig. 4) play another useful role. Relaxation times are very long for the various accessible states giving them long-term stability. Some other properties of this intermediate, weakly ferroelectric phase are: (i) absence of long-range order between spin sites and (ii) the presence of short-range correlations. This means that the system is very "soft" energetically, permitting a number of spin arrangements which are relatively

stable. However, there is no tendency towards the formation of large correlated spin clusters. This intermediate phase also allows easy formation of local ordered states, each of which carries an information content and is long-lived, i.e. relatively stable over time. On the other hand, it is not difficult to switch from one local state to another through various physical means by overcoming local potential barriers. Furthermore, a complete phase transformation can be achieved by:

(i) an application of an electric field along the axis. We estimate that intracellular fields on the order of $10^4\ \mathrm{Vm}^{-1}$ are sufficient to switch an MT from an intermediate state to a ferroelectric state (F). (Note that fields up to $10^7\ \mathrm{Vm}^{-1}$ are known to exist across cell membranes).

(ii) Raising the temperature above the ferroelectric transition temperature will drive the system to a disordered (paraelectric) phase.

We mentioned above that another ordered phase is favored when a moderate external field is applied (or indeed when the temperature is lowered further). This phase, called a ferroelectric phase, is characterized by long-range order manifested by an alignment of spin directions along the axis. This is shown in Fig. 5. Obviously, from the point of view of optimal information content, this is *not* a very useful phase. However, the ferroelectric phase can play a major role in signaling and the assembly/disassembly processes. This will be discussed at length in the next Section. Before we discuss this aspect, we investigate its general properties. The ferroelectric phase can also be destabilized by temperature when T exceeds T_c. To obtain a crude estimate of T_c we approximated the MT by an infinite triangular lattice with the exchange constants J_1, J_2 and J_3 given above and used the formula (Domb, 1960).

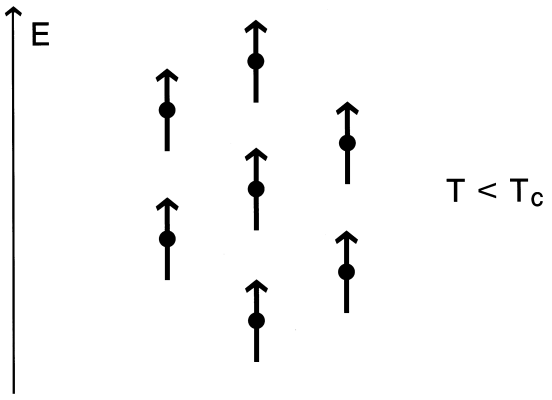

FIG. 5. The dipole orientations in the ferroelectric state.

$$\sinh\left(\frac{2J_1}{K_B T_C}\right)\sinh\left(\frac{2J_2}{K_B T_C}\right) + \sinh\left(\frac{2J_1}{K_B T_C}\right)\sinh\left(\frac{2J_3}{K_B T_C}\right) + \sinh\left(\frac{2J_2}{K_B T_C}\right)\sinh\left(\frac{2J_3}{K_B T_C}\right) = 1. \quad (3)$$

The result we obtained using the above crude estimate for an infinitely long lattice is $T_c \cong 402\ K$ *for the charge of* $q = 2e$, the permittivity $\epsilon = 10$ and the dipole displacement $d = 4$ nm. On the other hand, taking $q = 1e$, $\epsilon = 5$ and $d = 4$ nm yields $T_c = 201$ K. These two very rough estimates of T_c indicate nevertheless that it is feasible to expect an interesting phase behavior in the physiological temperature range around 300 K for a specific choice of model parameters. In addition, it is well known that the size of a lattice affects T_c greatly. In general, for size N, $T_c(N)$ is related to that for an infinite lattice $T_c(\infty)$ through (Binder *et al*., 1985):

$$T_c(N) = T_c(\infty) - \alpha N^{-1/\gamma}, \quad (4)$$

where α is an approximate proportionality coefficient and γ is the correlation length exponent (typically close to 1/2). Thus, for a finite-size lattice, the transition temperature is expected to be less than that for an infinite lattice. In other words, dipole ordering is more likely to occur when a critical size of the MT is achieved. In addition, other important factors may affect the value of T_c and thus provide sensitive control mechanisms. Through a coupling to the elastic degrees of freedom (conformational change), the value of T_c may be shifted. The dielectric constant ϵ may be altered by the presence of water molecules surrounding an MT structure. This would decrease the value of T_c and introduce disorder. Small changes in the angles between the dimer dipoles may remove the frustration mechanism effectively preventing the onset of the intermediate phase. Changes in the opposite direction can enhance frustration favoring the intermediate phase over the F phase and effectively switching from the growth mode of operation to an information processing behavior. Thus symmetry transitions or mechanical forces may effect switching between phases.

Once in the ferroelectric phase, the system is also very sensitive to the frequency of electromagnetic oscillations. It is known that in organic ferroelectric materials a resonant frequency exists W_0 which is inversely proportional to the length, stiffness constant

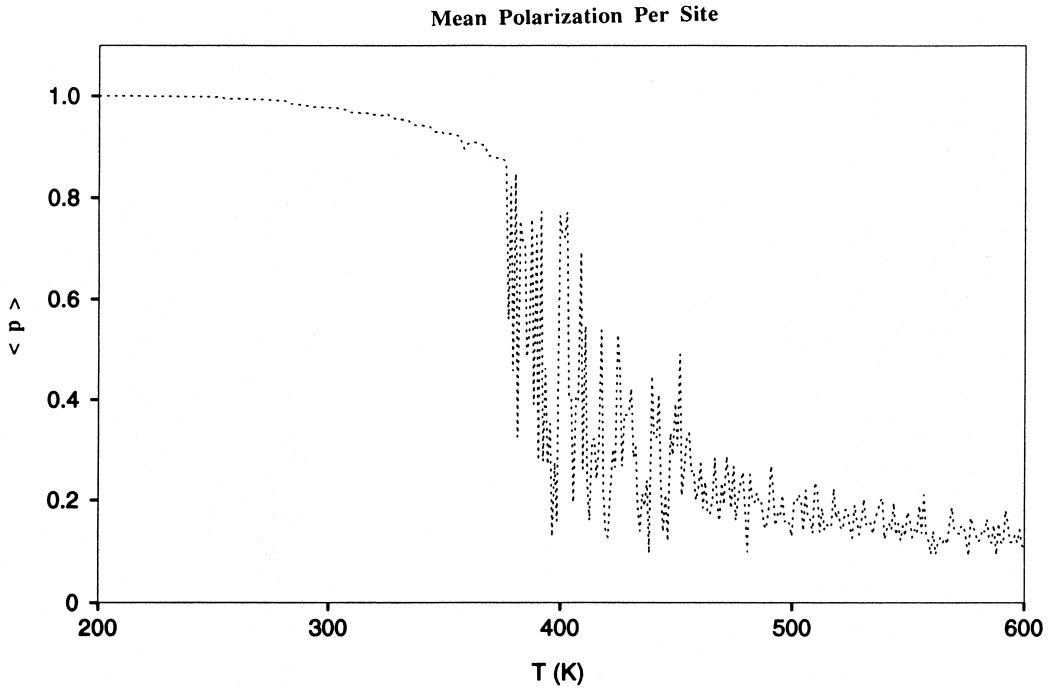

FIG. 6. A plot of the mean polarization per site for a triangular lattice whose size is 13×26.

and the square root of the density (Matthias, 1973). Extrapolating the data given by Matthias (1973), one finds for microtubules a resonant frequency range exceeding 10^8 Hz and thus being rather close to the microwave range predicted by Fröhlich (1980) to play a major role in living cells.

In Figs 6 and 7 we have shown the results of our Monte Carlo computations intended to reveal the size dependence of the phase behavior discussed above. Figure 6 is a plot of the mean polarization per site when the microtubule is composed of only 26 layers (i.e. it is a 13×26 lattice). It is clear that three distinct ranges exist: (i) the low-temperature ferroelectric range, (ii) the intermediate weakly ordered phase range and (iii) the high-temperature paraelectric range. Figure 7 illustrates the same dependence for a microtubule with 5000 layers (i.e. it is a 13×5000 lattice). We conclude that the intermediate weakly ferroelectric phase all but disappeared.

To summarize, in this section we have argued that two ordered phases are likely to govern the behavior of dipole moments in an MT. A ferroelectric phase is characterized by long-range order and has many characteristics useful in energy transfer properties discussed in the next section. An intermediate weakly ordered phase exhibits short-range order but has a multitude of equivalent, long-lived dipolar states. It appears that in the latter phase the system can explore a large subset of the phase space at a low energetical cost unlike in the ferroelectric phase. Having unhindered access to a multitude of conformational states indicates easy transitions from one configuration to another at little or no energy cost. A number of control mechanisms are possible which allow switching from one phase to the other and hence from one mode of operation to the other.

3. Ferroelectricity, Signaling and Assembly/Disassembly

It is well known that ferroelectrics are one of the few types of materials whose description is most adequately provided in terms of mean field models (Kretschmer & Binder, 1979). A typical approach is to postulate a double-well quartic on-site potential $V(S_n)$ that gives the overall effect of the environment on a selected dipole site n. Thus,

$$V(S_n) = -\tfrac{1}{2}AS_n^2 + \tfrac{1}{4}BS_n^4, \tag{5}$$

where S_n is the effective spin variable at site n and the coefficients A and B are model-dependent. It will be subsequently assumed that over long distances the variable S_n changes very gradually and can be treated as a continuous variable.

In the F phase, the MT cylinder taken as a whole represents a giant dipole. When the cross-section of an MT is viewed using electron microscopy, the outer surfaces of an MT are surrounded by a "clear zone" of several nm which apparently represents the oriented molecules of cytoplasmic water and enzymes (Steb-

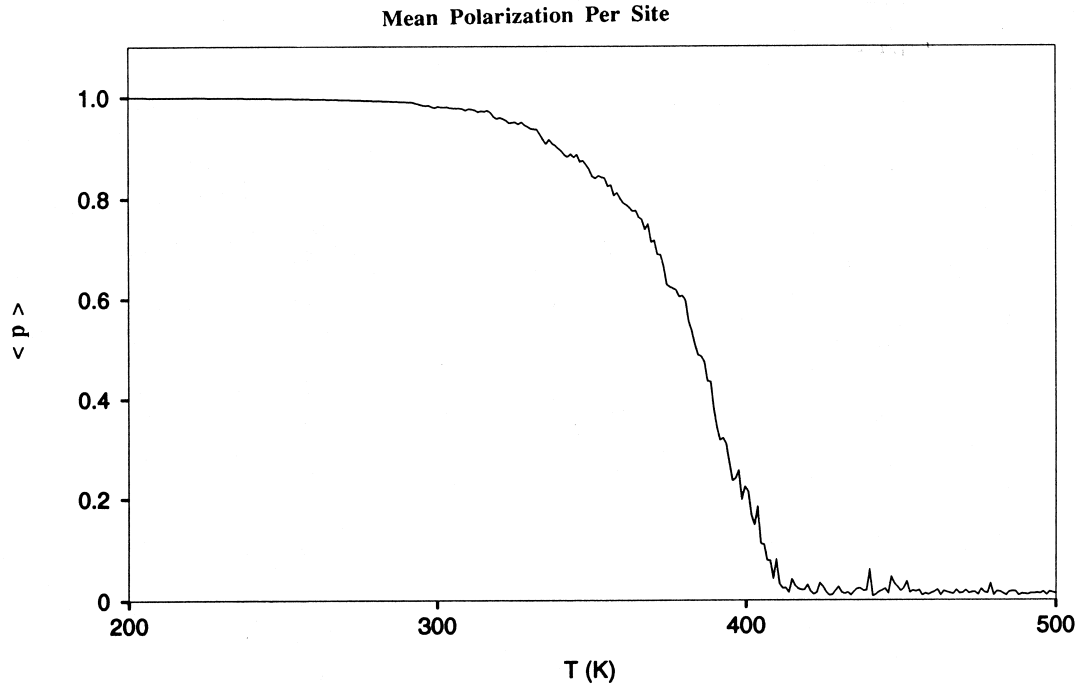

FIG. 7. A plot of the mean polarization per site for a triangular lattice whose size is 13×5000.

bings & Hunt, 1982). This could be explained by the presence of an electric field produced by an MT. Therefore, we assume that together with the polarized water surrounding it, an MT generates a nearly uniform intrinsic electric field parallel to its axis (see Fig. 1). Consequently, the additional potential energy due to this electric field and associated with each dipole is

$$V_{\mathrm{el}} = -CS_n, \quad C = qE, \tag{6}$$

where q denotes the effective charge of a single dimer and E is the magnitude of the intrinsic electric field. Within this picture, the model Hamiltonian for the dipole moments of a microtubule can be written as

$$H = \sum_{i=1}^{n} \left[\frac{1}{2} M \left(\frac{\mathrm{d}S_n}{\mathrm{d}t} \right)^2 + \frac{1}{2} K (S_{n+1} - S_n)^2 - \frac{A}{2} S_n^2 + \frac{B}{4} S_n^4 - CS_n \right]. \tag{7}$$

The first term above represents the kinetic energy associated with the longitudinal displacements of constituent dimers each of which has mass M. The second term arises from the restoring strain forces between adjacent dimers in the protofilament. If the stiffness parameter K is sufficiently large, then it is expected that large-amplitude long-wavelength excitations of the displacement field will be formed manifested by a slowly varying modulation of S_n along the MT axis.

In order to derive a realistic equation of motion for this system, the viscosity of the solvent is indispensable and the associated damping force must be introduced. Assuming for simplicity that the solvent is made up of only water molecules we may infer that water will provide a viscous medium that will damp out vibrations of dimer dipoles. This can be taken into account by adding the viscous force to the equation of motion with

$$F = -\gamma \frac{\mathrm{d}S_n}{\mathrm{d}t},$$

where γ is the damping coefficient.

Based on our assumption that the dipolar oscillations of dimers within an MT form a system that can be classified as displacive ferrodistortive, we can use the continuum approximation to obtain the corresponding equation of motion as

$$M \frac{\mathrm{d}^2 S}{\mathrm{d}t^2} - KR_0^2 \frac{\mathrm{d}^2 S}{\mathrm{d}x^2} - AS + BS^3 + \gamma \frac{\mathrm{d}S}{\mathrm{d}t} - qE = 0. \tag{8}$$

Note that the x-coordinate is along the protofilament axis. Moreover, for longitudinal sound waves the dispersion relation

$$\omega = \sqrt{K/M}$$

can be used to identify the sound velocity with

$$V_0^2 = \omega R_0 = \sqrt{K/M}\, R_0.$$

We now seek solutions of eqn (7) in the traveling-wave form where the moving coordinate ξ is given by

$$\xi = \left[\frac{|A|}{M(V_0^2 - V^2)}\right]^{1/2}(x - Vt) = \alpha(x - Vt), \qquad (9)$$

with V denoting the propagation velocity and the coefficient α is, of course,

$$\alpha = \left[\frac{|A|}{M(V_0^2 - V^2)}\right]^{1/2}$$

Consequently, eqn (8) is reduced to the ordinary differential equation below

$$M\alpha^2(V^2 - V_0^2)S'' - \gamma\alpha V S' - AS + BS^3 - qE = 0, \quad (10)$$

where $S' \equiv \mathrm{d}S/\mathrm{d}\xi$. This is an equation for an anharmonic oscillator with linear friction.

For the sake of convenience we now introduce a normalized displacement field as:

$$\Psi(\xi) = S(\xi)/S_0$$

where the normalizing coefficient

$$S_0 = \sqrt{|A|/B}$$

corresponds to the minimum of the double well potential in eqn (5).

It has been shown by Collins *et al*. (1979) that eqn (10) has a unique bounded solution which is given by the formula (and illustrated graphically in Fig. 8)

$$\Psi(\xi) = a + \frac{b - a}{1 + \exp(\beta\xi)}, \qquad (11)$$

where

$$\beta = (b - a)/\sqrt{2}$$

and the parameters a, b and d satisfy the cubic equation

$$(\Psi - a)(\Psi - b)(\Psi - d) = \Psi^3 - \Psi - \sigma, \qquad (12)$$

where

$$\sigma = q\sqrt{B}|A|^{-3/2}E.$$

Formula (11) describes a kink-like excitation (KLE) which takes the form of a domain wall separating two distinct ferroelectric domains.

It is also important to note that the above kink-like soliton propagates along the protofilament with a fixed velocity

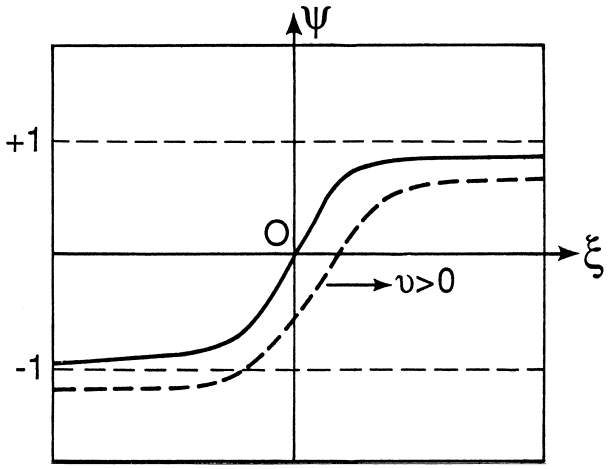

FIG. 8. The kink-like profile to the solution $\Psi(\xi)$ of eqn (11).

$$V = V_0/\left[1 + \frac{2\gamma^2}{9d^2MV_0^2}\right]^{1/2}, \qquad (13)$$

which is *less* than the sound velocity V_0 and decreases with an increase of the friction coefficient γ. It is clear that V depends on the magnitude of the electric field E through the parameter d.

For T well below T_c, V can be approximated by a linear relationship with E

$$V \approx \frac{3V_0}{\gamma|A|}\sqrt{\frac{MB}{2}}\, qE, \qquad (14)$$

where the coefficient of proportionality is called mobility and will be denoted by μ. Using simple arguments from fluid dynamics, μ can be estimated numerically as

$$\mu \approx 2 \times 10^{-5}\ \mathrm{m^2\ V^{-1}\ sec^{-1}}$$

Thus, for $E = 10^5\ \mathrm{V\ m^{-1}}$ we obtain $\mathrm{V} \cong 2\ \mathrm{m\ sec^{-1}}$ which can increase to $10^2\ \mathrm{m\ sec^{-1}}$ close to the MTs ends where E increases dramatically.

Assuming a smooth journey from one end of the protofilament to the other we estimate the average time of propagation $\bar{T}$ for a single KLE to be

$$\bar{T} = \frac{L}{\bar{V}} \approx 5 \times 10^{-7}\ \mathrm{sec}$$

A recent paper (Chou *et al*., 1994) also pointed to the possible role of solitary waves in the dynamics of microtubules.

To summarize, we showed that a unique kink-like excitation exists in the ferroelectric phase which

may propagate along an MT with a velocity that is proportional to the electric field E. KLEs in stable microtubules may constitute signals transducing membrane events via second messengers to other cell regions. Energy for such KLEs may come from GTP hydrolysis or phosphorylation via MAPs. In neurons, KLEs in microtubules may signal error information retrograde (i.e. from axon to dendrite) which would be useful in synaptic regulation and learning as in artificial neural network "back-propagation". In unstable MTs (i.e. whose ends are not stabilized by MAPs or other structures), KLEs can explain the fact that growth rates are different at the two ends of an MT. To this end, we assume that KLE formation is mainly due to the hydrolysis of GTP into GDP so that one act of hydrolysis corresponds to conformational change resulting in the formation of a single KLE. However, a KLE is preferentially oriented towards the direction of the intrinsic electric field. The propagation of a KLE will then distribute the energy of hydrolysis at the preferred end of an MT. This energy may then be used to detach dimers from the MT. This picture is in accordance with a hypothesis put forward by Kirschner & Mitchison (1986) who stated that on-rate (growth) is limited in principle only by the rate of diffusion of the monomer subunits into MT polymers (i.e. by the concentration of the constituent monomers in solution). On the other hand, the off-rate (depolymerization) can be extremely rapid and the net amount of MT polymer formed can be regulated independently by the hydrolysis of GTP.

It is reasonable to expect that at the onset of the MT assembly process, when MTs are very short, the formation of KLEs is very unlikely (or even impossible), since for a short chain the displacement field gradient required would be very high and the associated energy to form it prohibitively large. However, when the length of an MT reaches a threshold value, kink propagation could become a real possibility. Excitation of kinks being related to GTP hydrolysis would become dependent on the GTP concentration. As MTs become longer, KLE propagation accelerates leading to a disassembly at the "-" end. KLE propagation in stable MTs would depend on MAP phosphorylation or cytoplasmic kinase activity triggered by membrane events and second messengers.

4. Summary

We have argued in this paper that the spatial arrangement of dipole moments of a microtubule is crucial to its functioning as a dynamic system. Due to the presence of frustration in the dipole–dipole interactions, an intermediate weakly ferroelectric phase is predicted to arise at low enough temperatures and electric fields as well as for sufficiently short microtubules. Its attractiveness lies in maximal computational capabilities offered by a highly degenerate ground state and by long relaxation times giving relative stability to short-range correlated dipole patterns. Each pattern can be seen as containing binary information. This phase strongly resembles the well-known spin glass phenomenon which has received much attention in frustrated spin systems such as random-anisotropy magnets. Recently, spin-glass models have been applied in connection with biological systems (Stein, 1992).

The other possible ordered state is a ferroelectric phase with an almost perfect alignment of dipole movement along the protofilament axis. It is characterized by long-range order and hence its usefulness for information processing is dubious. However, it eagerly supports the formation of domain walls between the two stable orientations of dipole movements. The application of an external electric field preferentially directs kink-like excitations towards the properly aligned end. These kink-like excitations may be utilized as signaling mechanisms or causing disassembly due to energy release.

We have discussed the various possible control mechanisms (temperature, electric field, mechanical distortion) that could select the MT operating modes among information processing, weakly ordered and signaling and assembly/disassembly (ferroelectric) types.

FURTHER EVIDENCE FOR A FRÖHLICH INTERACTION OF ERYTHROCYTES

S. ROWLANDS, L.S. SEWCHAND and E.G. ENNS
Faculty of Medicine and Department of Mathematics and Statistics, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received 21 August 1981
Revised manuscript received 26 October 1981

The aggregation of red blood cells, of a single species and of mixtures of species, deviates from brownian aggregation theory. The deviations are compatible with Fröhlich's theory of a quantum mechanical interaction between living cell membranes.

In a previous paper [1] we showed that a newly discovered attraction between human erythrocytes was compatible with a theory of Fröhlich [2,3] of long-range coherent interactions in living cells. As necessary in the theory the attraction disappeared when the cellular membrane was disorganised (with glutaraldehyde) and disappeared reversibly when the transmembrane potential difference was abolished or when the cells were depleted of their supply of metabolic energy. The interaction is associated with subsequent aggregation or rouleau formation [4–7] and does not occur unless there are rouleau-inducing macromolecules in the suspending medium. In place of the simple geometrical analysis previously used we now employ an adaptation of the Smoluchowski theory of colloid aggregation by brownian movement [8]. This method gives an estimate of the range of the interaction and provides evidence that the interaction is specific, from experiments on the aggregation of mixtures of erythrocytes from different mammalian species.

Chandrasekhar [9] reviewed Smoluchowski's theory and gives an expression for the total number of particles (aggregates and singles) N_t, in a coagulating colloid suspension as a function of time t [9, eq. (461)]

$$N_t^{-1} - N_0^{-1} = (4kTZ/3\eta r)\, t, \qquad (1)$$

where η is the viscosity of the suspending medium, r the average radius of the particles and Z the radius of the hypothetical zone of attraction around each particle. In our experiments the brownian motion of erythrocytes in their own plasma, resting on the floor of a sealed siliconized haemacytometer chamber, is recorded by time-lapse cinémicroscopy [1]. When cells touch they quickly slide together [4,6,7] face to face. So linear aggregates, called rouleaux, form in time in the chamber (fig. 1). The process is similar to the coagulation of a colloid though the "particles" are much larger and the aggregates more regular. Eq. (1) would apply if the cells had the same density as the suspending fluid and so were distributed randomly in depth as well as in the horizontal extent of the chamber. In fact the cells have a slightly higher density and quickly fall to the floor. The three-dimensional process described by eq. (1) is thus compressed into two dimensions. The number of collisions in brownian motion and so the rate constant are accordingly increased by a factor of 3/2 giving

$$N_t^{-1} - N_0^{-1} = (2kTZ/\eta r)\, t\,. \qquad (2)$$

Einstein's theory of brownian motion [10] gives the mean square deviation in two dimensions as a function of time,

$$\langle U^2 \rangle = 4kTt\mu^{-1}\,, \qquad (3)$$

where μ is Stokes' drag coefficient for spheres,

$$\mu = 6\pi\eta r\,. \qquad (4)$$

To check that cells beyond the range of an interaction were executing brownian motion, U was measured for each of 30 cells which remained further than 6 μm

from other cells during the first 15 min of each experiment. Beyond 15 min fewer than 30 cells remained unassociated. For an average plasma viscosity (1.7 × 10^{-3} Pa s) and incorporating Perrin's correction to eq. (4) for oblate spheroids [11] the calculated value for μ = 1.54 × 10^{-7} N s m^{-1}. The experimental values for cells (table 1) are nearly twice as large and a similar discrepancy occurs with microspheres (table 1). We infer that the hydrodynamic drag is substantially increased when cells or microspheres are resting on the floor of the haemacytometer. In deriving eqs. (1) and (2) it is assumed [9] that the diffusion coefficient of the individual particles is given by the Stokes–Einstein relation

$$D = kT/6\pi\eta r\,, \qquad (5)$$

where the Stokes' drag coefficient appears as the denominator. The rate constant in eq. (2) must therefore be reduced by the ratio of the experimentally determined drag to the Stokes' drag, and this ratio is determined for each experiment. In seven experiments conducted on the same blood the standard error of the mean value of $\langle U^2 \rangle$, and so of μ was 19%. This sets a lower limit for the accuracy of the experiments as presently performed.

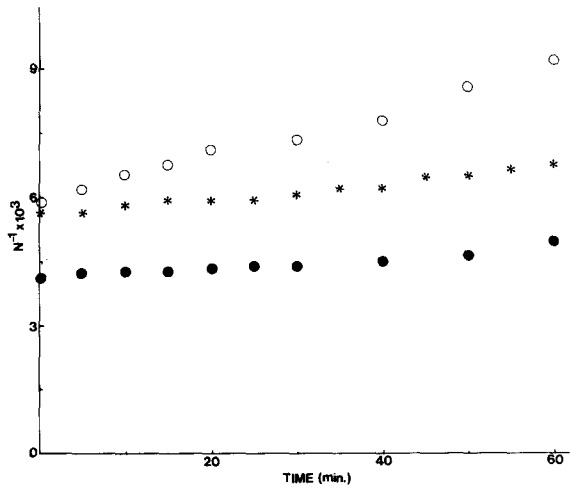

Fig. 2. Plots of the reciprocal of the total number of particles in an area of 10^5 μm^2 against time. ○ normal cells, Ξ = 3.37: ● glutaraldehyde-fixed cells, Ξ = 0.83: * microspheres, Ξ = 1.15.

For a typical experiment and if there is no interaction before cell contact ($Z = r$) the calculated corrected slope of the graph of N_t^{-1} against t will be 2.6 × 10^{-18} m^3 s^{-1}, a value which varies slightly from experiment to experiment. Experimental results are displayed in figs. 2–4 and in column 3 of table 2 as multiples of this base value (interaction coefficient Ξ = Z/r). In this table results obtained by the previous method [1] are displayed

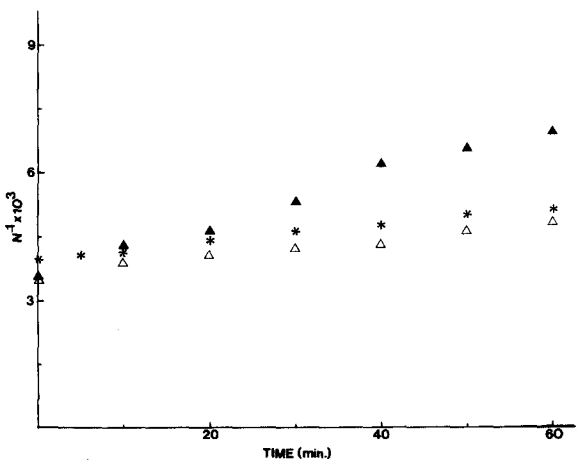

Fig. 3. As in fig. 2. △ membrane potential reduced to 1.5 mV by changing pH of plasma to 6.3, Ξ = 1.28: ▲ membrane potential restored by returning pH to 7.6, Ξ = 3.51: * membrane potential reduced by treatment of cells with ionophore A23187, Ξ = 1.66.

alongside (column 2). By having the same trend the results confirm each other though the relationship between the two sets of figures is non-linear as may be expected.

Fixed cells and microspheres have interaction coefficients close to unity and so, taking account of the added drag, show no significant deviation from brownian movement. For normal cells the interaction coefficient is three times the base value. Abolishing the membrane potential by reducing *pH* to 6.3 abolishes the interaction. Abolishing the membrane potential by the ionophore causes a significant decrease in Ξ but the two experiments suggest a remnant of interaction. Metabolic depletion causes a great fall in Ξ to a value which suggests a repulsion but both of these two last findings need further study for confirmation. Repleting energy-deprived cells and partially restoring the membrane potential after 3 h [1] brings the interaction back to the range of normal cells. Since the interaction coefficient $\Xi = Z/r$ we conclude that the interaction of normal cells extends on the average to a distance of three cell radii.

An assumption of the Smoluchowski theory of colloid aggregation is that all the aggregating particles are of the same size which is a reasonable assumption for the erythrocytes from a single individual. Mixtures of erythrocytes from different species of mammals will also aggregate into rouleaux when suspended in isotonic solutions of certain macromolecules [12]. Plasma cannot be used because of immunological reactions. In such interspecies rouleaux, cell volumes may differ by as much as a factor of two. Overbeek [13], in discussing the aggregation of polydispersed colloids, shows that

microspheres 8.0 μm		1.15	1	

[a] Probability of pairs of cells colliding in 3 h [1]. Value for no interaction ≈0.3.
[b] Interaction coefficient as defined in text. $\Xi > 1$ attraction.
[c] Standard deviation: $p < 0.001$ normal versus glutaraldehyde cells; normal versus *pH* = 6.3 cells; *pH* = 6.3 versus *pH* = 7.6 cells; normal versus metabolically depleted cells; $p < 0.003$ normal versus ionophore-treated cells.

the *least* likely collision is between particles of the same size. Yet in the interspecies experiments [12] cells of the *same* size and so of the same species show a preference to adhere to each other. In ten combinations of different species the only exception was a rat–mouse mixture though there is a significant difference in cell size, larger than in some pairs which did show a species preference. Perhaps rats and mice, being of the same biological family, have red cells indistinguishable in respect to a Fröhlich interaction.

The interspecies interaction is contrary to that expected of a passive phenomenon [13]. It gives a different type of evidence from that adduced above for a specific interaction at a distance between mammalian erythrocytes. Further work will reveal whether the interspecies interaction is a repulsion, a null interaction, or an attraction smaller than that between cells of the same species. Brownian motion could overcome a small repulsion allowing rouleaux to form at a slow rate.

During growth, particularly in the embryo, cells appear to have the ability to recognise and to adhere to like cells. Experimentally a random mixture of dispersed cells of embryonic liver and heart will sort itself out. The hepatocytes form a ring around, and an island within, the cardiac myocytes [14]. In synchronized Chinese Hamster Ovary-KI cells, GI cells adhere to each other at twice the rate S cells adhere, while GI cells adhere to S cells at an intermediate rate [15]. In explanation, cell motility and chemical and physicochemical mechanisms are invoked [16]. Mammalian erythrocytes are not motile so their mutual attraction is not chemotactic. The first time they touch they adhere and then quickly slide into the rouleau array [4]. So the process is not one of tentative random collisions followed by immobilisation as chemical binding sites interlock. Yet their interactions are not dissimilar from those reported for other groups of cells [14–16]. This suggests that a Fröhlich effect is playing at least some part in the interaction of a wide range of mammalian cells.

GENERAL THEORY OF COHERENT EXCITATIONS ON BIOLOGICAL SYSTEMS

H. Fröhlich

Department of Physics
Oliver Lodge Laboratory
The University of Liverpool Oxford Street
Liverpool L69 3BX ENGLAND

ABSTRACT

Coherent excitations, as first proposed in 1968, can arise in the presence of nonlinear interactions if metabolic energy is supplied at a rate s above a critical s_o. Three types of excitations will be shown to exist: A excitation of a single mode; B excitation of a metastable highly polar state; C excitation of limit cycles or Lotka-Volterra oscillations in complex systems. They may have far reaching consequences on the dynamics of biological systems.

Externally applied radiation may, at certain frequencies and at certain stages of development, act as trigger to biological events. In this case a steplike dependence on the intensity is to be expected.

Relevant experimental evidence will be indicated.

INTRODUCTION

A general theory of biological activity necessarily will be concerned with properties common to most biological materials. From the point of view of physics the extraordinary dielectric properties (1) are outstanding in this respect. Most remarkable amongst these are the very high electric fields of about 10^7 volt/m, usually present in biological membranes, leading to very strong polarization of the materials in them.

W. R. Adey et al. (eds.), *Nonlinear Electrodynamics in Biological Systems*
© Plenum Press, New York 1984

Biologically the term "life-cycle" already indicates a crude periodicity in biological dynamics, though here, each particular case exhibits individuality prohibiting the exact reproducibility of a period.

We shall take a vast step and assume that coherent excitation of electric vibrations in a large range of frequencies play an important role in biological activity. Modern physics offers this type of excitation arising through nonlinear interactions, with the necessary energy supplied, in general, from metabolic processes. Thus while supply of energy to a material usually leads to heating, coherent excitations may arise if certain conditions are satisfied.

This point of view was first presented more than fifteen years ago (2,3). It has led to far reaching consequences which stimulated a great number of experiments (review up to 1979 in (4). In a recent meeting on coherent excitations in biological systems (5,6) the assembled physicists and biologists have arrived at the conclusion that coherent excitation had now been shown to be an intimate feature of biological activity*.

COHERENT EXCITATIONS

Three types of coherent excitation have been proposed:

A. Coherent excitation of a single polar mode.

B. Excitation of a metastable highly polar state; this includes solitons.

C. Vibrations arising from more complex processes and giving rise to limit cycles or Lotka-Volterra oscillations.

All three involve essentially nonlinear processes.

Frequencies of type A processes in membrane vibrations have been estimated in the 10^{11} Hz region; this corresponds to the frequency of millimeter waves. Both, higher and lower frequencies of polar modes in biological molecules, and larger systems, do exist and must be relevant: Such vibrations interact with the

---

*Misrepresentation in this subject is fairly common. Thus in a recent book review in Bioelectromagnetics (December 1982) K.R. Foster seems to be quite unaware that experiments on the influence of millimeter waves on the rate of growth of yeast were undertaken to test the theoretical conjectures.

abundant cell water and thus will be strongly damped. Spectroscopy of non-excited systems thus shows broad bands only. Coherent excitation, however, as is well known from the theory of lasers, overcomes the damping and leads to sharp lines.

In the type A model, nonlinear interaction of the polar vibrations with a heat bath under the influence of energy supply at a rate s leads to the transformation of a Planck distribution of excitation at frequency s into a Bose distribution containing a chemical potential μ, i.e. to a replacement of $h\omega$ by $h(\omega-\mu)$. Here increases with increasing s and at a critical value s_o causes Bose condensation, i.e. high excitation of a single mode*.

A metastable highly polar state (B) may arise from the shape dependence of the electrostatic energy of a polarized material (7). Material deformation then must overcome the elastic energy, and the condition for the existence of the state B requires a certain softness which implies the sound velocity c to be below a certain critical value c_o. In extended regions where the sound velocity may vary spatially, those for which $c < c_o$ may exhibit the excitation.

Excitation of type C involves the consequences of A and B and will be discussed below.

Excitation of a metastable state (B) requires a single appropriate energy supply. Excitation of coherent vibrations, however, as mentioned above involves a rate of energy supply s above a critical s_o. When the existing s is just below s_o then small further supply at the rate s_o-s will induce the excitation.

It must also be pointed out that the frequency of the excited vibration need not be exactly reproducible. Assume an ion to be attached to the vibrating region in some cases but not in others. Through electrostatic interaction it may lead to a small shift in frequency through which in course of the nonlinear excitation may be stabilized. Also, nonlinear interaction may induce the frequency shifts which depend on the degree of excitation.

CONSEQUENCES

Coherent excitation of a single polar mode (A) leads to frequency selective long range interaction between systems with

---

*Extensive theoretical work in this direction has been carried out by Bhaumik et al., Mills and Wu et al.; quoted in (4). Regrettably, very faulty theoretical work has also been published in this field.

equal frequencies; in biological membranes this will be in the 10^{11} Hz region, but higher as well as lower frequencies, originating in other cell structures, will be expected. Such interaction may lead to selective attraction (or repulsion) of systems, to other control of their activities, and to communication within and between cells. It will be noted that electrostatic long range interaction is screened through counter ions.

Excitation of the metastable polar state (B) may lead to storage and transport of energy. It could represent the active state of enzymes and through the high internal field lead to a reduction of activation energies. It could also be effective in transporting energy from protein to protein. An array of proteins dissolved in a membrane would thus act as the energy transporting network postulated by current thinking (8).

The excitation discussed here may be switched on or off depending on the supply of energy at the appropriate time and place. In general this energy will arise from metabolic processes (or light in case of photosensitivity) and must be regulated by a control system. In the case of excitations A the energy must be supplied to the band of polar modes. According to the theoretical model, the system possesses storage capacity, and a certain time will be required to effect the excitation even if the rate of supply s exceeds the critical one, $s > s_o$. At this stage the system becomes sensitive to interference from the outside. When the relevant band of frequencies is in the microwave, in particular in the millimeter wave region, then low intensity external radiation may cause large biological effects as the switching on of the excitation depends on s in a steplike fashion.

Such effects will be noticeable whenever the externally applied frequency falls into the band of polar modes. When a coherent mode begins to be excited, however, then energy application at its frequency will be more effective. Biological effects dependent on resonance must be expected. The external radiation then acts as a switch. It will be effective at certain periods of the biological development only.

The selective attraction arising in excitation A may play a crucial role in multienzyme processes. Assume enzymes to be spatially organized as discussed by Clegg in (6). Then some of the energy liberated during the enzymatic process may be used to cause excitation A in substrates which then will attract other substrates. This leads to an increase in available substrates and in turn to an increase in the rate of enzymatic processes which decreases the number of substrates. A typical Lotka-Volterra oscillation arises - characteristic of our type C of coherent

oscillations. More complex situations may arise leading to limit cycles as discussed in these proceedings by Kaiser. Further consequences are also discussed by Del Guidice.

Such excitations may also be sensitive to external vibrations which might, by relatively weak supply of energy, liberate the stored energy and thus cause large biological effects.

EXPERIMENTS

Existence of three types of coherent excitations: A) a coherent single mode; B) a polar metastable state; C) a periodic activity arising from A and B, arises as the main conclusion of theoretical considerations. Detailed mechanisms might well differ considerably from the particular theoretical models; they might in fact be different in different cases.

Relevant experiments have been discussed in reference (6). They refer to the attraction of nutrients to a cell - similar to the attraction of a substrate as discussed above. The excitation is measured through non thermal excitation of anti-Stokes lines in Raman effect (Drissler et al. in (6). Rowland (6) gives evidence for the mutual attraction of blood cells satisfying the requirements of the theory.

Several contributions are related to biological effects arising from irradiation by very low intensity milimeter waves. Attempts to interpret these in conventional ways, e.g. in terms of the field turning a protein, are quite out of place as they would require (9) intensities of millions W/cm^2 when experiments use 10 mW/cm^2 or less.

Experiments conducted so far do not permit specification of the particular biological process on which electromagnetic fields act. Although recently important evidence in this direction has been obtained, the experiments will have to be continued to establish this evidence. For example, extremely sharp frequency dependence of the influence of millimeter waves on the rate of growth of yeast have been reported by Grundler et al. (6). They find the step-like intensity dependence required by the theory. Apart from a very sharp resonance in the region of 41700 MHz, the frequency dependence exhibits a fine structure of about twenty minima and maxima, spaced at 7-8 MHz. It is tempting to interpret the basic line in terms of a type A excitation with the low frequency arising from processes of type C which require a type A excitation. With very sensitive instrumentation, carried out in an electrically screened laboratory, C.W. Smith and A.H. Jafary have measured very sharp emission in the 7-8 MHz region from single yeast cells. They occur during the period of cell division only, and last only about 3 minutes. The frequencies are not always

exactly the same, but this should be interpreted in terms of individuality as discussed in reference 2. We should conclude that the excitation is closely connected with the highly organized processes occurring in cell division.

Long range interaction may also be expected relevant for the control of cell division, important in the cancer problem (4) IVD). Experiments on growing tissue cultures would, therefore, be highly desirable. They do require, however, development of new experimental techniques.

Cellular power

ABSTRACT

Microtubules are important structures in the cytoskeleton, which organizes the cell. Since microtubules are electrically polar, certain microtubule normal vibration modes efficiently generate oscillating electric field. This oscillating field may be important for the intracellular organization and intercellular interaction. There are experiments which indicate electrodynamic activity of variety of cells in the frequency region from kHz to GHz, expecting the microtubules to be the source of this activity. In this paper, results from the calculation of intensity of electric field and of radiated electromagnetic power from the whole cellular microtubule network are presented. The subunits of microtubule (tubulin heterodimers) are approximated by elementary electric dipoles. Mechanical oscillation of microtubule is represented by the spatial function which modulates the dipole moment of subunits. The field around oscillating microtubules is calculated as a vector superposition of contributions from all modulated elementary electric dipoles which comprise the cellular microtubule network. The electromagnetic radiation and field characteristics of the whole cellular microtubule network have not been theoretically analyzed before. For the perspective experimental studies, the results indicate that macroscopic detection system (antenna) is not suitable for measurement of cellular electrodynamic activity in the radiofrequency region since the radiation rate from single cells is very low (lower than 10^{-20} W). Low noise nanoscopic detection methods with high spatial resolution which enable measurement in the cell vicinity are desirable in order to measure cellular electrodynamic activity reliably.

1. Introduction

Electrodynamic activity of eukaryotic cells is a topic, which is gaining considerable theoretical and experimental support in recent years. In the 1960s Fröhlich postulated and theoretically treated a concept in which he presented the possible existence of the mechanical vibrations of electrically polar structures in living cell causing generation of electric oscillations around and in the cell. Firstly, he proposed electrically polar longitudinal vibrations interacting with an elastic field, giving rise to coherent cellular electric oscillations (Fröhlich, 1968b, 1969). Secondly, he showed that the energy condenses to the lowest frequency mode in his nonlinear model system (Fröhlich, 1968a). Lastly, he estimated that oscillating polar structures are situated in the cellular membrane and their oscillating frequency is in range $10^{11}-10^{12}$ Hz. However, with the advent of deeper understanding of the cellular structure the microtubules emerge as hot candidates for generation of endogenous electrodynamic activity of living cells (Pokorný et al., 1997, 1998).

A possible biological role of the endogenous cellular high-frequency electric field has been analyzed by several authors. Its role has been proposed in long-range protein interactions (Fröhlich, 1972, 1975), in chemical reaction transfer and consequently chemical reaction kinetics (Pokorný and Wu, 1998; Pokorný et al., 2005a, 2005b; Pokorný, 2001), in disrupted cellular organization state such as cancer (Fröhlich, 1978; Pokorný et al., 2008), and in intercellular interactions (Pokorný et al., 1983; Pokorný and Fiala, 1994; Pokorný, 2006; Pohl, 1981, 1980; Rowlands et al., 1981, 1982).

The electrodynamics of cellular structures is inseparably connected to the vibrational dynamics of biomacromolecules. Many marvelous biological functions in proteins and DNA and their profound dynamic mechanisms, such as switch between active and inactive states (Chou, 1984b; Chou et al., 2001; Wang and Chou, 2009), cooperative effects (Chou, 1989), allosteric transition (Chou, 1984a, 1987; Schnell and Chou, 2008), intercalation of drugs into DNA (Chou and Mao, 1988), and assembly of microtubules (Chou et al., 1994), can be revealed by studying their internal motions (Chou, 1988) or terahertz frequency motions. Such inferences have been later observed by NMR (Chou et al., 2001), and applied in medical treatments (Gordon, 2007, 2008;

doi:10.1016/j.jtbi.2011.07.007

Madkan et al., 2009). Recently, investigation into the internal motion in biomacromolecules and its biological functions is deemed as a 'genuinely new frontier in biological physics' (Vermont Photonics Technologies Corp, 2011). Likewise, to really understand the action mechanism of microtubules, we should consider not only its static structure but also its dynamical character. The electrodynamic behavior of microtubules inevitably underlies electrodynamic activity of living cells.

Electric oscillations of living cells have been experimentally investigated by several authors in the frequency range from kHz (Jelínek et al., 2008, 2009) through MHz (Pohl et al., 1981; Hölzel and Lamprecht, 1994; Hölzel, 2001; Pokorný et al., 2001) to the GHz (Jelínek et al., 2007; Cifra, 2009) region. These pioneering experiments suggest cellular electrodynamic activity in mentioned frequency region, but the measurement systems used were of the threshold sensitivity. It was recently explained (Kučera et al., 2010) which technical prerequisites must be fulfilled by the measurement system which is designed to detect cellular electrodynamic activity in kHz–GHz region. One of the biophysical aspects underlying the technical prerequisites for high gain and low noise of the first pre-amplifier is the obviously low power radiated from the cell. However, there are few theoretical calculations which provide quantitative evaluation of radiated power from cell and electric field intensity around the cell in the high-frequency region. Pokorný carried out calculations where the source of MHz–THz cellular electric oscillations were assumed to be membrane proteins (Pokorný and Wu, 1998; Pokorný, 1990, 1987) (some selected results are also in Pokorný et al., 1983, 1996; Pokorný, 1985). Shein and Kharlanov (2007) and Kharlanov (2006) represented the whole membrane by discrete dipole layer and considered acoustoelectric vibrations of the membrane in MHz–GHz region. The analysis of Russian authors was inspired by the earlier works of Devyatkov, Golant and Betskii (summarized in books Betskii et al., 1988; Devyatkov et al., 1991) who proposed that the acoustoelectric vibrations of the cell membrane can generate electric oscillations in the region of 30–300 GHz and made the first estimation of radiated electromagnetic power from single cell. Results from both groups of authors show clearly that single cell radiation under most conditions is of the power well below 10^{-20} W, thus hardly detectable in far field at room temperature if the exact frequency of radiation is not known a priori. As can be seen, all of these works considered only cell membrane as the source of the oscillatory electric field, although modern findings suggest that cytoskeleton, especially microtubules, is also very probable source of endogenous cellular high-frequency electric oscillations (Cifra et al., 2010d). Work presented here is filling the gap by calculating electric field and radiation of the whole cellular microtubule network.

2. Microtubules

Cytoskeleton is not only the mechanical support of the cell, but also the dynamic structure responsible for dividing the cell in two, for cellular motion and selforganization of the cell. Cytoskeleton is composed of three types of filaments. One of them are microtubules. Microtubules resemble hollow rods with inner and outer diameter 17 and 25 nm, respectively. These structures are mostly composed of 13 protofilaments, see Fig. 1. The subunits of protofilaments are tubulin heterodimers, which are constituted from α- and β-tubulin. Tubulin heterodimer is very polar structure with static dipole moment $p_{AXIS,STATIC} = 337$ D $(1.12 \times 10^{-27}$ C m) (Tuszyński et al., 2005) in the direction of the microtubule axis. In most of eukaryotic cells, microtubule nucleating and organizing center is a centrosome, which is a cell organelle near the nucleus. Microtubules grow up from this center through the cytoplasm to the cell membrane and

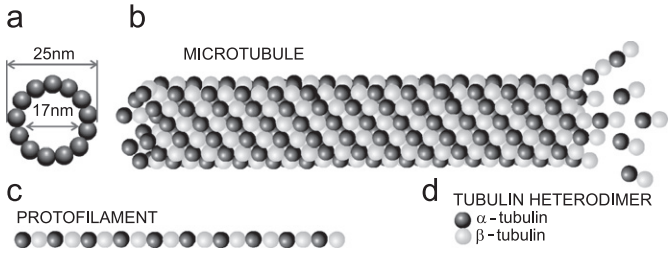

Fig. 1. (a) Cross section of a microtubule. (b) A single microtubule with 13 protofilaments. (c) One protofilament. (d) One tubulin heterodimer.

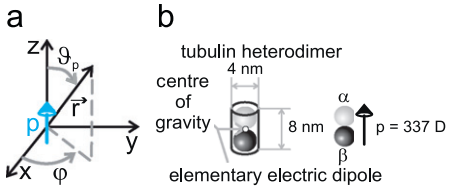

Fig. 2. (a) Dipole moment in the Cartesian coordinate system. (b) Tubulin heterodimer (dimensions and center of gravity).

create intricate network. Together with an extraordinary elasticity, microtubules fulfill all conditions for generation of electric oscillations (Cifra et al., 2010c).

2.1. Electric properties of microtubule

Electric properties of tubulin heterodimer were approximated by an elementary electric dipole (in further text the term "dipole" is used for brevity). Field of such dipole is described by

$$H_\varphi = -\frac{Idl}{4\pi}k^2\sin(\vartheta_p)\left(\frac{1}{jkr}+\frac{1}{(jkr)^2}\right)e^{-jkr} \quad (1)$$

$$E_r = -\frac{Idl}{2\pi}Zk^2\cos(\vartheta_p)\left(\frac{1}{(jkr)^2}+\frac{1}{(jkr)^3}\right)e^{-jkr} \quad (2)$$

$$E_\vartheta = -\frac{Idl}{4\pi}Zk^2\sin(\vartheta_p)\left(\frac{1}{jkr}+\frac{1}{(jkr)^2}+\frac{1}{(jkr)^3}\right)e^{-jkr} \quad (3)$$

where E is the electric field intensity, H is the magnetic field intensity, I is the equivalent current, dl is the length of the dipole, Z is the wave impedance, k is the propagation constant, ω is the angular frequency, p is the dipole moment, j is the imaginary unit ($j^2 = -1$) and other symbols are according to Fig. 2a.

All equations include:

$$Id\vec{l} = j\omega\hat{p} \quad (4)$$

In the near zone the dominant components are with $E \sim 1/(jkr)^3$ and $H \sim 1/(jkr)^2$ and the time-averaged Poynting vector (power density, or Poynting vector in further text, for brevity) composed of these components is zero in lossless medium, because the phase shift between E and H is $\pi/2$. Time-averaged Poynting vector $\vec{S}$ is defined as $\vec{S} = \frac{1}{2}\mathrm{Re}\{\vec{E} \times \vec{H}^*\}$, where Re{} denotes real part of complex number and * denotes complex conjugate.

Every tubulin heterodimer in one microtubule is approximated by elementary electric dipole to obtain the model of electrical properties of microtubule (Fig. 3).

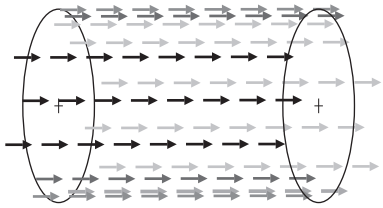

Fig. 3. Model of electrical properties of microtubule. Every arrow represents one dipole.

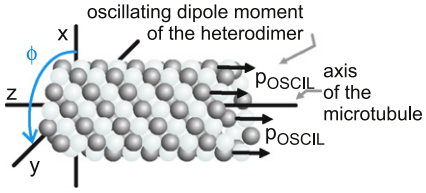

Fig. 4. Location of microtubule in coordinate system and sense of the angles ϑ and ϕ.

3. Method of calculation

Scripts for calculation of electromagnetic field generated by microtubule network were written in Matlab. It had to be dealt with three problems during calculations. The first is the distribution of points on the sphere with the smallest potential energy—to obtain the most symmetric distribution of arbitrary number of microtubules. The second is the rotation of microtubules and then creation of microtubule network. The last problem to deal with was a summation of small and great numerical values. The first problem was analyzed by Bulatov (1996). The solution of problem of microtubule rotation will be described in the following: The microtubule is situated in Cartesian coordinate system (Fig. 4) and coordinates of vector of elementary electric dipoles (both position and direction) are known.[1]

These coordinates were rotated according to the points distributed on the sphere[2] with the smallest potential energy. Two representative models of microtubule network were created in this way. The first model (symmetric) represents the microtubule network of nondividing cell. End points of microtubules' axes are distributed symmetrically and uniformly on the sphere in this model (the axes of microtubules are situated along radius vectors from center of the sphere to end points which are uniformly distributed on the sphere. Uniform distribution was obtained by an algorithm which calculates coordinates of point charges uniformly distributed on sphere—distributed according to their total smallest potential energy) (Fig. 5). This uniform and symmetric distribution of microtubules simulates complete (phase and geometric) symmetry in the cell. The second model (asymmetric) is the model of asymmetric distribution of microtubules (Fig. 6). This model represents microtubule network during mutual cellular interaction or during cellular interaction with solid substrates when cytoskeleton is redistributed. Both models are composed of 100 microtubules, which is reasonable estimate based on electron microscopy studies of eukaryotic cells (Sobel, 1997; Winey et al., 1995; May and Hyams, 1998). Each microtubule in our model is constituted of 1950 heterodimers.[3] We assumed that the ends of microtubules are in direct contact with the cell membrane, i.e. diameter of the model cell is 2.8 μm (0.4 μm diameter of the centrosome $+2\times1.2$ μm of microtubule length).

The problem of summation of small and large numeric values occurred in calculations of power mainly in lossless medium, because the value of field calculated only from near field

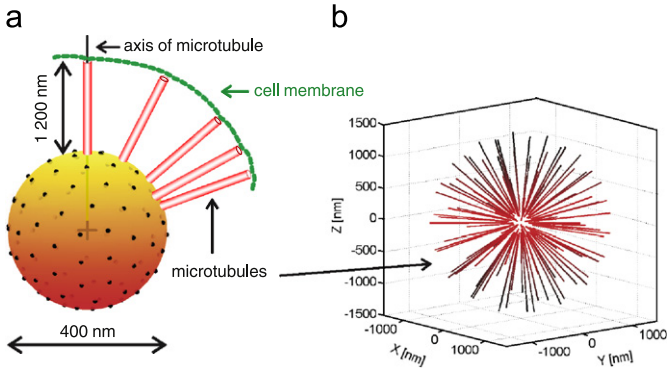

Fig. 5. (a) Model of centrosome with nucleation centers (black points) uniformly and symmetrically distributed on the sphere. (b) The symmetric model of a simple microtubule network with 100 microtubules. The ends of microtubules are distributed according to (a). Each red line represents one microtubule. Centrosome is in no way involved in the generation of mechanical or electric oscillations in the current calculations model, it is depicted here only for clarity and explanation of the geometrical distribution of microtubules. The ends of microtubules are distributed according to (a). Each red line represents one microtubule. Centrosome is in no way involved in the generation of mechanical or electric oscillations in the current calculations model, it is depicted here only for clarity and explanation of the geometrical distribution of microtubules. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

components is much greater than value of field calculated from far field components. This was solved by decomposition of Eqs. (1)–(3) into parts $1/jkr$, $1/(jkr)^2$ and $1/(jkr)^3$ and by calculation of small and large values separately. All three problems and their solutions were described closely by Havelka (2010).

The calculation is executed by vector summation of contributions from all dipoles in the point of space in which the value of electric and/or magnetic field (in further text the term "point" is used for brevity) has to be calculated and then this procedure is repeated for all points in the chosen set (sets included either plane, coaxial surface of microtubule or spherical surface around

[1] Coordinates of the initial point of dipole vector are in the center of gravity of tubulin heterodimer and coordinates of the endpoint of dipole vector depend on angle ϑ. ϑ is the angle between the axis of dipole vector and the axis of microtubule. Thus, $\vartheta=0$ corresponds to case when the dipole vector is parallel with the microtubule axis. In other words, when we consider longitudinal axial oscillations of microtubule (and heterodimer from which it consists), only component of the dipole vector which oscillates significantly is the one which is parallel with the microtubule axis.

[2] Sphere with radius 200 nm represents simple approximation of spherical surface of centrosome, from where the microtubules grow.

[3] Thirteen protofilaments $\times150$ heterodimers in one protofilament, corresponds to the length of 1.2 μm of a single microtubule.

cell). This method was used for calculation of the power radiated from models and electric intensity in radiant distance from a cell membrane. The effect of the cell membrane is neglected in our calculations. To obtain the radiated power P, numerical integration of Poynting vector (power density) was performed over the sphere concentric to cell center using summation $P = \sum_i^N S_i \cdot A_i$ (N, number of elementary surfaces, A_i, i-th surface with S_i power density flowing through it) which is discrete equivalent of continuous integration $P = \int \vec{S}\, d\vec{A}$, where P is the power flowing through the surface A and S is the Poynting vector (power density). Electric field of the whole microtubule network was calculated along the radius vector, either in the direction from the "pole" or from the "equator" (Fig. 6).

4. Parameters used for calculations

Calculations were performed in frequency regions in which various workers have been attempting to measure electric oscillations of cells (Jelínek et al., 2007, 2008, 2009; Pelling et al., 2005; Pohl et al., 1981; Hölzel and Lamprecht, 1994; Hölzel, 2001; Pokorný et al., 2001; Cifra, 2009). Two different surrounding media were taken into account: lossy and lossless. The parameters of surrounding media are in Table 1 (ε_r and σ have subscript 1 for lossy medium and subscript 2 for lossless medium). Longitudinal shift between neighboring protofilaments is 4.92 nm (corresponds to the microtubule lattice A, Tuszyński et al., 2005) as can be seen in Fig. 4. Longitudinal oscillations of tubulin heterodimers are represented by oscillating dipole moment in the direction of microtubule axis ($p_{AXIS,STATIC} = 337$ D static part of dipole moment). We note for clarity that every tubulin in microtubule is oscillating. This follows from the fact that oscillations of microtubules as wholes are considered in this paper. Amplitude of oscillatory component of the tubulin dipole moment around kHz was estimated based on Pelling et al. (2004, 2005). In this work Pelling measured oscillations of yeast cell wall, likely connected with cytoskeleton oscillations, in the amplitude range 1–10 nm, so the amplitude of 1 nm was accepted. Amplitudes of oscillations for higher frequencies are assumed to be of the level of thermal motion amplitude of proteins (Chou, 1988), which is around 0.1 nm. Thus, taking ratio of the oscillatory amplitude (1 and 0.1 nm) and the length of the dipole (tubulin heterodimer length of 8 nm) amplitude of the dipole oscillatory component were estimated: for kHz $p_{OSCIL1} = \frac{1}{8} p_{AXIS,STATIC}$ and for higher frequencies $p_{OSCIL2} = \frac{0.1}{8} p_{AXIS,STATIC}$.

Oscillations of tubulin heterodimers in one protofilament were approximated by longitudinal oscillations of the chain of rigid particles of two types, optical branch (Kittel, 1976). Optical branch is able to generate and absorb electromagnetic field effectively. Movement of particles (tubulin heterodimers) and corresponding oscillations of the dipole moment are described by spatial modulation function:

$$p_m = p_{OSCIL} \cdot \sin(mv) \tag{5}$$

Table 1
Parameters of surrounding medium around microtubules and cell model for eight frequencies. ε_r and σ have subscript 1 for lossy medium and subscript 2 for lossless medium.

f (Hz)	1 k, 1 M, 10 M, and 100 M	1 G	10 G	42 G	100 G
ε_{r1} (–) (relative permittivity)	81	81	71	20	10
σ_1 (S/m) (conductivity)	1	1.33	17.22	39.67	68.50
ε_{r2} (–) (relative permittivity)	81	81	71	20	10
σ_2 (S/m) (conductivity)	0	0	0	0	0

where p_m is the modulated dipole moment, p_{OSCIL} is the oscillatory component of the dipole moment and mv is basically distance along the microtubule. Modulation function is specific for each mode, minimal mode number is zero, maximal mode number (max) depends on the number of tubulin heterodimers, i.e. length of microtubule. The mode zero represents oscillations of all dipoles in phase and the max mode represents oscillations of neighboring dipoles in antiphase.

For the illustration, modulation function of the 1st protofilament is depicted in Fig. 7 for the mode 3. Modulation functions of other protofilaments (2nd–13th) are axially shifted, according to the position of protofilaments in the real microtubule A lattice. Each circle in Fig. 7 represents the value of dipole moment of one heterodimer. Modulation function represents effect of a vibrational longitudinal wave on dipole moments of individual tubulin heterodimers. This wave can be described as the wave which has the same phase in the cutting plane orthogonal to the axis of the microtubule (Fig. 8—mode 3). Integer values of mode numbers correspond to boundary conditions of rigidly bound ends of microtubule. It is important to note that in our models of microtubule network, phase difference between oscillations of individual microtubules is zero, i.e. microtubules oscillate in phase. The distribution of electric field around microtubule excited by vibration modes min (mode 0) and max (mode 50, in this case) can be seen in Fig. 9. The intensity of

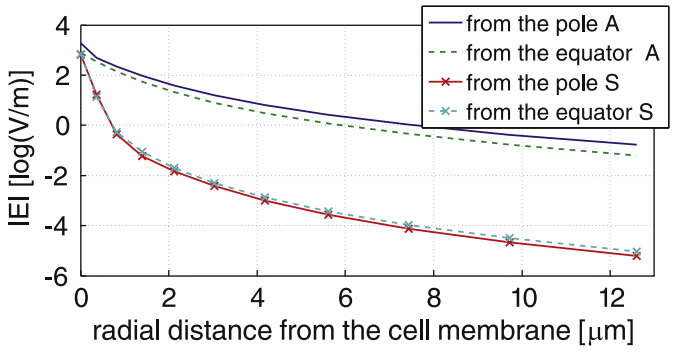

Fig. 11. Radial dependence of the electric intensity from the cell membrane in the direction from the equator (dashed lines) and from the pole (full lines) up to 12.6 μm. A and S stands for the asymmetric and the symmetric model, respectively (mode 0, f=100 GHz, lossy medium).

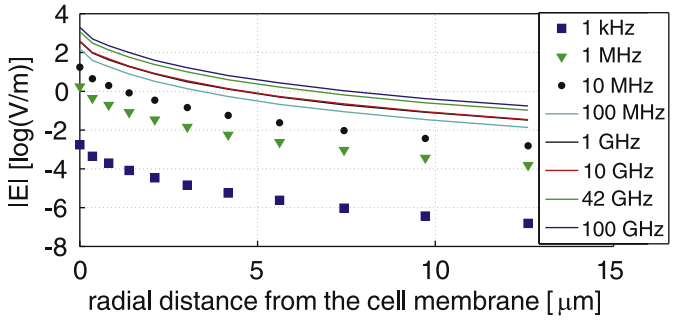

Fig. 12. Radial dependence of the electric intensity from the pole of the cell membrane—comparison of frequencies which are in the legend of the figure in Hz (asymmetric model, mode 0 and lossy medium).

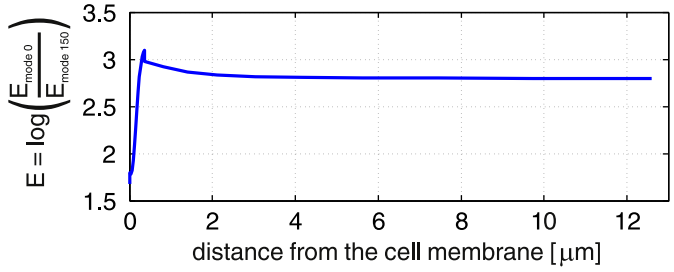

Fig. 13. Logarithm of the ratio of the electric intensity generated by mode 0 and that generated by mode 150 in dependence on radial distance from the pole of the cell membrane ($\log_{10}(E_{mode0}(r)/E_{mode150}(r))$). Electric intensity generated by mode 0 has higher values (asymmetric model, f=100 GHz and lossy medium).

electric field around microtubule generated by mode 50 is smaller by several orders of magnitude compared to electric field intensity generated by mode 0.

5. Results

At first, selected results of calculations of power of asymmetric microtubule network are presented. Eight frequencies (Table 2) and mode 0 were used for excitation of microtubules. The mode 0 is the most effective for generation of electric oscillations. Lossy and lossless medium was considered. The calculated results show that the values of radiated power from microtubule network generated by oscillations of mode min and of mode max are negligibly different (see Figs. 1–4 in supplementary material) and the values of power radiated from asymmetric and symmetric model are the same (see Figs. 5 and 6 in supplementary material). Therefore, from the calculations of radiated power results from asymmetric model only are shown. Poynting vector computed from near-field components ($E\sim 1/(\mathrm{j}kr)^3$ and $H\sim 1/(\mathrm{j}kr)^2$) has zero value in lossless medium. In contrast, the Poynting vector calculated from far field components ($E\sim 1/(\mathrm{j}kr)$ and $H\sim 1/(\mathrm{j}kr)$) is not zero. The values of power radiated from asymmetrical model in lossless medium for all eight frequencies are in Table 2.

The phase shift between near field components of intensity of electric and magnetic field is not $\pi/2$ but $\pi/2+2\phi_k$ in lossy medium (ϕ_k is a phase of propagation constant k of electromagnetic field in lossy medium, in lossless medium $\phi_k=0$). Consequently, the values of Poynting vector calculated from components of near field are not zero and are higher than Poynting vector calculated from other components in lossy medium. On the one hand the values of power near the membrane in lossy medium are higher than in lossless medium but on the other hand the values of power in lossy medium decrease steeply with distance from cell membrane. Fig. 10 shows the dependence of power generated by asymmetric microtubule network in lossy medium for all eight frequencies on radial distance. The value of power is the highest in the proximity of the cell membrane and decreases fast with growing distance.

Further results are from the calculations of intensity of electric field depending on radial distance from the pole or equator of cell (Fig. 6) for both models (Fig. 11). Fig. 12 depicts intensity of electric field depending on the distance from pole of the cell membrane for all eight frequencies. The difference between the electric intensity ΔE generated by mode 0 and that by mode 150 (maximal mode for the 1.2 μm long microtubule) in dependence of radial distance from the pole of asymmetric model in lossy medium and for frequency 100 GHz is shown in Fig. 13. The intensity of electric field on the border (at the cell membrane) of asymmetric model of the microtubule network is depicted in Fig. 14.

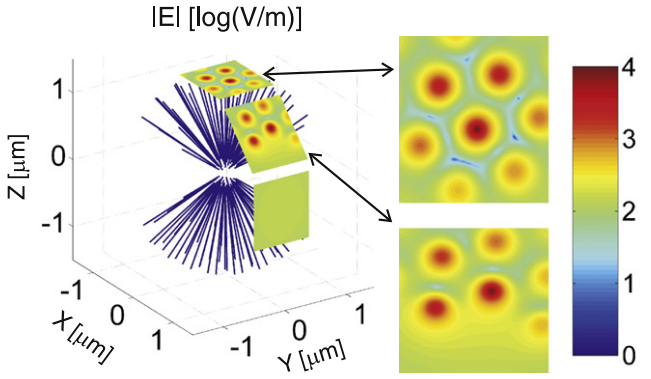

Fig. 14. The electric intensity on the border (at the cell membrane) of asymmetric model of the microtubule (mode 0, f=42 GHz, lossy medium).

6. Discussion

6.1. Approximations and assumptions on the level of the single microtubule

On the level of the single microtubule approximations and assumptions used include:

- integer mode numbers used;
- magnitude of oscillating dipole moment;
- shift of protofilaments in microtubule;
- microtubule protofilament approximated by chain of rigid particles, usage of axial longitudinal vibration modes, optical branch;
- coherent or at least quasi-coherent oscillations of individual dipoles, which require low damping of microtubule vibrations.

All of these points were discussed in the previous works of current authors (Cifra, 2009; Cifra et al., 2010d) where electric field generated by vibrations of single microtubule was already analyzed, so they are touched only briefly here.

Integer values of vibration mode number is related to boundary conditions of rigidly bound ends of microtubule. In real physiological conditions all microtubules grow from centrosome or other microtubule organizing center and can be considered to be bound rigidly (or quasi-rigidly) on the centrosome connected end (minus end). However, not all microtubules are capped and bound on its other end, the plus end. Substantial number of microtubules (exact fraction depends on the cell state and the phase of the cell cycle) undergoes dynamic instability and perpetual growth and shrinkage (Alberts et al., 2008). Vibrations of microtubules with one free end could assume infinite number of noninteger mode numbers.

Value of oscillating dipole moment used in calculations presented here represents the lower boundary of the possible values. This means that in real conditions the oscillating dipole moment can be also higher and consequently the generated electric field intensity may be higher, by approximately one order of magnitude. Axial shift of protofilaments in microtubule which was used in the model presented here corresponds to the real arrangement of protofilaments in microtubule lattice and is called lattice A, as already mentioned in Section 4. Another arrangement of protofilaments also often found in microtubules in vivo is lattice B (Tuszyński et al., 2005).

Vibrations of microtubule protofilament were approximated by vibrations of chains of rigid two-type particles, optical branch. A similar model of microtubule vibrations was used by Pokorný et al. (1997). On the level of the whole microtubule, this corresponds to axial longitudinal vibration modes of microtubules, such as treated by Wang et al. (2006), but is a special case in which neighboring tubulin particles oscillate against each other (optical branch). Vibrations of single microtubules were treated based on tubulin atomic coordinates obtained from crystallography (Deriu et al., 2010) but this approach is not computationally feasible for the whole cellular microtubule network. Therefore the approximation of tubulin as single rigid particles is considered reasonable for the current purpose.

Calculations presented here assume that there are coherent or at least quasi-coherent oscillations of individual dipoles (tubulin heterodimer). Coherent excitation can be provided by external coherent electromagnetic radiation or can be provided endogenously if system of oscillators fulfills conditions such as described by Fröhlich (1968a,b, 1980). Microtubules fulfill necessary conditions of the Fröhlich system (Cifra, 2009). Recently, Reimers et al. (2009) and McKemmish et al. (2009) performed computational studies of Fröhlich system based on using Wu–Austin Hamiltonian. They concluded that condensation of energy in certain modes strong enough to provide coherent excitations (one of the main features of Fröhlich system) is not feasible in biological systems. It is not necessary to go into details here but it has been pointed out (Cifra et al., 2010a,b) that the studies of Reimers and McKemmish treat incomplete Fröhlich system (nonlinear temperature dependence of coupling coefficients is missing) and contains several further flaws. Also another group of authors (Salari et al., 2011) noticed several errors in Reimers' study. Thus, conclusion of Reimers et al. (2009) and McKemmish et al. (2009) that the "…coherent Fröhlich condensates are not biologically feasible,…" cannot be fully accepted and definitely cannot be used for overgeneralization.

6.2. Damping of microtubule vibrations

Regardless of the mechanism for selective excitation of certain microtubule mode, it is necessary that the modes to be excited have low damping so the energy may be stored quasi-coherently in them. This requires that the energy supplied to microtubules is not dissipated rapidly to surrounding medium. Physically the problem is related to the damping of microtubule vibrations. If the microtubule vibrations are treated classically like for a cylinder immersed into bulk water, the result will be that the vibrations will be overdamped (Foster and Baish, 2000), i.e. $Q<1$ (Q, quality factor of oscillations). This may not be the case if one considers ions on the microtubule surface behaving as a slip layer (Pokorný, 2005), especially for longitudinal vibrations where negligible or no water at all will be displaced as for example in the case of standing waves with a zero vibration amplitude at the ends of microtubule. The quality factor (and the lifetime) of the biomolecule vibrations depends also on the organization of the water around the biomolecule surface: the higher the ability of the surface to attract water molecules (i.e. the higher the hydrophilicity of the surface), the higher is the Q (and lifetime) of the vibrations (Liu et al., 2009a,b). The physical mechanism is such that the water due to the electric polarity of its molecules is organized by the electric field of the surface charge of the hydrophilic biomolecule and the water undergoes visco-elastic transition (Van Zandt, 1986, 1987). There is extensive experimental evidence that the water is organized at the hydrophilic surfaces. Several layers of organized water molecules above the biomolecule interface can be detected and visualized by atomic force microscopy (Fukuma, 2010; Kimura et al., 2010). However, ordering of the water is not a matter of only a few molecular layers but can extend to macroscopic distances from strongly hydrophilic interfaces, e.g. few hundreds of micrometers as in the case of exclusion zone found by Zheng and Pollack (2003) and Zheng et al. (2006). These zones carry their name "exclusion zones" after the process they are

visualized with; the zones exclude micrometer sized particles (e.g. latex particles) in such a manner that two distinct water phases (zones) are visible at the hydrophilic interface observed under the microscope. The zone of water adjacent to the surface contains no particles (they are excluded to the outer zone), while beyond rather sharp boundary, particles are present in the second, outer water zone. It was experimentally proved that the organized water in the exclusion zone has different physical properties compared to bulk water including higher viscosity (Pollack et al., 2006), lowered thermal motion of molecules (Zheng et al., 2006), further it exhibits separation of charge, different pH (Chai et al., 2009), different spectroscopic properties (Chai et al., 2008), solvent exclusion (Zheng and Pollack, 2003; Zheng et al., 2006) and that infrared radiation promotes formation of the exclusion zones (Chai et al., 2009), etc. (Pollack et al., 2006, 2009).

Direct evidence of damping can be obtained from spectroscopy. While some spectroscopic and theoretical studies suggest that collective vibrations of proteins are overdamped by the water (Hayward et al., 1993) which is a major constituent of the cytosol, there are indications (Romanovsky et al., 2003) that the broadening of the spectral lines (a physical signature of a damping) may not be solely due to the damping but also due to inhomogeneous broadening of the spectral line—slight difference in the mode frequency due to conformational differences in the protein molecules in the ensemble under study. Actually, nonlinear spectroscopy already brought experimental evidence that lifetime (similar to quality factor Q of the oscillating system—inversely proportional to damping) of certain protein modes can be rather large, over 1000 (Xie et al., 2001). Currently, published data from direct spectroscopic studies on microtubules in MHz–GHz region are very limited. Hameroff et al. (1986) reported 8 GHz acoustic mode of microtubules with Brillouin spectroscopy, from the sole figure they provided the half width of the peak (Δf) is about 2 GHz, giving Q factor ($f/\Delta f$) about 4. Pizzi et al. (2011) measured very weak microwave absorption (0.5 dB) of in vitro microtubules with mean length of 2 μm at 1510 MHz which probably corresponds to some bending modes of microtubules which are overdamped (Samarbakhsh, 2010). Regarding these two past and any future experiments, it needs to be noted that inhomogeneous broadening contributes to broadening of the peak, thus leads to underestimation of the real Q factor. If the spectral resolution of the spectroscopy technique used is low, multiple spectral peaks will be merged into one broad peak, additionally clouding the real Q factor of oscillations. Further, longitudinal axial modes (which are most electromagnetically active in comparison with twisting or bending modes because the "stretching" of the tubulin dipole moment is greatest for longitudinal axial wave on microtubule) which conserve microtubule length will be damped much more weakly since they do not cause any displacement of the surrounding water. It is also important to realize that microtubules are naturally present in a cellular environment where the surrounding water is strongly organized due to numerous interfaces (Pollack, 2001) and by strong static electric field of mitochondria (Tyner et al., 2007). It can be expected that the in vivo damping of microtubule elastic vibrations will be lower than that measured on extracted microtubules. This can be reasonable if the amplitude of oscillations is small and comparable to size of damping units (water molecules or water clusters). In such case, classical hydrodynamic treatment of the damping (Stokes' formula) fails (Mitrofanov et al., 2006) and it underestimates the Q factor of protein oscillations especially in the THz region.

6.3. Related works on microtubule and protein vibrations (low-frequency phonons)

It may be of interest for readers to discuss several related works of Sinkala (2006) and Chou et al. (1994) and their relation to the topic of the current paper. Sinkala analyzed possibility of soliton/exciton transport in proteins which would enable non-dissipative transport of energy and related his model to the model of Resonant Recognition Model of Cosic (1994). The main connection with the current work is that solitons treated in Sinkala's paper are having low-frequency phonon (vibrational) component. In the current work, low frequency (low compared to higher frequencies of the protein vibrations) collective vibrations of the whole microtubules are the basis for the calculation of the distribution of the electric field around them. However, vibrations considered in the current paper are not of the soliton type but of simple standing harmonic wave of longitudinal axial type, optical branch, as described in our earlier paper focused on the field calculation around single microtubules (Cifra et al., 2010d). Chou et al. (1994) has focused on the soliton-like solution of the kink waves generated by the GTP hydrolysis and the possible role of these waves in the regulation of the microtubule polymerization dynamics. In the current paper, we focus on the electric field characteristic of the whole microtubule network. Regarding Davydov's solitons in proteins (namely the α-helix) and its relation to the generation of electromagnetic field we can refer reader to the works of Brizhik (Brizhik and Eremko, 2001, 2003; Brizhik, 2003), where emission of electromagnetic waves due to acceleration of the soliton involving charge transfer has been studied. The connecting work between microtubule soliton propagation and electric field generation seems to be in work of Satarić and Tuszyński. They carried out analysis of propagation of soliton type (kink) of tubulin dipole moment tilt on protofilament, which can have effect on microtubule polymerization kinetics (Satarić et al., 1992), energy transfer along microtubules (Satarić et al., 1993; Trpisová and Tuszyński, 1997), provide a possible elucidation of the unidirectional transport of cargo via motor proteins (Sataric and Tuszyński, 2005; Sataric et al., 2008). To summarize this paragraph regarding microtubules, soliton propagation and intrinsic microtubule electric field, it can be said that another approach to the problem treated in this paper could be based on calculation of electric field around microtubules generated by propagation of solitons on microtubules involving phonon–charge or phonon–dipole interaction.

6.4. Approximations and assumptions on the level of the whole cellular microtubule network

Regarding the model of the whole cellular microtubule network there are following approximations in the models in the study presented here:

- geometry of the models,
- in phase and single frequency oscillations of individual microtubules,
- size of the cell.

Geometry of the symmetric model was chosen to correspond to geometry of nondividing cell (interphase). Asymmetric model cannot be attributed to specific phase of the cell cycle, although it resembles the position of astral microtubules during the cell division. Asymmetric model was constructed in order to study influence of simple asymmetry of cytoskeleton distribution on radiation and electric field characteristic. Current work of the present authors involves modeling of complete mitotic spindle—microtubule formation during the cell division. It should be also noted that the microtubule organizing center (centrosome in many eukaryotic cells) is not always located in the center of the cell, so the microtubules do not grow exactly radially from the cell center.

In the model used in the study presented here the mutual phase difference between oscillations of individual microtubules is zero, i.e. microtubules oscillate in phase. This situation is probably very natural. Oscillations of individual microtubules can be coupled mechanically through the centrosome (or other microtubule organizing center) from which microtubules grow and coupling can be also established via microtubule electrodynamic field. From the time of Huygens it is known and nowadays very well established that coupled oscillators tend to synchronize each other (Bennett et al., 2002) in frequency (see Maffezzoni, 2010 for illustration) under certain conditions. In principle, even if the microtubules are of different length, they can support oscillations of the same frequencies (same modes). The condition of in phase oscillations of microtubules also corresponds to the requirement of minimal energy of the system. The radiation rate is lowest for such configuration since geometrical symmetry together with in phase oscillations causes effective canceling of radiative component of generated electromagnetic field. In the case when the minimum energy state is perturbed, models using random or quasi-random phase distribution of microtubules on the one hand or models using opposite phases of microtubule on opposite hemispheres on the other hand could be used.

Size of the cell (diameter 2.8 μm) used in models presented here corresponds to a rather small cell since typical diameter e.g. of standard eukaryotic model cell, yeast *Saccharomyces Cerevisiae* is 5−10 μm. Nevertheless, the total amount of microtubules used in current model corresponds to amounts present in larger cells. Work in progress includes parametric analysis of influence of number of microtubules and cell sizes on radiated power and electric field intensity at the cell membrane.

6.5. Discussion of results

Intensity of electric field and magnitude of the radiated power are comparable with the results obtained from the calculations using membrane proteins as the sources of the electric oscillations (Pokorný and Wu, 1998). Models presented here give good quantitative estimates of power and intensity of the cellular microtubule network unperturbed and unloaded by the detection electrodes. However, few other biophysical aspects influencing the technical requirements for measurement system (Kučera et al., 2010) could not be covered in current models. Electrodynamic activity probably arises from coupled oscillatory system of polar cellular structures, i.e. cytoskeleton coupled to membrane. Vibrations excited at various points of the membrane (e.g. where the cytoskeleton binds to the cell membrane) would create very complex interference pattern of multiple standing waves on the membrane. In such general case, spatial distribution of electric field intensity associated with the vibrations of the membrane will resemble high order spherical harmonics, having closely spaced regions of opposite orientation of the electric field vector. In order to resolve the spatial minima and maxima, detector electrode needs to have tip with radius of few hundreds of nanometers, ideally units of nanometers. Another aspect is related to the "softness" of the source. Providing the Q factor of oscillating system is high, energy accumulates in the system. Once the system is loaded by the detector and the energy is drained, the effective power supplied to the detector drops to the value of power delivered by the metabolism.

Models presented here do not take into account the effect of the cell membrane. It should be noted that the cell membrane behaves due to its capacitive character as a high pass filter. Therefore electric oscillations up to few MHz (or up to few hundreds of kHz only, depending on the cell type and effective capacitance of its membrane) (Asami and Yonezawa, 1996; Wang et al., 1993) which originate inside the cell cannot pass through the membrane. However, if there are mechanical vibrations present in cytoskeleton, they can be transferred into cell membrane through the cytoskeleton-membrane protein junctions. Consequently, electric oscillations can be generated by vibrations of the polar cell membrane.

7. Conclusion

Electromagnetic radiation and electric field of the whole cellular network consisting of 100 microtubules have been calculated for microtubule oscillations in the frequency region from 1 kHz to 100 GHz. Two basic models have been used for microtubule distribution, symmetric and asymmetric model. Microtubules are uniformly distributed in the symmetric model and they are distributed toward the poles of the cell in the asymmetric model. Total radiated power of the single cell for the lossless medium from the symmetric model is the same as from asymmetric model, being highest (10^{-20} W) for the highest frequency (100 GHz) calculated and lowest (10^{-52} W) for the lowest frequency (1 kHz) calculated. Electric field intensity of the symmetric model decreases steeper with the distance from the cell membrane than that of the asymmetric model, the difference is 4 orders of magnitude at the distance of 10 μm.

From current results, there are serious implications for the measurement system which is aimed to detect cellular electrodynamic activity. It is clear that macroscopic detection of the cellular far field radiation at room temperature with classical antennas is very doubtful. Cellular electrodynamic activity in radiofrequency region will be detectable under most conditions only within 10 μm from the cell membrane, conditions are more favorable when the symmetry (both phase and geometrical symmetry) of the microtubule network is perturbed. Further requirements for detectors, which cannot be quantitatively evaluated from the current models but have been enumerated and reasoned by Kučera et al. (2010), include minimal draining of the energy from biological nanosource (oscillating microtubule) and spatial resolution of hundreds to tens of nanometers. Development of sensors with these parameters is necessary to elucidate the biological role of the cellular electrodynamic activity.

Abstract Using comparative modeling, we have generated structural models of 475 α and β tubulins. Using these models, we observed a global, structural similarity between the tubulin isotypes. However, a number of subtle differences in the isotypes physical properties, including net electric charges, solvent accessible surface areas, and electric dipole moments were also apparent. In order to examine the roles that these properties may play in microtubule (MT) assembly and stability, we have created a model to evaluate the dipole–dipole interaction energies of varying MT lattice conformations, using human tubulin isotypes as particularly important examples. We conclude that the dipole moments of each tubulin isotype may influence their functional characteristics within the cell, resulting in differences for MT assembly kinetics and stability.

Introduction

Microtubules (MTs) are hollow cylinders constructed from linear chains, or protofilaments, of repeating subunits of α and β tubulin. MTs are involved in many cellular processes within eukaryotic organisms, including maintenance of cell morphology and active transport of proteins and organelles throughout the cytoplasm (Pichichero and Avers 1973; Hyams and Stebbings 1979). MTs go through periods of assembly and disassembly, a property known as dynamic instability (Mitchison and Kirschner 1984). Dynamic instability has been extensively investigated and is critical during mitosis when a delicate equilibria of forces are necessary for proper chromosome alignment prior to segregation (Margolis and Wilson 1981; Horio and Hotani 1986; Kirschner and Schulze 1986; Melki et al. 1989; Walker et al. 1991; Mandelkow and Mandelkow 1992). The correct assembly of MTs into the mitotic spindle is essential, as it likely provides the mechanical force for mitotic chromosome segregation (Westermann et al. 2006). The failure of this assembly process generally results in mitotic arrest and for this reason, several chemotherapeutic agents disrupt normal cell division by targeting MTs (Jordan and Wilson 2004).

Most eukaryotic organisms have multiple genes which encode distinct isoforms or isotypes of α and β tubulin. In humans, several isotypes have been identified and characterized (Lu and Luduena 1994; Roach et al. 1998; Luduena 1998). In addition to α and β tubulin, three other tubulin homologues are required for efficient MT assembly in vivo. The first, γ tubulin, is not essential for assembly, yet is found at MT-organizing centers and is thought to aid in initial MT nucleation (Oakley et al. 1990). Two other

homologues, δ and ε tubulin, have uncertain roles in MT assembly, although models have been proposed that describe their possible involvement in MT self-assembly (Inclan and Nogales 2001). At the molecular level, the roles and interactions of tubulin are complex and differ between isotypes. For instance, MT dynamics appears to change significantly with β tubulin isotype composition (Panda et al. 1994). This result implies that if MT assembly/disassembly equilibria are disrupted, cells might respond by producing an appropriate isotype mix to restore normal balance. While the presence of numerous tubulin isotypes, whose differences are often highly conserved in evolution (Ludueña 1998), suggests that they may play specific roles in MT function, there are no precise models to describe differences between them.

A major advance in our understanding of MT structure and function was the solution of tubulin's three-dimensional crystallographic structure (Nogales et al. 1998). Several crystallographic structures of tubulin are now available from the RCSB Protein Data Bank (PDB) and we refer to these structures by their PDB ID (Berman et al. 2000). The first approach to obtain tubulin crystals was taxane-stabilized bovine-brain tubulin (mixed isotypes) in flat Zn^{2+} induced sheets, producing protofilament-like end-to-end α/β dimer repeats. The earliest structure, 1TUB, utilized a drug known as docetaxel to stabilize protofilaments for crystallography (Nogales et al. 1998). Due to difficulties in fitting to the electron density, this structure contains several misalignments and density omissions and was superceded by 1JFF, which utilized paclitaxel, a drug similar to docetaxel, to stabilize the protofilaments (Lowe et al. 2001). Similarly, the structure 1TVK utilized the drug epothilone A, which binds at the paclitaxel/docetazxel binding site (Nettles et al. 2004). One final structure from this group, 1IA0 contains direct copies of the 1TUB monomers which were docked with the monomeric kinesin motor KIF1A (Kikkawa et al. 2001). A second approach to producing tubulin crystals utilizes the stathmin-like domain RB3-SLD, which complexes a pair of α/β dimer repeats. The earliest of these, 1FFX, utilized molecular replacement from the 1TUB data (Gigant et al. 2000). Most recently two higher resolution structures, 1SA0 and 1SA1, were co-crystallized with colchicine and podophyllotoxin, respectively (Ravelli et al. 2004), while both colchicine and vinblastine are included in 1Z2B (Gigant et al. 2005). Other, non-eukaryotic or tubulin-like structures also exist. The structures, 1Z5V and 1Z5W, are of human γ tubulin crystals (Aldaz et al. 2005). Related prokaryotic structures include 2BTO and 2BTQ products of *Prosthectobacter dejongeii* genes BtubA and BtubB (Schlieper et al. 2005). Additionally, several structures of the prokaryotic tubulin homolog FtsZ are also available.

The availability of high quality structural data for tubulin has enabled us to create comparative models of all currently known α and β tubulin isotypes. Comparative modeling uses known protein structures as templates to produce 3D structural models of a target protein with a known, related amino acid sequence. By assuming that parts of the target and templates with similar sequences have similar 3D structures, portions of the template structures may be copied and amino acids substituted, inserted, or deleted to produce models. Any part of the target not obtained from the template structure must be constructed via de novo methods. Finally, the resulting model must then be optimized to a protein-like geometry. This technique has been verified for a small number of homologous protein families and can yield accurate results for template/target pairs with strong sequence identity (Chothia and Lesk 1986).

From such comparative models, we have calculated the energy associated with MT lattice dipole–dipole interactions for all the human tubulin isotypes. Schoutens (2005) estimated that MT dipole–dipole interactions destabilize the MT structure by 50–60% of the elastic energy of the underlying lattice. The strength of these interactions is roughly proportional to the squares of the dipole moments; increased tubulin dipole moments should therefore make MTs less stable. From our estimates we hope to understand how tubulin isotype sequences may affect both MT assembly and stability through basic electrostatic properties of protein.

Materials and methods

Tubulin sequences

Tubulin sequences were obtained from the Uniprot Knowledgebase, consisting of Swiss-Prot release 42.1 and TrEMBL release 25.12 (15 March 2004) (Boeckmann et al. 2003). The entire database was downloaded and sequences annotated with the term ''tubulin'', were extracted, producing an initial set of 2,294 entries. This initial set was then filtered to remove entries labeled as fragmentary, leaving only 652 complete tubulin sequences. These sequences were then aligned and using cluster analysis assembled into a guide tree, or dendrogram using default parameters within Clustal W (version 1.82) (Higgins and Sharp 1988). This step identified sequences that are not tubulin, but unrelated

proteins with tubulin in their name (e.g. tubulin tyrosine ligase or tubulin-folding cofactor D). Since these nontubulin sequences differ significantly from the tubulins, they clustered separately in the dendrogram, providing a clear delineation between 557 ''tubulin-like'' and 95 nontubulin sequences. A second dendrogram guide tree was then produced using only the ''tubulin-like'' sequences resulting in three major branches, one of 190 α tubulin sequences, one of 285 β tubulin sequences, and the third of 82 tubulin sequences that were neither α nor β tubulin.

Template selection

As we were constructing models of eukaryotic α and β tubulins, we rejected γ tubulin and bacterial proteins as structural templates. We chose to use only monomers from the 1JFF and 1SA0 structures as these are high-resolution representatives of the two crystallographic approaches. We also reasoned that all three tubulin dimers within these structures have distinct environments and would produce variation in the models. In the 1SA0 structure, the colchicine molecule is at opposite ends of the two dimers and each dimer has a different interaction with the stathmin-like domain, while the 1JFF dimer is in a different crystal packing. Thus, for α tubulins we used the 1JFF A chain and the 1SA0 A and C chains, while for β tubulins we used the 1JFF B chain and the 1SA0 C and D chains.

Modeling

To build the models, we used Modeller (version 6v2) (Sanchez and Sali 2000). While Modeller provides many options for model refinement and fine-tuning, default parameters and settings were deemed sufficient for generating the models presented here. (See Table 1 for a sample script building sequence P05218 on the 1JFF β monomer.) For each tubulin sequence, three models were built, each using a different one of the three templates (Table 1). To check the correctness of each of the models, some were tested with PROCHECK and WHAT_CHECK (Laskowski et al. 1993; Hooft et al. 1996). Since the results of these programs require human inspection, only a small subset of models was tested in this way. These results suggested to us that the isotype models are likely of similar quality to the input template structures. As a final step, models were re-positioned onto the coordinates of the templates used to create them by RMSD (root-mean-square deviation) fitting over corresponding alpha-carbons.

Generation of human isotype models

Among the 190 α and 285 β tubulin sequences are 22 human sequences. Two are quite different in length from the templates, one short (Q8WU19), and one long (Q8WUL7). The other 20 were used to examine the stability of the modeling technique and accuracy of the models by producing 100 models of each target. As Modeller uses pseudo-random noise in model construction, each differs slightly, providing a sample of 100 Modeller output conformations for these human sequences.

Calculations of the surface areas, charges, and dipole moments

After models were built, surface areas, total charges, and dipole moments were estimated using analysis tools in Gromacs v. 3.3 (Lindahl et al. 2001). Models were converted using pdb2gmx with the GROMOS96 43a1 force field (van Gunsteren 1996), providing atomic charges, sizes, and some hydrogen atom

locations. As a side effect, the net charge of the sequence is reported, assuming charges of $+1e$ for lysine and arginine, $-1e$ for aspartic and glutamic acids, and no charge for other residues. Using g_sas, Connolly solvent accessible surfaces (SAS) were then calculated (Connolly 1983). Next, editconf was used to shift the co-ordinate origin to the model's geometric center, which is expected to be a good approximation of the monomer's center-of-mass. Dipole moments were then calculated using g_dipoles. These dipole components were then converted to a cylindrical coordinate system based on MT geometry. Each 1SA0 monomer was α-carbon RMSD fit onto the corresponding 1JFF monomer, these transformations taken as conversions between the 1SA0-based co-ordinate space and a 1JFF-based one; 1JFF co-ordinates were converted to the MT-based one by 63° rotation about the protofilament axis, a value chosen with data presented by Li et al. (2002). Each dipole moment was transformed identically to its model's template.

Calculations of the microtubule dipole–dipole interaction energies

The same MT geometry based cylindrical coordinate system, as described above, was used for dipole interaction energy estimates. We defined a direction away from the central cylindrical axis as radial, one parallel to the central axis as longitudinal, and one perpendicular to both of these (around the surface of a cylinder) as tangential. Following the description by Li et al. (2002), we position dipoles at a radius of 112 Å, in 13 parallel protofilament-like rows, at the 13 angular multiples of (360/13)°. Along these rows, dipole values were placed every 81.2 Å

The interaction energy between two dipoles $\vec{p}_1$ and $\vec{p}_2$ separated by $\vec{r}$ is given by:

$$U = \frac{1}{4\pi\varepsilon\varepsilon_0}\left(\frac{\vec{p}_1\cdot\vec{p}_2}{r^3} - 3\frac{(\vec{p}_1\cdot\vec{r})(\vec{p}_2\cdot\vec{r})}{r^5}\right). \quad (1)$$

Each dipole is described as

$$\vec{p} = (p_r, p_\theta, p_z),$$

having a radial, tangential, and longitudinal component. The interaction energy of two dipoles of known positions can then be rewritten:

$$\begin{aligned} 4\pi\varepsilon\varepsilon_0 U = {} & c_1 p_{r1} p_{r2} + c_2 p_{r1} p_{\theta 2} + c_3 p_{r1} p_{z2} \\ & + c_4 p_{\theta 1} p_{r2} + c_5 p_{\theta 1} p_{\theta 2} + c_6 p_{\theta 1} p_{z2}, \\ & + c_7 p_{z1} p_{r2} + c_8 p_{z1} p_{\theta 2} + c_9 p_{z1} p_{z2}, \end{aligned} \quad (2)$$

where the nine c_i are known geometry-dependent constants dependent on $\vec{r}$ and the rotation of coordinate system components between the two dipoles.

To calculate the interaction energy between a reference dipole and those in an adjacent protofilament, as the adjacent protofilament is displaced along its length, we take several dipoles from the adjacent protofilament near the reference and evaluate the c_i of (2) between adjacent dipoles and the reference. Then with all the adjacent dipoles identical, and $4\pi\epsilon\epsilon_0$ uniform, the p are common factors for all interaction pairs, so each of the nine c_i terms can be separately summed over all pairs to obtain a total dipole–dipole energy of the same form as (2), with a new set of c_i.

We evaluated summations over adjacent sections of length $2l + 1$, expecting that as we summed longer sections we would approach a limit, more separated dipole pairs having weaker interactions. We placed the reference dipole at $z = 0$ Å and the adjacent dipoles at $z = (81.2\text{ Å})(i + d)$ where integer $i \in [-l,+l]$, and the displacement, d, varied from 0 to 1. At $d = 0$, we found that a limit is rapidly approached in our calculations, with little difference in the summed c_i for several $l \geq 10$, and those of $l = 10{,}000$.

For $l = 1{,}500$ and d = 0.00, 0.01, 0.02,...,1.00 we calculated the summed values of the nine coefficients c_i and observed near sinusoidal variation with displacement (Fig. 1). Fits to the three lowest frequency Fourier components,

$$c_i(d) = A_i + \sum_{k=1}^{3} B_{ki}\cos kd + C_{ki}\sin kd,$$

give coefficients where either the sine or the cosine series coefficients are large (more than one part in 10^6) relative to those of the other series. In this significant series the second-order terms are all less than 5% of the first-order terms, and the third-order terms less

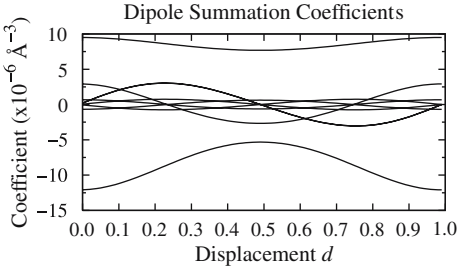

Fig. 1 The nine coefficients c_i as functions of the displacement, d for the case of an adjacent protofilament. Note the high level of symmetry, and that two of the nine curves are identical and superimposed in the plot

than 3% of the second-order terms. In only two of the nine cases are the constant terms significantly nonzero. Thus, we take only the first order and constant terms and obtain the approximations $c_i(d) \approx A_i + B_i \cos d$ or $c_i(d) \approx C_i \sin d$. We note that this approximation implies sinusoidal variation with displacement to the energy in (2).

This calculation can be easily extended to the dipole interactions between a reference dimer and an adjacent protofilament when each monomer has its own dipole moment. Treating the α and β contributions in the two filaments separately gives four cases. In the first, we can place all the α dipoles at the locations discussed above and obtain the same result. The case of the row of β dipoles midway between adjacent α row interacting with the reference α dipole has the same form but an additional one-half displacement is included. Similarly, a reference β dipole may be placed at $z = 40.6$ Å, the same as subtracting one-half from the displacements when interacting with the row of α dipoles. In the β–β interactions case, the two additional displacements cancel out. By summing the contributions of the four cases, a single sum is again obtained. For simplicity, we use only one α and one β monomer in both the adjacent and reference positions. Then by symmetry, many coefficients cancel and the result may be rewritten as

$$4\pi\varepsilon\varepsilon_0 U = F + G\cos d \tag{3}$$

where both F and G have the form

$$\begin{aligned} &e_1(p_{r\alpha}^2 + p_{r\beta}^2) + e_2(p_{\theta\alpha}^2 + p_{\theta\beta}^2) + e_3(p_{z\alpha}^2 + p_{z\beta}^2) \\ &\quad + e_4(p_{r\alpha}p_{r\beta}) + e_5(p_{\theta\alpha}p_{\theta\beta}) + e_6(p_{z\alpha}p_{z\beta}) \end{aligned} \tag{4}$$

for particular values of the geometric constant coefficients e_i.

Results and discussion

Comparative modeling is a theoretical method with predictive power limited by the degree of similarity between target and template structures and input template quality. Quality is further limited by the choice of refinement approximations following model construction. Further constraints on predictive power arise from failures to include environmental factors, such as ligands, ranging from ions to protein complexes, and chemical modifications such as post-translational modification, both of which are relevant in the case of tubulin.

Tubulin sequences

Our set of α and β tubulin sequences includes animal, plant, fungal, and protist tubulins. We believe that this set is likely large enough to well sample the diversity present within the tubulin family. In general, the tubulin sequences modeled were similar to those of the templates. However, some of the tubulin sequences vary greatly in length from the template sequences. It seems likely that some of these sequences may not assemble into MTs, e.g. a γ tubulin sequence. Such cases would be less well modeled using this technique than other sequences. Except for the two human sequences omitted during the human repeat calculations, such possible problems were ignored and all sequences were treated identically.

It should be noted that the assignments generated by the initial clustering did not always agree with the database labels. Alignments and scoring were performed without knowledge of each isotypes cellular function, close similarity between the isotypes occasionally produced ambiguous results. For instance, the Uniprot Knowledgebase sequence Q94EN1 is described as ''Pi-tubulin'' in the database, but clustered within the α tubulin set using the procedure described above.

Template selection

All of the available tubulin structures would likely provide good templates for modeling. All structures of crystallized α and β tubulin are similar, being nearly indistinguishable at 6 Å, even with only 40% amino acid identity between them (Li et al. 2002). Since sequences within the α and β tubulin groups are more similar to sequences within the same group than with those of the other group, it is reasonable to expect that any given sequence likely has a structure very similar to that of other members of its group. An example is the 1TUB and 1JFF structures which are of a porcine sequence, but fit to structural data from inhomogeneous bovine samples. Accordingly, either crystallographic structure can be used as a template to produce models with some confidence. However, each of these template structures contains missing or weakly defined residues. Trivially, neither template contains the initial methionine residue. Additionally, one α tubulin loop is incomplete with residues Q35–L60 missing from the A chain in 1JFF and residues P37–D46 and S38–D46 missing from the A and C chains of 1SA0, respectively. Both of the 1SA0 β monomers, chains B and D lack residues R278–A285 and several side chains within these structures are also truncated. Further, all

template structures lack a 20–30 residue region, commonly referred to as the C-terminal tail (approximately residue 440 to the C-terminus); this region is believed to be highly flexible. Within these missing regions the model is being created with few constraints and less confidence should therefore be placed in the reality of the results.

Comparison of the tubulin models shows that regions found within the templates have well-defined structures, and those without templates are more disordered. The region missing from the 1JFF α tubulin template (Q35–L60) produces a large unstructured loop away from the core of the monomer in many models. The large variability of this region within the human repeats led us to reject the 1JFF α tubulin derived models from further consideration. In the 1SA0-based models, due to the resolved structure of more of the template, this region has a more compact structure, although it is more variable than most other regions in the models. In all the models, loops corresponding to residues 360–371 and 275–286 are also of high variability, owing to unresolved structures in the templates. Such variations within the structure of tubulin could have an effect on dimer–dimer interactions, which may translate into significant changes in assembly/disassembly rates for MTs. These differences are fairly well studied experimentally (Panda et al. 1994) but poorly understood theoretically. It should be noted that the generated C-terminal regions are too flexible and variable for models to represent, at best, more than one of many possible conformations. To what extent the variation in the models is experimental artifact, and to what extent real variation in the tubulin structures is unknown.

Estimation of physical properties

It is possible to estimate various physical characteristics from these models. These properties can then be considered for possible effects of these on tubulin dimer–dimer interactions, and thus MT assembly and stability. One contribution to the interactions between tubulin dimers is the electrostatics of each tubulin monomer, in particular, net charges and dipole moments. The net charge or monopole is perhaps the simplest approximation to the complicated electrostatic field around a protein. Slightly more complex is the electrostatic dipole moment, which has opposing positive and negative directions along a central axis, and is radially symmetric about this axis. Like the monopole, the dipole is an average over a real system and is generally inadequate for representing the complex field near a protein, and is also subject to attenuation by solvent mediated effects, but having both a position and an orientation, a dipole may give more complex interactions. With charges at points in space, we can calculate a dipole moment about a chosen coordinate origin. If a system has zero net charge, this dipole moment is independent of the choice of origin, but is otherwise dependent upon the origin. For protein dipole calculations, the center-of-mass is commonly used.

Solvent accessible surface area

For each tubulin model, we estimated the solvent accessible surface areas and show that they are largely the same for α and β tubulins with mean areas of approximately 220 nm^2, and standard deviations of 10 and 30 nm^2, respectively. This difference in variance is visible where surface areas for α and β tubulins are compared with their estimated dipole moments (Fig. 2). Little correlation between these two properties is evident from these scatter plots. However, there does appear to be an observable difference within the mean dipole between the alpha and beta tubulin.

Electrostatics

Tubulin sequences generally contain more acidic than basic residues and accordingly we report negative electrostatic charges. In an overly simplistic analysis we could expect that these negative charges would repel, thereby preventing MT formation. However, at short ranges charge is partially screened and some close charge pairs can dominate the electrostatic interaction

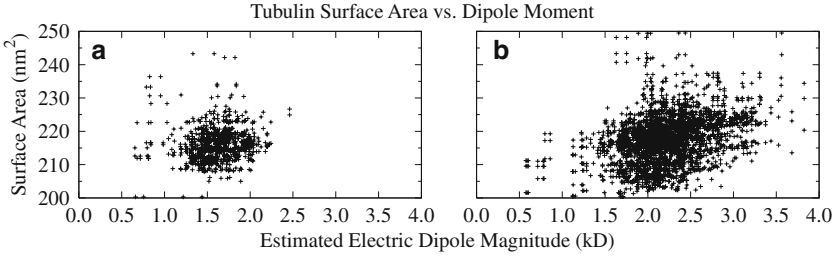

Fig. 2 Comparison between tubulin isotype models solvent accessible surface areas and estimated dipole moment magnitudes. Panel **a** illustrates correlation within α tubulin models. Panel **b** illustrates correlation within β tubulin models

over more distant pairs. The extreme of this occurs between monomers, where contacting regions have interactions strong enough to form a stable bond.

The α tubulins are estimated to have dipole magnitudes about their centers in the range 1,000–2,000 D, while β tubulin magnitudes are generally higher, in the range 2,000–3,000 D (Fig. 3). The β tubulins are, on average, more highly charged with an approximate mean of –24*e*, compared with –22*e* for the α tubulins. The β tubulins also have a slightly broader net charge distribution than α tubulins (standard deviation of 3.0*e* versus 2.6*e*). There appears to be little if any correlation, in the scatter plots, between the dipole moment and the net charge as might be expected since polynomial expansions coefficients such as the electrostatic potential generally have no dependence on one another (Fig. 4).

In this work we give specific values for tubulin charges and dipole moments. It is important to recognize that these values only consider the protein and not effects due to the surrounding solution. A significant solvation effect is on mean protonation state; net tubulin charge becomes more positive as pH decreases. In particular, near pH 5, tubulin is electrically neutral (pI from SWISS-2DPAGE, see Hoogland et al. 2004). However, our electrostatic numbers are derived with a charge model (Gromos96 43a1) with a specific charge for each atom, appropriate near pH 7. Another solvation effect is counter-ion cancellation of the electrostatic field about a charged object. Charge effects only occur when there is some separation of this screening charge and the charge. Trivially, objects in close proximity will exclude some or all of the screen. More generally, this separation will depend on the solution composition. Since the extent of screening will depend on the circumstance we report values for unscreened systems, and as a further simplification use uniform dielectric constants.

Comparing our calculated values to experimentally based values reveals the possible magnitude of these solvent effects. For instance, experiments orienting or dragging MTs with external electric fields have reported per dimer charges equivalent to –0.9*e* and –0.2*e* (Minoura and Muto 2006; Stracke et al. 2002). These results may also be interpreted as a measure of the screening charge pulled away from the tubulin. In a different example, the addition of tubulin to a solution is reported to affect the high-frequency dielectric constant by 0.0050 mL/mg (Schuessler et al. 2003). Using this value in the dilute limit Oncley formula gives a tubulin dipole moment of 78 D for a dimer at 300 K. While our values do not compare well with these numbers, but it must be emphasized that we did not expect them to be considered absolute and are only valid within the results presented here.

Human isotypes

The 100 models of the human tubulin sequences allow the reproducibility of results for an isotype sequence to be assessed. In particular, the dipole moment estimates have roughly a 300 D standard deviation. These values suggest that much of the observed variation between sequences may be attributed to model variability and not intrinsic differences among the sequences. For one of the 55 sequence-template pairs in this repeat set, Modeller stopped prematurely with an error, so 64 of the 5,500 repeat models were not built.

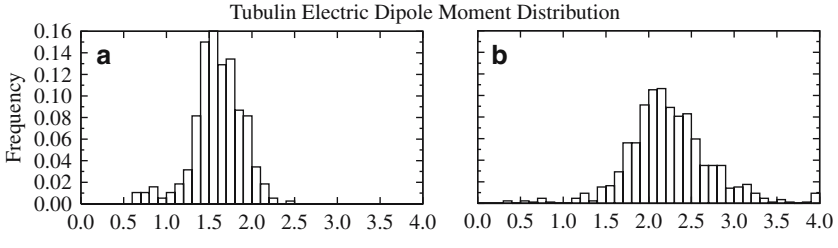

Fig. 3 Distribution of the estimated dipole moment magnitudes for α tubulin (**a**) and β tubulin (**b**)

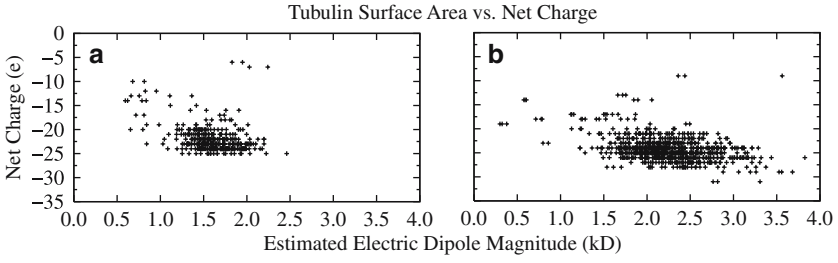

Fig. 4 Comparison between the dipole moments and net charges for α tubulin (**a**) and β tubulin (**b**)

Human microtubule dipole interaction energies

We considered all the α/β pairings of models from our set of replicate human runs, and evaluated all of the dipole moments with (3). We noted G, the sinusoidal magnitude, is typically small compared to F, the offset term, and so we ignored the sinusoidal term. The results show a great deal of similarity, with the five α monomers being largely indistinguishable, as are many of the β monomers; only the Q99867 sequence is significantly different. The distribution of interaction energies for $\epsilon\epsilon_0 = 1$ of each human β tubulin sequence is shown in Fig. 5a. A similar calculation can be done within a single protofilament by replacing a dimer in the ''adjacent'' protofilament with the reference dimer. Displacement makes no sense in this case, avoiding the sinusoidal term (Fig. 5b). Again, only Q99867 stands out as significantly different in this regard.

Summary and conclusions

We have used comparative modeling as a computational tool to generate structural models of 475 α and β tubulin sequences. We note a structural similarity across tubulin isotypes, along with some subtle differences in physical properties, including net electric charges, solvent accessible surface areas, and electric dipole moments. In order to examine the roles these properties may play in MT assembly and stability, we evaluated dipole–dipole interaction energies of MT lattice conformations with various human tubulin isotypes. In this case, we already know that isotype composition affects MT assembly kinetics (Panda et al. 1994). We therefore expected that properties, such as the dipole moment, may influence the functional behavior of tubulin monomers and dimers within the cell, resulting in differences for MT stability and assembly kinetics. It was demonstrated that electrostatics contributes to the energy of relative longitudinal offsets between two protofilaments, helping to shape the energy minima corresponding to the two MT lattice types, especially the A-lattice (Sept et al. 2003).

Further, besides its involvement in MT stability, the dipole moment of tubulin may play a role in other processes involving tubulin, for example, docking of molecules such as kinesin or MT associated proteins to tubulin and in creating the proper steric configuration of a tubulin dimer as it approaches an MT for binding. Interestingly, in an MT, dimers have near parallel dipole moments relative to their nearest neighbors, suggesting energy minimization takes place during MT assembly. However, when all dimer–dimer interactions in a MT are summed, the total is a positive energy leading to MT destabilization. Hence the greater the magnitude of the individual dipole moments (assuming all are identical), the less stable the MT since these interactions will be repulsive, pushing dimers apart. The strength of these interactions is proportional to the squares of the dipole moments; MTs made up of tubulin with larger dipole moments should be more prone to disassembly than those composed of lower dipole moment tubulins. For cells expressing more than one isotype, one can conceive MT dynamics regulated by altering relative amounts of isotypes. However, these effects are moderated by local interactions with more complicated electrostatic fields than the above simplified assembly of dipoles; for details see Baker et al. (2001). Nonetheless, it is possible that the differing kinetic properties of different isotypes are linked to the electrostatic differences.

From the discussion of experimental determinations of electrostatic properties of tubulin and MTs it is clear that the experiment and its precise conditions can ultimately affect the outcome of any measurement. Hence, we require more accurate and systematic analyses under a range of conditions such as pH, ionic concentrations, tubulin concentration, and temperature values. It is, however, clear that electrostatics, and in particular the dipole moment, plays an important role in the interactions of tubulin with itself, with other proteins, molecules, and ions.

(Received 21 August 2017; accepted 20 January 2018; published online 6 February 2018)

In this paper, we report the propensity to excitability of the internal structure of cellular microtubules, modelled as a relatively large one-dimensional spatial array of electrical units with nonlinear resistive features. We propose a model mimicking the dynamics of a large set of such intracellular dynamical entities as an excitable medium. We show that the behavior of such lattices can be described by a complex Ginzburg-Landau equation, which admits several wave solutions, including the plane waves paradigm. A stability analysis of the plane waves solutions of our dynamical system is conducted both analytically and numerically. It is observed that perturbed plane waves will always evolve toward promoting the generation of localized periodic waves trains. These modes include both stationary and travelling spatial excitations. They encompass, on one hand, localized structures such as solitary waves embracing bright solitons, dark solitons, and bisolitonic impulses with head-on collisions phenomena, and on the other hand, the appearance of both spatially homogeneous and spatially inhomogeneous stationary patterns. This ability exhibited by our array of proteinic elements to display several states of excitability exposes their stunning biological and physical complexity and is of high relevance in the description of the developmental and informative processes occurring on the subcellular scale. *Published by AIP Publishing.*

The existence of a mechanical signal due to some applied centrifugal force, though marginal, has been suspected to be responsible of the positional information in cortical microtubules. On the same footing, their electrical activities due to a constant state of flux, continually polymerize and depolymerize them (as observed in animal cells), unless stabilized by the binding of guanosine triphosphate to the ends, which inhibits depolymerization. The dynamics and nature of the information processes underlying these functional mechanisms at the subcellular scale are still not completely understood. We have developed an electrical model with nonlinear resistive properties that can model the excitability of these biological systems. This tunable excitable model, where the dispersion, nonlinearity, and dissipation can be easily regulated, demonstrates rich dynamics, and can serve as a tool for studying the physiological complexity of cortical microtubules.

I. INTRODUCTION

During the last decades, quite a sizable amount of mathematical treatment has been performed in the field of complex nonlinear systems as a whole and in the area of nonlinear excitable media, in particular. Typical examples of such systems include chemical excitable milieux, namely, the Belousov-Zhabotinsky reaction[1,2] and the reaction of oxidation of *CO* on platinum catalysts.[3] They equally incorporate biological paradigms such as intracellular waves of calcium induced calcium release, head-on collisions of waves in excitable FitzHugh-Nagumo systems,[4] the electrical membrane excitation in nerve and muscular tissues (relevant in cardiac arrhythmia for instance), and some simple morphogenetic systems,[5] to name just a few.

Nowadays, biological systems have been the core components in the development of nonlinear science due to their outstanding complexity both at small and large scales. Their baroque complexity then requires some strong computational treatments safely guided by mathematical insights, based on simple nonlinear systems, or rationally reduced models. Starting from the ground that biological systems usually emerge as a large collective set of topologically connected (all-to-all, sparsely, or nearest neighbors interactions) biochemical units (cells), their computational modelling, crucial for their quantitative and qualitative dynamical studies, forms a key ingredient of the interpretation of the mathematical and experimental outcomes obtained from their inspections. Structurally speaking, the basic building block of the architecture of any biological system is the cell. It is mainly made up of a substance called the cytoplasm, containing 80% of water in its composition. Throughout the cytoplasm of eukaryotic cells (cells that have membrane-bound organelles such as nucleus and endoplasmic reticulum) the cytoskeleton, which comprises tubular polymers called microtubules, is found.[6,7] Microtubules play some key roles in living organisms. They are triggered by the signalling processes occurring within the cellular milieu. Microtubules

[a)]Author to whom correspondence should be addressed: moukamkakmeni@gmail.com

play some crucial roles in a number of cellular processes and are involved in maintaining the structure of the cell. Together with microfilaments and intermediate filaments, they form the cytoskeleton. They also make up the internal structure of cilia and flagella which play a great role in movement.[7–10] The act of withdrawing the hand when it comes into contact with a hot object, the act of an organism displacing itself to locate food when in need, and many other occurrences are evidence of some degree of information processing and transmission within the internal structure of living beings. These processes usually occur in the form of wave phenomena.[2] Such information or impulse called ionic wave is in the form of an electric field. This ionic wave follows a pattern that sometimes emerge in the form of a localized wave, solution of a widespread class of weakly non-linear dispersive partial differential equations referred to as non-linear localized waves of soliton types.[11,12]

References 13–15 model microtubule as a nanobioelectronic nonlinear circuit possessing the polyelectrolyte features of cylindrical biopolymers, with the assumption that microtubules play a fundamental role in sub-cellular computation and signalling via electronic and protonic conductivity and can then be made useful in hybrid material that offer novel electronic characteristics. Based on these considerations, the nature of the wave solution (or energy) resulting from the model is observed to be a solitonic pulse. Recently, on the same footing, the authors in Ref. 16 investigated the phenomena of wave transmission and amplification in a similar electrical model of microtubules. Therein, a comparison is made between the results obtained on one hand in the absence of a negative nonlinear resistance, and on the other hand, with those obtained in its presence. The signal was found to be decreasing in the former case and to be amplified in the latter.

In this work, considering the strong intrinsic nonlinear character of these biological systems, we consider an electrical model of microtubule with a nonlinear resistance at the level of each electrical unit. This is motivated by the fact that the previous models failed to display some features of excitability as it has been experimentally reported to exist to some extent in microtubules.[17–26] This consideration accounts for the fact that the processes of opposition to the flow of calcium ions within and between microtubules are more than just linear. We believe that the fluctuations in the internal resistance of the dynamical unit, occurring in the course of the information processing mechanisms occurring along the structure of the microtubule, and which depend to a great extent on the content of the microtubule, may impact significantly on the nature of the physical and biochemical solicitations of these biological systems. Therefore, the aim of this work is to investigate under the aforementioned circumstances (conditions), the related liability of these biological systems to display some interesting features of excitable media. The main goal of this exploration is to throw more light on the puzzling processes pertaining in the robust internal functional activities of cells, which have relevance in maintaining homeostasis in living beings, via stable internal operating conditions, crucial for the perpetuation of life.

This article is organized as follows. In Sec. II, we present our electrical model of microtubule (*MT*) with nonlinear resistive elements. This model aims at emulating the dynamics of the voltage stimulus, compelling calcium ions to move within and in between microtubule protofilaments (PF). Subsequently, we derive a discrete differential equation of motion for the voltage stimulus of the calcium ions, following some circuit analysis principles. At this stage, we propose ourselves to solve this equation while seeking for solitary waves solutions. For this purpose, we shall use a perturbation technique in the form of the multiple scales expansion method with semi-discrete approximation. The description of this method is coarsely provided, and its development related to the issue at hand is as well expounded. Afterward, an equation of evolution for the ionic wave amplitude is obtained in the form of a complex Ginzburg-Landau equation (*CGLE*), and the Benjamin-Feir stability analysis of the plane waves solutions of this equation is conducted numerically. In Sec. III, we analytically examine the stability of the plane waves solutions of the *CGLE* based on the Eckhaus stability analysis approach. The outcomes of this analytical inquiry are compared to those obtained numerically in Sec. II in order to check for their consistency. In Sec. IV, based on the Nozaki-Bekki approach, we propose an analytical solution for the solitary wave solution of our *CGLE*, whose characteristics will be analyzed in the entire computational domain. Next, we perform the analytical resolution of our *CGLE* based on the harmonic balance method, in order to work toward the determination of exact travelling symmetric-like ionic waves, solutions of our nonlinear equation. Section V is dedicated to the direct numerical treatment of the main discrete voltage equation of motion, while assuming Ansatz as the exact analytical solution obtained in Sec. IV. Finally, Sec. VI concludes the work.

II. THE ELECTRICAL CIRCUIT MODEL OF MICROTUBULES AND THE WAVE AMPLITUDE EQUATION

A. The model

Microtubules (MTS) are essential components of the cytoskeleton, found throughout the cytoplasm of eukaryotic cells. They are hollow cylinders made up of protofilaments (PF) representing series of proteins known as tubulin dimers. Each PF is assimilated to a succession of N adjacent electrical units. Each unit cell number n of the lattice is constituted of a linear inductance L in series with a linear resistance r, shunted by a non-linear capacitance $C(V_n)$ in parallel with a non-linear resistance R_n.[16] In standard models, the non-linear components are only represented by a conductance and a capacitance.[9,14,27,28] Most mathematical models for transmitters[27,29] add a cubic non-linear resistance for ionic current flow through nano-pores of neurons. Freedman *et al.*[27] observed that the current-voltage characteristic of the MT lumen resistance in the presence of cations can be fitted by a cubic polynomial. Thus, a non-linear resistance was suggested for modelling cation flow through nano-pores of MT.[16] Priel *et al.*,[16,30] in an experiment, isolated

microtubules and infused electrical signals through one end. Overwhelmed by the reception of the emitted signal at the other end of the microtubules, they could ascertain the fact that microtubules can be looked upon and described as biological conducting wires, suitable for electrical pulses transmission. Therefore, microtubules play an important role in electrical activities within cells.

It is noteworthy that excitable systems usually appear as spatially extended systems, which as a result of the application of a super-threshold stimulus, are capable of generating and conducting nonlinear waves of excitations. These regenerative waves travel without decrement as a solitary propagating wave or wave train. In this case, subsequent to the excitation, the medium needs some time to recover its excitability. During this time interval called the refractory period, the medium cannot be excited again. Thus, based on these facts, our proposed electrical model of microtubule should be consistent with these features of excitable media. In an attempt to do so, we suggest below in Fig. 1 an electrical circuit model for the microtubules, with a variety of specifications, including nonlinear resistive elements. In this model, we focus mainly on the voltage stimulus V_n urging cations (calcium ions or currents) within and between microtubule protofilaments.

The mathematical description of the model at hand is based on Kirchoff's network rules. The microtubule, being assimilated to a succession of N adjacent unit cells, depicts a transmission line. This transmission line then portrays one protofilament of a microtubule. Each unit cell number, n, of the lattice is made up of a linear inductance, L, in series with a linear resistance r, shunted by a nonlinear capacitance $C(V_n)$ in parallel with a nonlinear resistance R_n. The proposed circuit model combines two models where on one hand the $C(V_n)$ characteristics is a nonlinear function of the voltage,[15] and on the other hand, the resistance is a nonlinear function of the voltage.[16] The characterizations of the origins of the current, capacity, and resistance are well described in Ref. 15.

However, these models were better suited to explore the ability of microtubules to act as transmission lines supporting wave amplification phenomena. They could not display properties of excitability which have been experimentally shown to exist in microtubules.[17–26] The role played by microtubules in neuronal excitability had been proposed several years ago by Matsumoto and Sakai, based on experiment using squid giant axons which resulted in the direct correlation between excitability and microtubule assembly.[17–19] In fact, the excitability of the axon membrane, once suppressed by intracellular perfusion with solutions unfavourable for microtubule assembly, can be restored by perfusing the axon

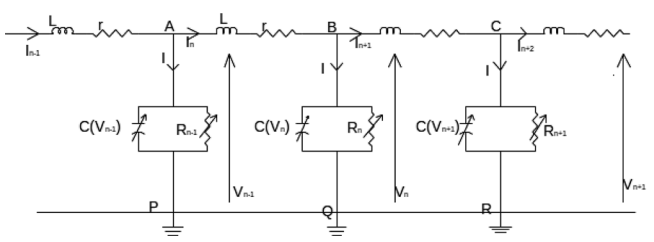

FIG. 1. The electrical circuit model of microtubule.

with a solution containing tubulin and its polymerizing reagents.[19,25] In Ref. 25, Terakawa *et al.*, following experimental observations, suggested that the submembranous cytoskeletons, including microtubules, provide an important mechanical support to the excitable membrane but are not essential elements in channel activities. Also, Ichikawa *et al.* artificially controlled the physiological conditions of axonal microtubules in squid giant axons under an optical microscope by perfusing them intracellularly with artificial solutions and by clamping the membrane voltage to measure membrane currents.[26] Their observations enabled them to conclude that axonal microtubules determine the generation and maintenance of membrane excitability in squid giant axons. In the same line, Braak *et al.*[20] reported from experimental studies that the microtubule-associated protein Tau is implicated in neurodegenerative disorders and described briefly how the Tau protein may modulate neuronal excitability by interacting with the microtubules at the axon initial segment. The authors in Ref. 9 have hypothesized that microtubules may exhibit some features of excitable media as they support the creation and propagation of some sort of solitonic ionic waves along their axis. In the context of their analysis, the origin of the nonlinearity in microtubules stems from the nonlinear capacitance of each tubulin dimer. Similarly, in this work, it is keynote that the polynomial form of the nonlinearity we use here, as shown in Eq. (2), stems from its electrical charge and is well known to be appropriate in excitable neural models,[31] in replacement of the previously used logarithmic form which has been shown to have some limitation in mimicking enough the experimentally observed physiological features of excitability of these cellular systems.

Applying the current rule to the circuit at points A and B of the circuit, and the voltage rule to the loops BCRQB and ABQPA, where the entire transmission line represents a protofilament of a microtubule and V_n denotes the voltage stimulus of the calcium ions (cations), we obtain the equation

$$V_{n+1} - 2V_n + V_{n-1} = L\frac{d^2Q_n}{dt^2} + 3B_1LV_n{}^2\frac{dV_n}{dt} - B_2L\frac{dV_n}{dt} + r\frac{dQ_n}{dt} + rB_1V_n{}^3 - rB_2V_n, \quad (1)$$

where Q_n denotes the quantity of charge that flows through the n_{th} unit cell (i.e., the number of calcium ions driven across the n_{th} unit cell multiplied by the quantity of charge in one calcium ion). $C(V_n)$ denotes the nonlinear capacitance element, which represents quantity of charge urged across the n_{th} unit cell per unit voltage. $C(V_n)$ possesses an electrical charge, Q_n, which takes the form

$$Q_n = C_0(1 - \alpha V_n - \beta V_n{}^2)V_n, \quad (2)$$

obtained by using the form of the charge proposed in Ref. 31.

Here, C_0 is the capacitance in the linear regime and α and β are positive parameters that account for non-linearity in the charge.

The nonlinear resistance effects are characterized by the relation

$$I_{R_n} = f(V_n) = B_1 {V_n}^3 - B_2 V_n, \tag{3}$$

that is, I_{R_n} is the current flowing through the non-linear resistance R_n; B_2 is a positive parameter that accounts for linearity in the current; and B_1 is a positive parameter that accounts for non-linearity in the current.[16] Equation (3) is approximately the I-V relationship of the nonlinear resistance and the nonlinear differential equation [Eq. (1)] becomes

$$\begin{aligned}&\ddot{V}_n - \Omega^2 V_n + (\gamma_0 + \gamma_1 V_n + \gamma_2 V_n^2)\dot{V}_n + (\eta_1 + \delta V_n)\dot{V}_n^2 \\ &\quad + (\eta_1 V_n + \lambda {V_n}^2)\ddot{V}_n + \eta_2 V_n^3 = D_0(V_{n+1} - 2V_n + V_{n-1}),\end{aligned} \tag{4}$$

where

$$\Omega^2 = \frac{rB_2}{LC_0}, \quad \gamma_0 = \frac{r}{L} - \frac{B_2}{C_0}, \quad \gamma_1 = -2\frac{\alpha r}{L}, \quad \gamma_2 = 3\left(\frac{B_1}{C_0} - \frac{\beta r}{L}\right),$$
$$\eta_1 = -2\alpha, \quad \delta = -6\beta, \quad \lambda = -3\beta, \quad \eta_2 = \frac{rB_1}{LC_0}, \quad D_0 = \frac{1}{LC_0}.$$

Equation (4) describes the spatiotemporal evolution of the voltage $V_n(t)$. The terms containing B_1 and B_2 are the contribution of the ionic flow. The terms with r represent the contribution of the linear resistance r. After the equality sign, we have the coupling entity between nearest neighbors $(n-1)$, n, $(n+1)$ of the dimer lattice. The system is dimensionless and it is needless to insist on space and time units. An approximate solution to Eq. (4) can be obtained using perturbation methods. In order to do so, we introduce the variables

$$V_n = \epsilon \phi_n,$$

where $\epsilon \ll 1$.

We consider that γ_0 is a perturbed parameters of order ϵ^2. This perturbation arises from the fact that we are looking for solutions in a weakly dissipative medium. Keeping the first two nonlinear terms of the development, the equation becomes

$$\begin{aligned}&\ddot{\phi}_n - \Omega^2 \phi_n + \epsilon(\epsilon\gamma_0 + \gamma_1 \phi_n + \epsilon\gamma_2 \phi_n^2)\dot{\phi}_n + (\epsilon\eta_1 + \epsilon^2 \delta\phi_n)\dot{\phi}_n^2 \\ &\quad + (\epsilon\eta_1 \phi_n + \epsilon^2 \lambda \phi_n^2)\ddot{\phi}_n + \epsilon^2 \eta_2 \phi_n^3 = D_0(\phi_{n+1} - 2\phi_n + \phi_{n-1}).\end{aligned} \tag{5}$$

The resolution of Eq. (4) reveals the nature of the voltage signal within and between dimer molecules. However, its solution is obtained through the use of Eq. (5).

It is keynote to mention that several authors investigated the mechanical and electrical features of microtubules.[6–10,13–28,30,32–35] Indeed, due to their electrical properties, microtubules are known to play important roles in many cellular functions including motility, mitosis, transport, and the maintenance of cell shape by forming cytoskeletons.[30,32,33] Nerve tissues contain a large amount of tubulin and microtubules, and experimental evidence has been accumulated in support of the view that neuronal microtubules are directly involved in axonal transport.[34,35] Motivated by these facts, Sekulic *et al.*[32] suggested that microtubules (by for instance the collective dynamics of the flexible C-terminal tails decorating its outer surface) could crucially act as a mechanical support of localized waves aimed for communication between microtubules and associated proteins.

B. The wave amplitude equation

At this stage, let us reiterate the fact that our major concern is to investigate for the existence of low-amplitudes non-linear ionic waves in a microtubule. For this purpose, it is convenient to use the multiple scale expansion method which can be applied with a semi-discrete approximation in order to find the solution to our differential equation. The semi-discrete approximation is a perturbation technique in which the carrier waves are kept discrete while the amplitude is treated in the continuum limit. Applying this method allows one to study the modulation of a plane wave caused by nonlinear effects. We proceed by making a change of variables according to the new time and space scales $U_n = \epsilon^n u$ and $T_n = \epsilon^n t$. It should be noted that the principal purpose of using the multiple scale expansion is to find a solution $V(u, t)$ depending on these new sets of variables as a perturbation series of functions. We will consider here that

$$V(u,t) = \sum\nolimits_{n=1}^{\infty} \epsilon^n \phi_n(U_0, U_1, U_2, \ldots, T_0, T_1, T_2, \ldots), \tag{6}$$

where each U_n or T_n is treated as an independent variable. Thus, we also obtain a perturbation series of operators from both independent variables. The temporal derivatives can be expressed as

$$\frac{\partial}{\partial t} = \frac{\partial T_0}{\partial t}\frac{\partial}{\partial T_0} + \frac{\partial T_1}{\partial t}\frac{\partial}{\partial T_1} + \frac{\partial T_2}{\partial t}\frac{\partial}{\partial T_2} + \cdots. \tag{7}$$

Similarly, the spatial derivatives can be expressed as

$$\frac{\partial}{\partial u} = \frac{\partial U_0}{\partial u}\frac{\partial}{\partial U_0} + \frac{\partial U_1}{\partial u}\frac{\partial}{\partial U_1} + \frac{\partial U_2}{\partial u}\frac{\partial}{\partial U_2} + \cdots. \tag{8}$$

An important feature of this method is that the solution of the original problem will only be obtained if the multidimensional space generated by the new set of variables U_n and T_n comes from the physical line.[11] Worth noting is the fact that these auxiliary variables permit us to impose appropriate conditions to the system thus assuring that the asymptotic expansion converges uniformly for small values of ϵ.[39]

In order to solve the equation of motion of the voltage stimulus, we consider the following form of solution (ansatz) for the dynamics of our discrete electrical circuit model of microtubule:

$$\begin{aligned}\phi_n = {} & F_n e^{j\theta_n} + F_n^* e^{-j\theta_n} + \epsilon(G_n + H_n e^{2j\theta_n} + H_n^* e^{-2j\theta_n}) \\ & + O(\epsilon^2),\end{aligned} \tag{9}$$

with $\theta_n = qn - wt$, where q is the normal mode wave vector, n denotes the unit cell number in the dimer lattice, and w is the angular velocity of the wave.

The fact that there are nonlinear terms in Eq. (5) leads one into the prediction that through frequency superpositions, the first harmonics of the wave will contain terms in

$e^{\pm 2j\theta_n}$ as well as terms without any exponential dependence. We will equally consider that the amplitudes F, G, and H change slowly in space and time. This is formalized in a multiple scale expansion in a method referred to as semi-discrete approximation because it preserves a carrier wave which obeys a discrete dispersion relation and only the variation of the amplitude is treated in the continuum limit.

In this semi-discrete approximation, F, G, and H are set to be independent of the "fast" variables t and u. but to depend on the "slow" variables $U_1 = \epsilon u$, $U_2 = \epsilon^2 u$, $T_1 = \epsilon t$, and $T_2 = \epsilon^2 t$. Applying now the continuum limit approximation on these amplitudes will yield $F_n(t)$, $G_n(t)$, and $H_n(t)$ becoming $F(U_1, U_2, T_1, T_2)$, $G(U_1, U_2, T_1, T_2)$, and $H(U_1,U_2,T_1,T_2)$, respectively. $F_{n\pm1}$ is obtained up to ϵ^2 by a Taylor expansion

$$F_{n\pm1} = F \pm \epsilon \frac{\partial F}{\partial U_1} \pm \epsilon^2 \frac{\partial F}{\partial U_2} + \frac{\epsilon^2}{2}\frac{\partial^2 F}{\partial U_1^2} + O(\epsilon^3).$$

Similar equations are written for G_n and H_n. These together with Eq. (9) are inserted into the two equations depicting our model, that is, Eq. (5). We seek relations for which terms in $e^{\pm j\theta_n}$, $e^{\pm 2j\theta_n}$ and terms without exponential dependence cancel out at different orders of ϵ (at different orders of perturbation).

At the zeroth order of perturbation, we obtain the dispersion relation of linear waves of the system described by Eq. (5)

$$w^2 = -\Omega^2 + 4D_0 \sin^2\frac{q}{2}. \tag{10}$$

By definition, the coefficients, B_1, B_2, r, L, and C_0 are positive constants. Therefore, Eq. (10) is valid if the wave number satisfies the condition[16]

$$q \geq q_c = 2\arcsin\sqrt{\frac{\Omega^2}{4D_0}}. \tag{11}$$

It follows from Eq. (11) that the system is a low band pass filter with the allowed band defined by the frequency interval $[0, \omega_c]$, where $\omega_c^2 = -\Omega^2 + 4D_0$ is the square of the upper cut-off frequency.[16] The dispersion relation, Eq. (10), is indeed that of a discrete model and thus meets up with expectations. Figure 2 presents the graph of this dispersion relation. It depicts a scenario whereby there are limited intervals of values of the wave number which are suitable for the existence of linear waves within the medium. These epochs of values of q suitable for existence of linear waves are regularly separated by forbidden intervals of values of the wave number. These forbidden gaps then naturally indicate that linear waves are not accessible for the system for some given values of q.

At the first and second orders of perturbation, we obtain the coefficient

$$G = 0, \tag{12}$$

the relation

$$H = -\left[\frac{\omega D_0(2\omega\eta_1 + j\gamma_1)}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}\right]F^2, \tag{13}$$

the group velocity of the ionic waves conveyed by our model

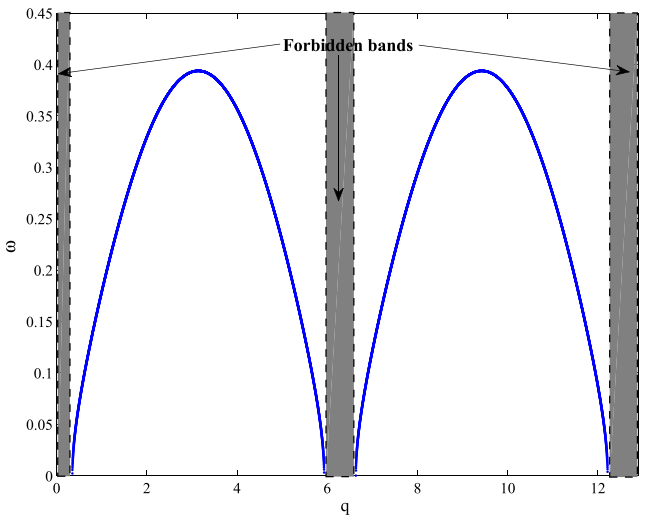

FIG. 2. The dispersion relation of the ionic wave. $D_0 = 0.04$ and $\Omega^2 = 0.0049$.

$$v_g = \frac{D_0 \sin q}{w}, \tag{14}$$

and at higher order, the equation of evolution of the solitonic function

$$j\frac{\partial F}{\partial \tau_2} + \frac{P}{2}\frac{\partial^2 F}{\partial \xi_1^2} + Q|F|^2 F + j\frac{R}{2}F = 0, \tag{15}$$

where we have used the rescaling (change of variables)

$$\xi_n = U_n - v_g T_n, \quad \tau_n = T_n. \tag{16}$$

Equation (15) shows that the evolution of ionic waves in this electrical circuit model of microtubules is described by the Complex Ginzburg-Landau equation (CGLE) where the coefficients of dispersion and dissipation, P and R, respectively, are real, while the coefficient of nonlinearity, Q, is complex. It can be seen that the wave propagates in a frame of reference that travels with velocity, v_g (the group velocity), where

$$P = \frac{D_0 w^2 \cos q - D_0^2 \sin^2 q}{w^3}, \tag{17}$$

$$Q = Q_r + jQ_i, \tag{18}$$

$$R = \gamma_0, \tag{19}$$

where Q_r and Q_i are the real and imaginary parts of the nonlinearity coefficient, respectively, such that

$$Q_r = \frac{\omega D_0}{2}\left(\frac{2\omega^2{\eta_1}^2 - 3{\gamma_1}^2}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}\right) - \frac{3\eta_2 + \omega(\delta - 3\lambda)}{2\omega}, \tag{20}$$

$$Q_i = \frac{\omega D_0}{2}\left(\frac{7\omega\gamma_1\eta_1}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}\right) + \frac{\gamma_2}{2}. \tag{21}$$

The variation of the coefficient of dispersion P, the real and imaginary parts of the coefficient of nonlinearity Q_r and

Q_i, and the product PQ_r, as functions of the wave number q, are plotted in Fig. 3.

When the dissipation is not considered in some cases, the Complex Ginzburg-Landau equation reduces to the Nonlinear Schrödinger equation.[40] However, that is not the case in this model because if the dissipation is neglected, the nonlinearity coefficient will still have complex and imaginary parts. Therefore, our amplitude equation will always be described by the Complex Ginzburg-Landau equation.

The dispersion coefficient is real. It follows that the modulational instability depends on the sign of PQ_r. According to Benjamin-Feir instability analysis, plane waves are unstable for positive values of PQ_r whilst they are stable for negative values. Note that this stability criterion does not depend on the manner with which the wave propagates.

In Fig. 3(a), it is observed that the dispersion coefficient P is always negative. Also, in Figs. 3(b) and 3(c), we see that the real and imaginary parts of the coefficient of nonlinearity are always negative and positive, respectively, irrespective of the accessible values of q. In accordance with these observations, as expected from the outcomes of Figs. 3(a) and 3(b), Fig. 3(d) illustrates the fact that the product PQ_r is permanently positive. This suggests that in line with the Benjamin-Feir instability criteria, plane waves' solutions of our biological system are unconditionally unstable. As a result of this, our model of microtubule steadily exhibits a tendency to promote the generation of modulated amplitude waves along the structure of the subcellular lattice. Thus, based on these facts, our biological model depicts an environment purposely conducive for the existence of stable solitary waves, as solutions of our dynamical system. The determination of these soliton solutions in this proteinic network model shall be the core of Secs. III–VI. First of all, in order to be relatively complete in this survey, Sec. III will be dedicated to analytically ascertain this startling predilection to excitability by the means of the Eckhaus instability analysis of the plane waves solutions of our *CGLE*.

III. NONLINEAR ANALYSIS OF THE ECKHAUS INSTABILITY OF THE MODEL

The complex Ginzburg-Landau equation that describes our model is given in Eq. (15).

A plane wave is a field of energy that propagates with constant frequency and amplitude. An amplitude modulated wave is a wave whose amplitude varies spatiotemporally, while a phase modulated wave is a wave whose phase changes spatiotemporally. In order to study the stability of our wave amplitude equation, we use the following ansatz for our saturated amplitude modulations:[44,45]

$$F(\xi_1, t) = a(z)e^{j[\phi(z)+\omega_1 t]}, \tag{22}$$

where a and ϕ are real-valued functions of $z = \xi_1 - v_g\tau_2$. Substituting the ansatz in Eq. (22) into Eq. (15), separating the real and imaginary parts and setting $b = a_z$ and $\psi = \phi_z$ yield the set of three coupled nonlinear ordinary differential equations (ODEs)

$$\begin{cases} a_z = b \\ b_z = \dfrac{2\omega}{P}a + \dfrac{2}{P}a\psi + a\psi^2 - \dfrac{2}{P}a^3Q_r \\ \psi_z = \dfrac{2v_g}{P}\dfrac{b}{a} - \dfrac{R}{P} - 2\dfrac{b\psi}{a} - \dfrac{2Q_i}{P}a^2. \end{cases} \tag{23}$$

Therefore, the system of Eq. (23) describes the dynamics of amplitude-modulated waves in our electrical circuit model of microtubules.

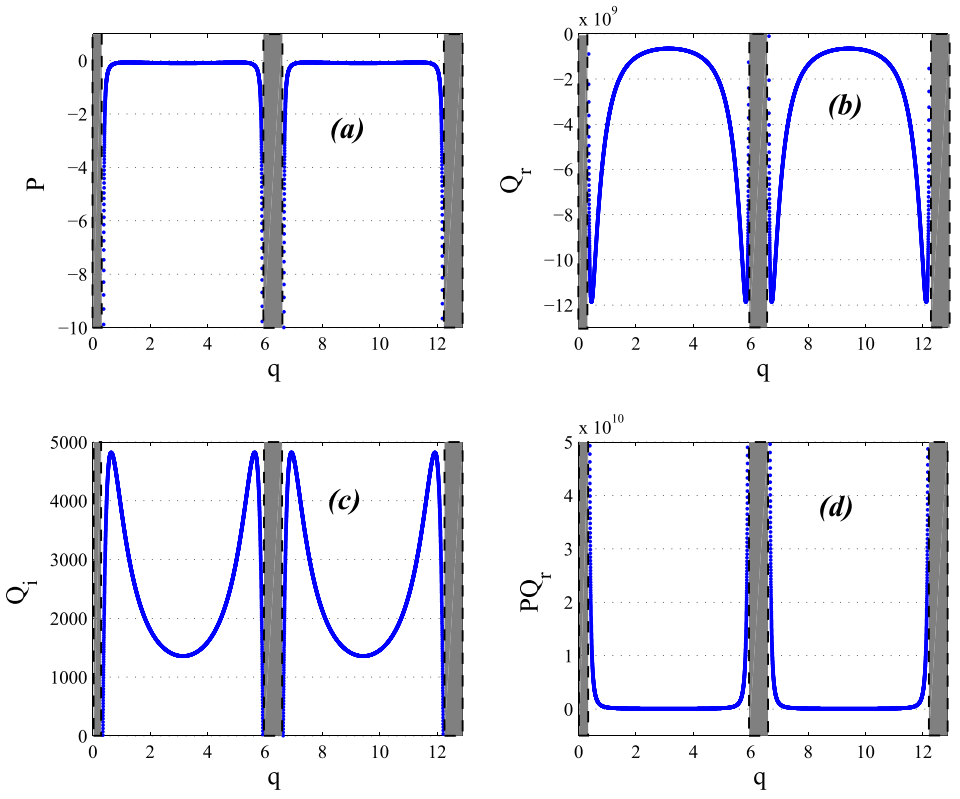

FIG. 3. Variations of the coefficient of dispersion P, the real and imaginary parts of the coefficient of nonlinearity Q_r and Q_i, and the product PQ_r, as functions of the wave number q. The parametric values are $D_0 = 0.04$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta_2 = 0.005$, $\gamma_1 = 40\,000$, $\gamma_2 = 5.0$, $\lambda = 0.05$, and $\delta = 0.8$.

We proceed to perform a stability analysis of the fixed points of our model. Since the equilibria of dynamical systems are not always stable, it behooves us to characterize the stability of the fixed points pertaining to our model due to the fact that stable and unstable equilibria play quite different roles in the dynamics of a system. If the fixed points are stable, then the plane waves become stable; if the fixed points are unstable, the plane waves become unstable. The equilibrium points are determined by setting all gradients to zero, that is, $a_z = b_z = \psi_z = 0$, and, taking only positive square roots, we find that the procedure starts from the fixed point $(a,\ b,\ \psi_z) = (\sqrt{\frac{R}{2Q_i}}, 0, \frac{1}{p}[-1 + \sqrt{1 + P\left(\frac{Q_r}{Q_i}R - 2\omega\right)}])$, which corresponds to a plane wave solution. In a bid to characterize the stability of the fixed point, we obtain the characteristic polynomial

$$a_0\lambda^3 + a_1\lambda^2 + a_2\lambda + a_3 = 0, \tag{24}$$

where

$$\begin{aligned} &a_0 = 1, \quad a_1 = 0, \\ &a_2 = 4\psi^2 + \frac{4\psi}{P} + \frac{6Q_r}{P} - \frac{4v_g\psi}{P} - \frac{4v_g}{P^2} - \psi - \frac{2\psi}{P} - \frac{2\omega}{P}, \\ &a_3 = \frac{4av_g\psi}{P} + \frac{4av_g}{P^2} - 4a\psi^2 - \frac{4a\psi}{P}. \end{aligned} \tag{25}$$

For the fixed point to be stable, all the eigenvalues, λ_k for $k = 1$, 2, and 3 of Eq. (24) must have negative real parts. Using the *Routh-Hurwitz stability criteria*, the necessary and sufficient conditions for stability to occur are

$$a_1 > 0, \quad a_3 > 0, \quad \textit{and} \quad a_1a_2 > a_3. \tag{26}$$

The simultaneous fulfillment of these criteria implies that all the eigenvalues of the characteristic equation have negative real parts, synonym of convergence of our dynamical system, following some perturbation deeds, toward the plane waves solutions. Yet, from Eq. (26), $a_1 = 0$. Then, this implies that the Routh-Hurwitz stability criteria can never be concomitantly fulfilled. Thus, the plane waves solutions of our *CGLE* are always unstable. This fact is in perfect agreement with the results obtained numerically in Fig. 3(d) in Sec. II, using the Benjamin-Feir stability condition. Therefore, our *CGLE* admits modulated amplitude waves as only stable solutions. It then suitably describes the dynamics of our lattice of biochemical units as an excitable medium.

IV. NONLINEAR IONIC WAVE SOLITON SOLUTION

A. The Nozaki-Bekki soliton solution

A form of the soliton solution of the amplitude Eq. (15) can be obtained using the Nozaki and Bekki ansatz[36,38,40,41]

$$F(\xi_n, t) = \frac{F_0 e^{\varphi}}{1 + e^{(\varphi+\varphi^*)^{(1+j\alpha)}}}, \tag{27}$$

where

$$\varphi = q\xi_n - w\tau, \tag{28}$$

$$\alpha = \beta \pm (2 + \beta^2)^{\frac{1}{2}}, \tag{29}$$

$$\beta = \frac{3Q_r}{2Q_i}. \tag{30}$$

Now, rewriting the ansatz in Eq. (27) by considering the real and imaginary parts and transforming its coefficients following the process in Ref. 37, we arrive at the solution for the calcium wave propagation in the microtubule described by

$$\begin{aligned} V_n = {} & \epsilon F_0\left[\frac{e^{\varphi}\cos(\theta - 2\alpha\varphi) + e^{-\varphi}\cos\theta}{(\cosh 2\varphi + \cos 2\alpha\varphi)}\right] + \epsilon^2 F_0^2\left[(x\cos 2\theta\right. \\ & \left. - y\sin 2\theta)\left(\frac{e^{2\varphi}\cos 4\alpha\varphi + 2\cos 2\alpha\varphi + e^{-2\varphi}}{2(\cosh 2\varphi + \cos 2\alpha\varphi)^2}\right)\right] \\ & - \epsilon F_0^2\left[(x\sin 2\theta - y\cos 2\theta)\left(\frac{e^{2\varphi}\sin 4\alpha\varphi - \sin 2\alpha\varphi}{(\cosh 2\varphi + \cos 2\alpha\varphi)^2}\right)\right], \end{aligned} \tag{31}$$

where

$$x = -\frac{2\omega^2\eta_1 D_0}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}, \tag{32}$$

$$y = -\frac{\omega\gamma_1 D_0}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}. \tag{33}$$

Figure 4 portrays the depiction and behavior this ionic wave in all the computational domains. From Figs. 4(a)–4(c), It is clearly noticed that this analytical solution emerges in the form of a single asymmetric pulse, propagating along the medium. These figures show the three-dimensional spatiotemporal evolution of the travelling ionic impulse [Fig. 4(a)], its upper view [Fig. 4(b)], and its profiles at different times [Fig. 4(c)], respectively. The snapshots of the lattice at several distinct times [as seen in Fig. 4(c)] reveal the fact that the pulse is structurally unstable, as it changes its shape in the course of its propagation through the lattice. Indeed, this asymmetric solution is indicative of the presence of a bright envelope soliton propagating within the one-dimensional spatial array of biochemical units, and whose amplitude is correspondingly depicted in Fig. 4(d) (three-dimensional spatiotemporal evolution), Fig. 4(e) (upper view), and Fig. 4(f) (lattice snapshots at different times).

Equally, it is important to note that the parameter ϵ helps us to differentiate the orders of development of the solitonic pulse. Its effect on the ionic wave can be seen in Fig. 5. This figure represents the snapshots of the lattice structure at the time $t = 46$, for different values of the perturbation, namely, $\epsilon = 0.0001$ [Fig. 5(a)], $\epsilon = 0.001$ [Fig. 5(b)], $\epsilon = 0.01$ [Fig. 5(c)], and $\epsilon = 0.1$ [Fig. 5(d)]. We notice that as the perturbation increases the amplitude of the ionic wave also increases. A similar phenomenon has already been observed in other biological excitable media, namely, in diffusively connected Hindmarsh-Rose neural networks.[37] A generalization of this fact is depicted in Fig. 6.

Thus, the previously obtained outcomes show that information processing and transmission along the structure of a

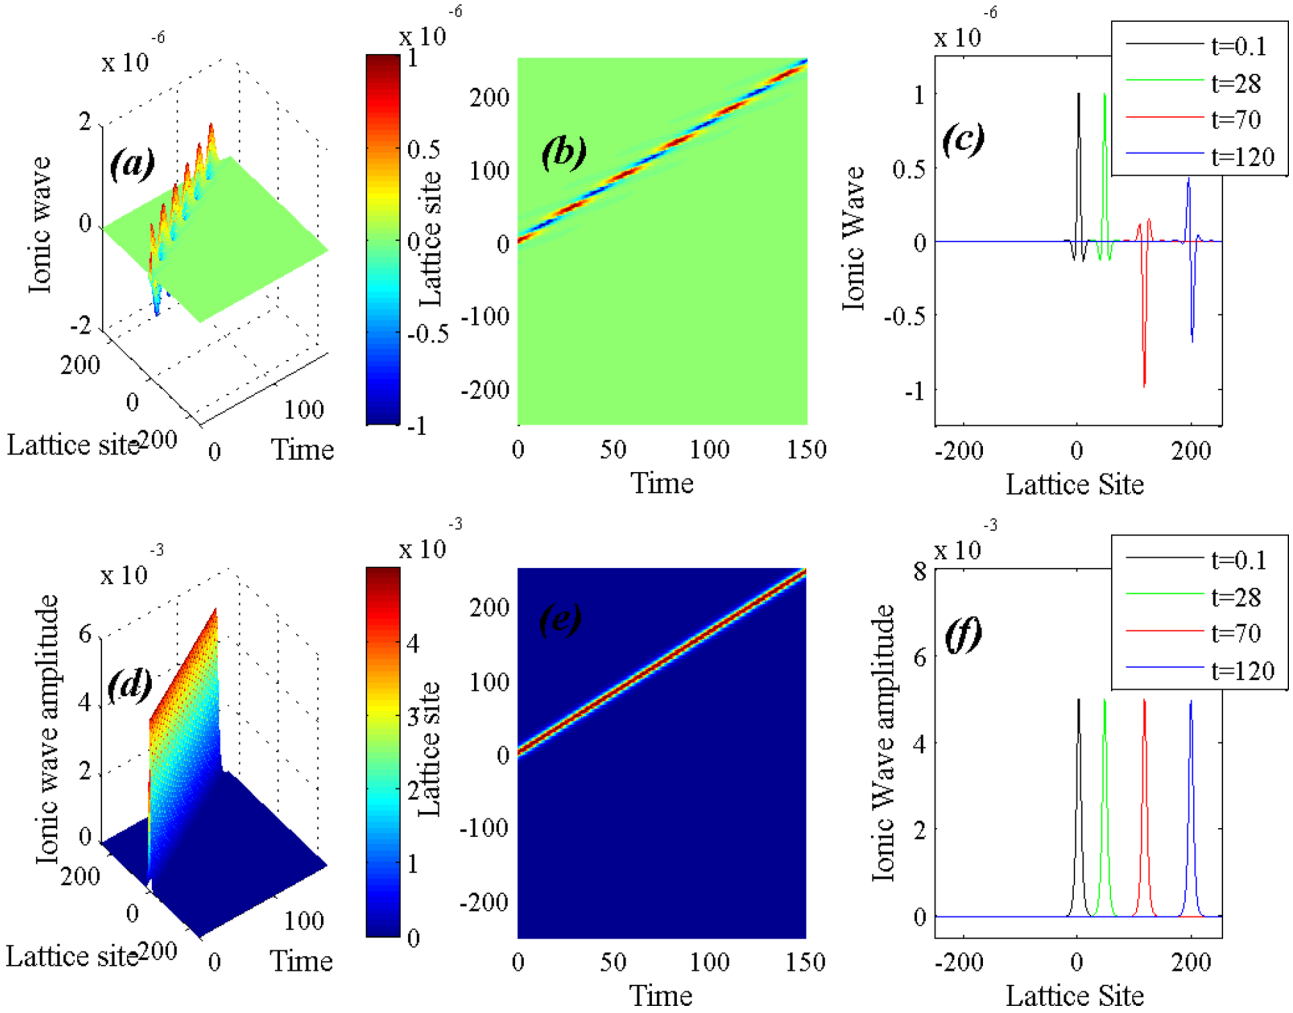

FIG. 4. Spatiotemporal evolution of the ionic wave and its corresponding envelope. The ionic wave is presented in (a) three-dimensional view of the travelling pulse, (b) upper view of the pulse, and (c) ionic wave profiles at different times. The corresponding envelope is depicted in (d) three-dimensional view of the propagating envelope, (e) upper view of the envelope, and (f) envelope profiles at different times. The parametric values are $D_0 = 0.04$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta_2 = 0.005$, $\gamma_1 = 40\,000$, $\gamma_2 = 5.0$, $\lambda = 0.05$, $\delta = 0.8$, $q = 1.5$, $F_0 = 0.01$, and $\epsilon = 0.0001$.

microtubule are achievable by means of localized excitations. These solitary waves, because of their robustness and stability, are ideal tools to secure the transmission processes taking place along some relatively large arrays of biological dynamical systems. Their remarkable robustness is predominantly due to their regenerative feature. Yet, one of the challenges usually faced in communication processes is the ability to concomitantly convey not only safely but also quantitatively, a huge diversity of information. This implies the simultaneous transmission of a huge set of harmonics along our biochemical milieu. A typical means to achieve that is to relay the stimulus in the form of a wave packet. Subsequent to these facts, we propose ourselves to seek for wave packets solutions of our nonlinear equation of motion. In an attempt to meet this target, in Sec. IV B, we use the harmonic balance method to solve our wave amplitude equation and derive the expression of the ionic wave propagating in the model.

B. The symmetric solution using the harmonic balance method

Here, we seek exact solutions of the CGLE that pertain to our model. We use the harmonic balance method with a nonlinear transform to find solutions in terms of Fourier series.[42] This method, which is a technique used in determining the limit cycle of a dynamical system, will be utilized in this section to obtain the exact travelling solution of the equation describing the dynamics or evolution of our model (the CGLE). In this technique, we define and use a nonlinear transform $l(\xi)$ such that

$$\frac{dl}{d\xi} = f, \tag{34}$$

where $f = f(l) = f(l(\xi))$ is a periodic function of period 2π. Trigonometric functions, which are easier to handle, will be used here.

For our system, we choose

$$f(l) = \cos l. \tag{35}$$

Since the equation describing the evolution of our model, the complex Ginzburg-Landau equation (CGLE), is a complex equation, we consider an ansatz (solution) to it of the form:

$$F(\xi, t) = g(\xi) e^{j[s(\xi) + wt]}, \tag{36}$$

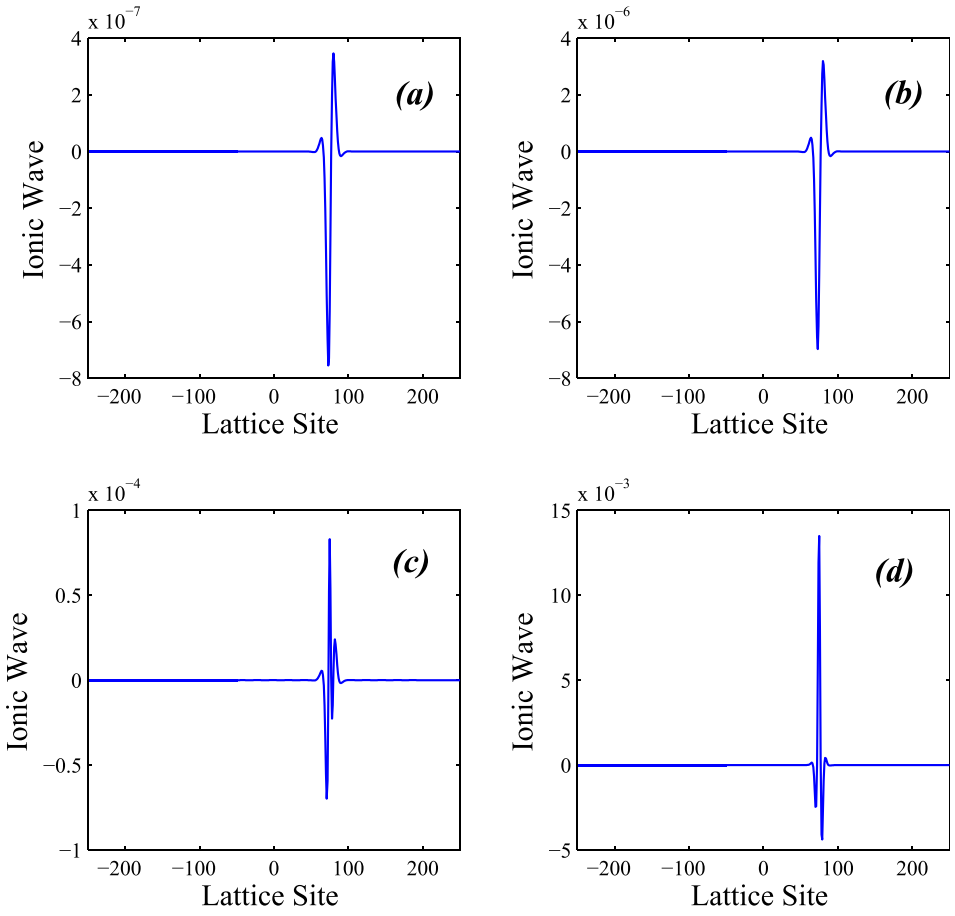

FIG. 5. Effects of small perturbations on the ionic wave. Snapshots of the wave profile taken at $t=46$. (a) $\epsilon=0.0001$, (b) $\epsilon=0.001$, (c) $\epsilon=0.01$, and (d) $\epsilon=0.1$. The parametric values are the same as in Fig. 4.

where $g(\xi)$ and $s(\xi)$ are real functions and $\xi=n_1u+n_2t$, n_1 and n_2 being constants.

Inserting Eq. (36) into Eq. (15) yields, for real and imaginary terms

$$g_{\xi\xi}-gs_\xi^2-n_2n_3gs_\xi+n_4g^3-n_5g=0, \tag{37}$$

$$gs_{\xi\xi}+2g_\xi s_\xi+n_2n_3g_\xi+n_6g^3+n_7g=0, \tag{38}$$

where

$$n_3=\frac{2}{Pn_1^2},\quad n_4=n_3Q_r,\quad n_5=wn_3,\quad n_6=n_3Q_i,\quad n_7=n_3\frac{R}{2}.$$

In order to find travelling wave solutions, we shall use the ansatz (solutions) suggested by Porubov and Velarde[43]

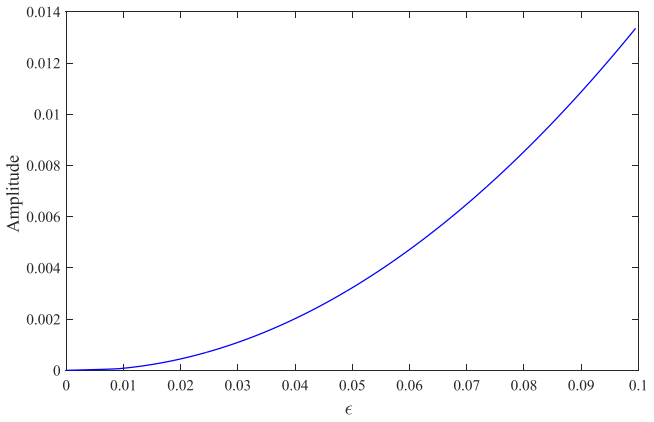

FIG. 6. Plot of the ionic wave amplitude as a function of the amplitude of the perturbation. The parametric values are the same as in Fig. 4.

$$R=g^2, \tag{39}$$

$$A=g^2s_\xi. \tag{40}$$

Inserting these in Eqs. (37) and (38) yield

$$\frac{1}{2}RR_{\xi\xi}-\frac{1}{4}R_\xi^2-A^2-n_2n_3RA+n_4R^3-n_5R^2=0, \tag{41}$$

$$A_\xi+\frac{1}{2}n_2n_3R_\xi+n_6R^2+n_7R=0. \tag{42}$$

The harmonic balance method is carried out by choosing a solution that utilizes terms which enhance a check at different orders of neglected harmonics. Thus, one needs to have an insight into the possible solution of the system in order to apply this method. The idea here is to express solutions in a periodic form at different harmonics. We therefore suppose that

$$R=r_0+s_1\sin l+r_2\cos 2l, \tag{43}$$

$$A=c_0+a_1\sin l+c_2\cos 2l+a_3\sin 3l. \tag{44}$$

In terms of l, we can show that

$$R_\xi=f\frac{dR}{dl},\quad A_\xi=f\frac{dA}{dl},\quad R_{\xi\xi}=f^2\frac{d^2R}{dl^2}+f\frac{df}{dl}\frac{dR}{dl}. \tag{45}$$

Revisiting our nonlinear transform Eq. (34) and Eq. (35), we obtain $d\xi=\frac{dl}{f(l)}\Rightarrow\xi=\int\frac{dl}{\cos l}$, which leads us to the identities

$$\sec h\xi = \cos l, \quad \textit{and} \tag{46}$$

$$\tanh\xi = \sin l. \tag{47}$$

We therefore obtain different equations at the different harmonics $\sin wl$ and $\cos yl$, where w is odd (1, 3, 5, etc.) and y is even (0, 2, 4, 6, etc.). The equations at the different harmonics are then solved to obtain expressions for the required coefficients in Eqs. (43) and (44).

From the above deductions, one obtains the factors of the Porubov and Velarde ansatz solution to the equation that describes our model as

$$R = 2r_2 \sec h^2\xi, \tag{48}$$

$$A = -\left(\frac{1}{2}\eta + \frac{2}{3}m\sin l\right)R - \frac{8}{3}mr_2\sin l, \tag{49}$$

where $n_6 r_2 = m$ and $n_2 n_3 = \eta$.

We therefore obtain the ionic wave or voltage stimulus in our transmission line or model as

$$\begin{aligned} V_n(u,t) = {} & \left(2\epsilon\sqrt{2r_2}\sec h\xi\right)\cos\left[\theta_n - \left(\frac{1}{2}\eta\xi\right)\right. \\ & \left. -\left(\frac{2}{3}m\right)\ln(\cosh\xi) - \left(\frac{1}{3}m\right)\cosh 2\xi + wt\right] \\ & + 4\epsilon^2 r_2 x\sec h^2\xi\cos\left[2\theta_n - \eta\xi - \left(\frac{4}{3}m\right)\ln(\cosh\xi)\right. \\ & \left. -\left(\frac{2}{3}m\right)\cosh 2\xi + 2wt\right] - 4\epsilon^2 r_2 y \\ & \times \sec h^2\xi\sin\left[2\theta_n - \eta\xi - \left(\frac{4}{3}m\right)\ln(\cosh\xi)\right. \\ & \left. -\left(\frac{2}{3}m\right)\cosh 2\xi + 2wt\right], \end{aligned} \tag{50}$$

where

$$x = -\frac{2\omega^2\eta_1 D_0}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}, \tag{51}$$

$$y = -\frac{\omega\gamma_1 D_0}{D_0(\Omega^2 + 2\omega^2) + 2(\omega^4 - 2\omega^2\Omega^2 + \Omega^4)}, \tag{52}$$

$$\xi = n_1 u + n_2 t. \tag{53}$$

The voltage stimulus in Eq. (50) is that of the ionic wave propagated in our model of microtubules. This wave has its origin from the drifting of calcium ions from the region where they are more concentrated (region of higher potential) to the region where they are less concentrated (region of lower potential) within a microtubule protofilament between dimer molecules. An electric field is thus built up and is depicted by our transmission line or model.

Figure 7 presents this ionic wave on all the computational domains. It is observed that this analytical solution emerges in the form of a symmetric localized wave packet, travelling along the one-dimensional spatial subcellular network. Figures 7(a)–7(c) show its three-dimensional spatiotemporal evolution, its upper view, and its profiles at three different propagation times, respectively. This ionic wave is indicative of the existence and propagation along the array of biochemical systems of a symmetric bright envelope soliton. It is noteworthy that by definition, a bright soliton is a solution of a partial differential equation that is localized in space with the characteristic that it vanishes at infinity on the spatial domain.[39] Furthermore, in soliton theory, keeping in mind the concept of amplitude modulation of signal, it is well known that a carrier wave (wave front) can change its profile in the course of time since it can possibly be structurally unstable,[37,39,40] while its corresponding envelope preserves its shape. In other words, several profiles of a carrier

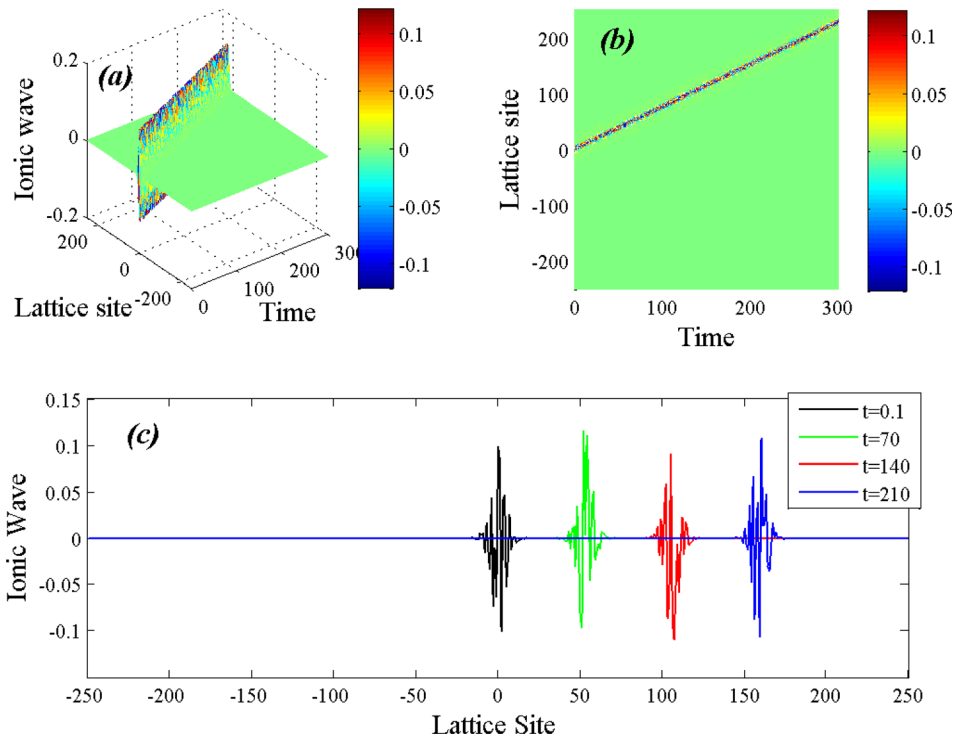

FIG. 7. Spatiotemporal evolution of the ionic wave in all the computational domains: (a) Three-dimensional view of the ionic wave, (b) upper view of the ionic wave, and (c) ionic wave profiles at different times. The signal appears in the form of a nearly symmetric wave packet. The parametric values are $D_0 = 0.04$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta = 1.0$, $\gamma_1 = 40\,000$, $r_2 = 1.0$, $n_1 = 1.0$, $n_2 = 0.069441$, $q = 1.5$, and $\epsilon = 0.001$.

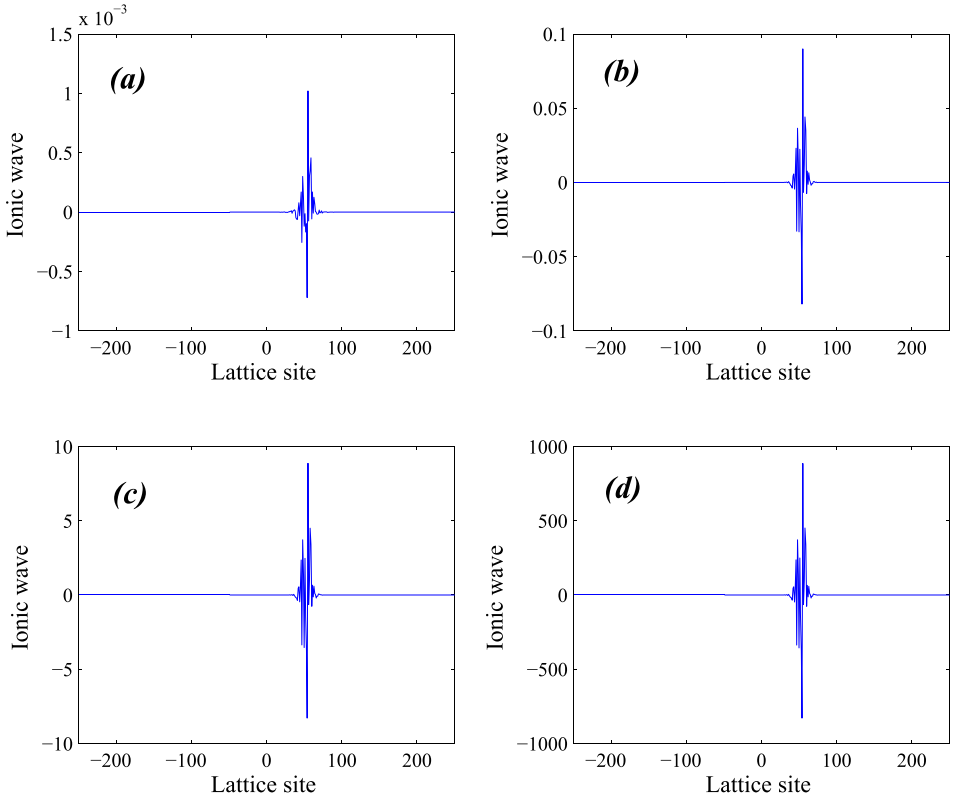

FIG. 8. Effects of small perturbations on the ionic wave. Snapshots of the wave profile taken at $t = 71$. (a) $\epsilon = 0.0001$, (b) $\epsilon = 0.001$, (c) $\epsilon = 0.01$, and (d) $\epsilon = 0.1$. The parametric values are the same as in Fig. 7.

wave can support the same envelope (or amplitude). Indeed, a close look at the wave front in Fig. 7 shows that the wave packet, in the course of its propagation, retains its width and amplitude. Therefore, its corresponding envelope naturally maintains its shape as it moves in the lattice.

The impact of the perturbation on the ionic wave can be seen in Fig. 8. This figure depicts the snapshots of the internal spatial state of the microtubule at the time $t = 71$, for different values of the perturbation, specifically, $\epsilon = 0.0001$ [Fig. 8(a)], $\epsilon = 0.001$ [Fig. 8(b)], $\epsilon = 0.01$ [Fig. 8(c)], and $\epsilon = 0.1$ [Fig. 8(d)]. We notice that as the perturbation increases, the amplitude of the ionic wave is tremendously enhanced. A similar trend has been reported in Sec. III in the case of the asymmetric ionic wave. A generalization of this fact is equally displayed in Fig. 9.

It therefore follows that, for very small perturbations of microtubules, impulses are exchanged between microtubules and equally amid their inner parts in the form of nearly symmetric envelope solitons. These impulses are steadily transmitted at a constant velocity with no change in the topology of the conduction medium. Microtubules play crucial roles in higher neuronal functions including mechanisms of consciousness and memory; and it is well known that some reasonable degree of disturbances may usually occur during the events of loss of consciousness and memory in living beings. In such scenarios, an increase in the amplitude of the wave is noticed. This is as a result of the energy released from the bursting of bubbles that are formed due to the agitations stirred up in the medium by the perturbations.

Unlike the results obtained with the asymmetric solitary wave in Subsection IV A above, Fig. 7(c) shows that this symmetric ionic wave propagates in the form of a train of localized pulses embedding a series of harmonics. Therefore, this solitary wave satisfactorily meets our expectations.

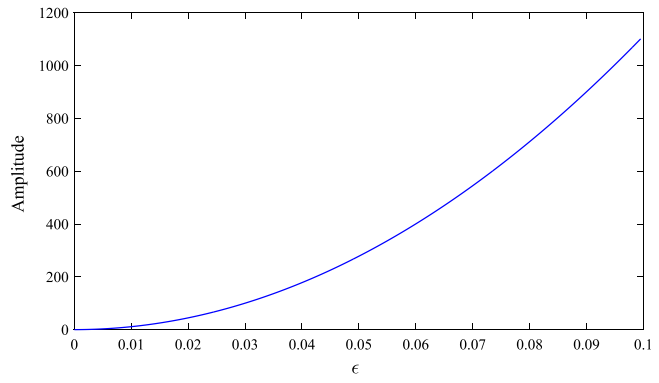

FIG. 9. Plot of the ionic wave amplitude as a function of the amplitude of the perturbation. The parametric values are the same as in Fig. 7.

V. NUMERICAL ANALYSIS OF THE VOLTAGE EQUATION: EXCITABILITY AND COLLISION

This section is solely dedicated to the direct numerical resolution of the original discrete equation of the voltage stimulus obtained in Sec. II and given by Eq. (4). The aim of this study is to check if our model of microtubule, in its full dimension, can equally display the features of excitability by supporting strongly nonlinear localized waves along its structure. For the purpose of this examination, we assume a huge partition of 100 electrical units in a one-dimensional spatial domain [–L, L], with a time step of 0.1. We numerically analyze our second order ordinary differential equation based on the fifth-order Runge-Kutta scheme. We take in this case $L = 50$, with periodic boundary conditions.

This initial value problem will be resolved while assuming as Ansatz, the exact analytical solution obtained in Sec. IV as Eq. (31). An inspection of the collective dynamical behavior of our electrical network enables us to witness several distinct wave phenomena occurring in our subcellular milieu within several parametric conditions.

In the upper part of Fig. 10, it is observed that after sending the impulse in the system, the structure preserves this excitation state permanently, with no event of propagation, for some given set of the system parametric values. This suggests that stationary localized pulses are accessible for our biological system. This intimates the existence of a stationary bright envelope soliton solution of our discrete voltage equation. Figures 10(a)–10(c) show the three-dimensional spatiotemporal display, the upper view, and the profile of this ionic wave at all times, respectively.

Interestingly, a further numerical study in other parametric conditions exhibits scenarios whereby, subsequent to the insertion of the Ansatz, it breaks down into a bi-pulse (that is two pulses) propagating in opposite directions within the lattice. This phenomenon is observed in both the lower part of Fig. 10 and in Figs. 11 and 12, for different lattice settings. Due to the periodic boundary conditions, these two pulses collide at the boundaries of the biological lattice and subsequent to this collision, several physical events may occur. First, Figs. 10(d)–10(f) disclose a situation where the two pulses merge into a non-trivial spatially homogeneous steady state for the biological ensemble. This stationary state is reminiscent of the phenomenon of oscillation quenching (observed in many physical and biological systems), alongside with the concept of synchronization as all the dynamical units states saturate at the same value of the amplitude of the ionic signal (voltage).

Second, in Fig. 11, with some additional boundary conditions, namely, the homogeneous Dirichlet boundary conditions, the two pulses after the collision, coalesce into a stable stationary dark soliton. Figures 11(a)–(11c) portray the three-dimensional spatiotemporal evolution of the bi-pulse propagation and collision, its upper view, and the profiles of the ionic wave at different times, respectively. Figures

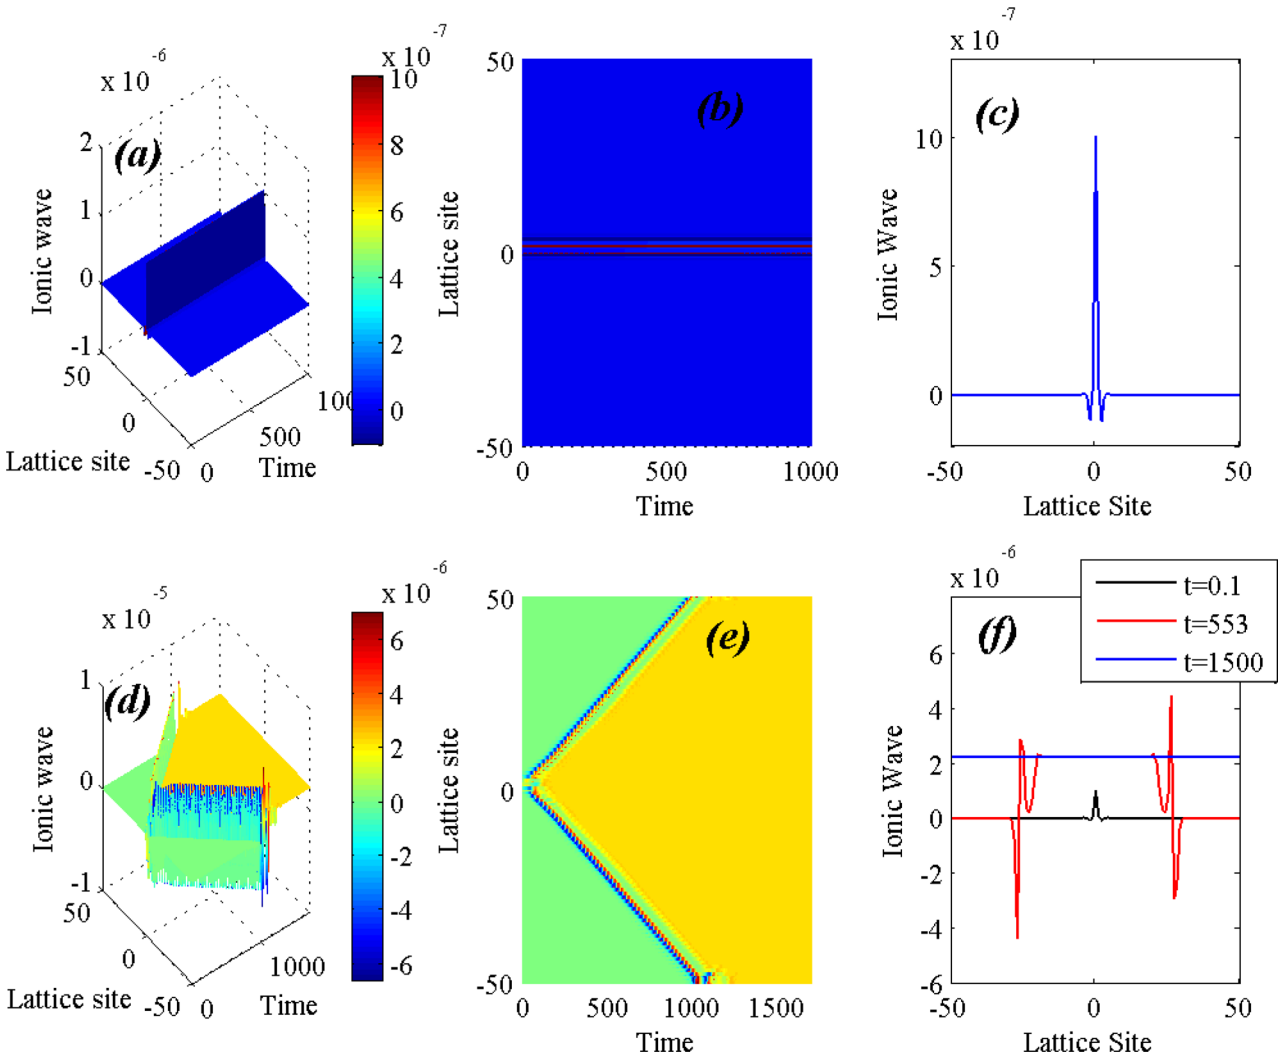

FIG. 10. Ionic waves solutions of the discrete voltage equation (4) in two different parametric conditions. The *upper figures* depict a stationary localized pulse. (a) Three-dimensional view, (b) upper view, and (c) profile at all times. The parametric values are $\gamma_0 = 65.0$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta_2 = 0.005$, $\gamma_1 = 40000$, $\gamma_2 = 5.0$, $\delta = 0.1$, $\lambda = -1.0$, and $D_0 = 0.0024$. The *lower figures* depict a Bi-pulse solution travelling in opposite directions, yielding after collision a non-trivial spatially homogeneous stationary pattern. (d) Three-dimensional view, (e) upper view, and (f) profiles of the wave at different times. The parametric values are $\gamma_0 = 0.0$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta_2 = 10^9$, $\gamma_1 = 40\,000$, $\gamma_2 = 5.0$, $\delta = 0.1$, $\lambda = -1.0$, and $D_0 = 0.0024$.

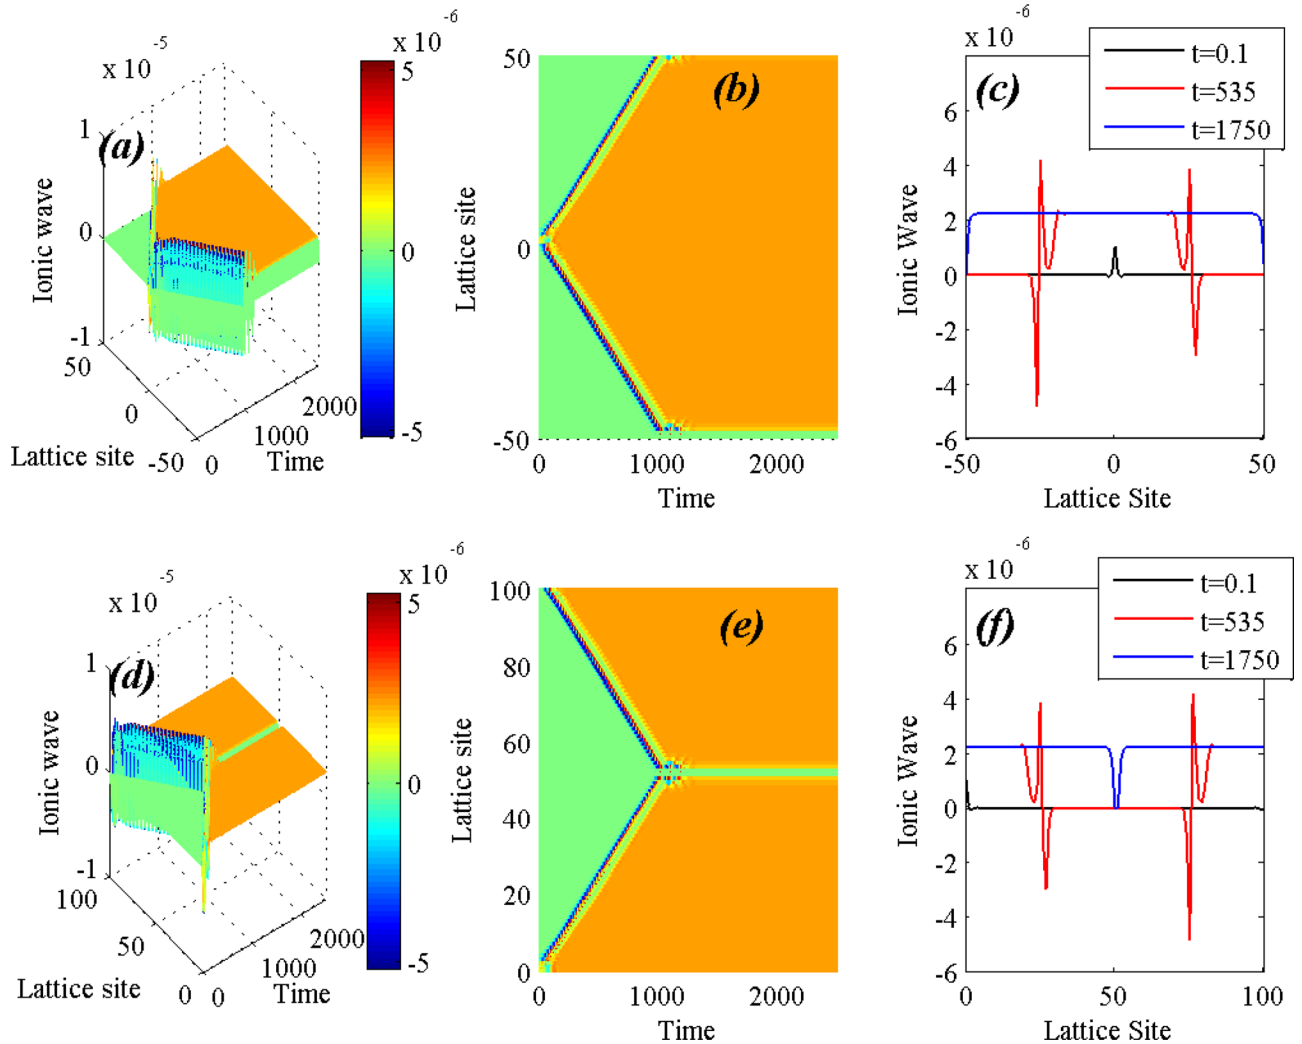

FIG. 11. Ionic waves solutions of the discrete voltage equation (4). The *upper figures* show a Bi-pulse solution travelling in opposite directions, yielding after collision, a stationary dark soliton. (a) Three-dimensional spatiotemporal evolution, (b) upper view, and (c) profiles at three different times. The parametric values are $\gamma_0 = 0.0$, $\Omega^2 = 0.0049$, $\eta_1 = 0.09$, $\eta_2 = 10^9$, $\gamma_1 = 40000$, $\gamma_2 = 5.0$, $\delta = 0.1$, $\lambda = -1.0$, and $D_0 = 0.0024$. The *lower figures* (d), (e), and (f) depict a rotation of the cyclic lattice observed in the upper figure in order to clearly highlight the collision process of the two pulses and the emergence of the dark soliton.

11(d)–11(f) show a rotation of this large cyclic network in order to underscore the formation of the dark soliton in the lattice, after the collision process of the two propagating pulses has taken place.

Third, in other parametric conditions, Fig. 12 shows that the two pulses, as they propagate through the spatial domain, leave behind them a permanent deformation of the lattice that leans toward generating a spatially inhomogeneous stationary pattern, in the form of stripes disseminated all over the spatiotemporal domain. Figures 12(a)–12(e) depict the three-dimensional spatiotemporal evolution of the travelling ionic waves, its upper view, and the profiles of the lattice at four different times, respectively. It is important to note here that after the collision, the two pulses annihilate each other.

Therefore, the aforementioned facts stress the existence, prior to the collision process, of a robust bisoliton solution propagating along the biochemical medium.

Furthermore, in cellular automata, the state of a particular cell in the next time steps depends on the state of the cells around it (that is its neighbors) at current time. The Greenberg-Hasting cellular automaton, for instance, can be conveniently used to model the excitability of heart tissues.[46] In general, it is well known that each cell can be in one of the following states: quiescent (or excitable) state, excited state, or refractory state. In the last case, the cell has recently been excited and is temporally not excitable. This refractory cell possesses a refractory period which is lessened at the next time step, until it reaches the end of the refractory period and becomes excitable once more. Thus, the refractory period is indeed the time interval elapsed between the time step that follows the onset of excitation, and the time step at which the cell returns to a quiescent state, when it becomes excitable again. At this stage, we numerically assess this refractory period in the context of our work. For this purpose, we select a specific cell, namely, the cell at location $n = 25$ and numerically compute its refractory period on the basis of its local dynamics as highlighted in Fig. 13.

Indeed, based on its time series observed in the same parametric conditions as in Fig. 10, we obtain a refractory period of 372.1 time units whose span is indicated by the double arrow (Magenta online). It is noteworthy that in the

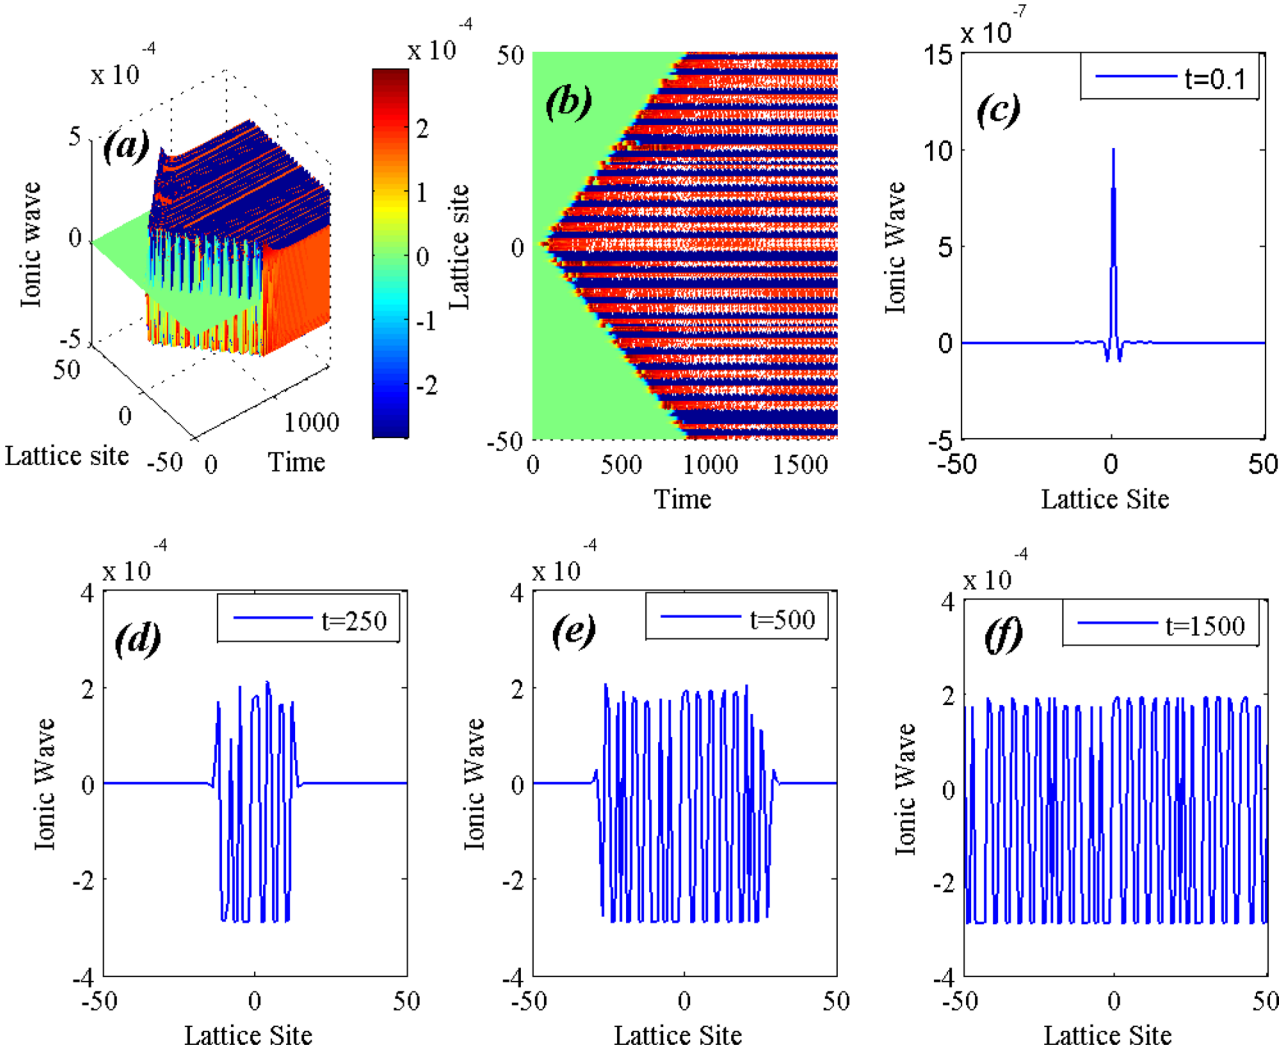

FIG. 12. Ionic waves solutions of the discrete voltage equation (4). Bi-pulse propagation, generating the emergence of a spatially inhomogeneous stationary pattern along the lattice. (a) Three dimensional spatiotemporal evolution of the bi-pulse; (b) upper view of the propagating phenomenon; (c)–(f) snapshots of the structure of the lattice at different times. The parametric values are $\gamma_0 = 65.0$, $\Omega^2 = (2.85)^2$, $\eta_1 = 0.09$, $\eta_2 = 10^8$, $\gamma_1 = 4000$, $\gamma_2 = 5.0$, $\delta = 0.1$, $\lambda = -1.0$, and $D_0 = 0.0024$.

parametric conditions of Fig. 12, this same value of the refractory period was retrieved. This fact appears to be logical due to the fact that we assumed from the onset that our lattice is made up of identical dynamical units. Therefore, based on these facts, the minimum time interval needed for any dynamical unit along our biological lattice to regain its excitability subsequent to the onset of its excitation is about 372.1 time units.

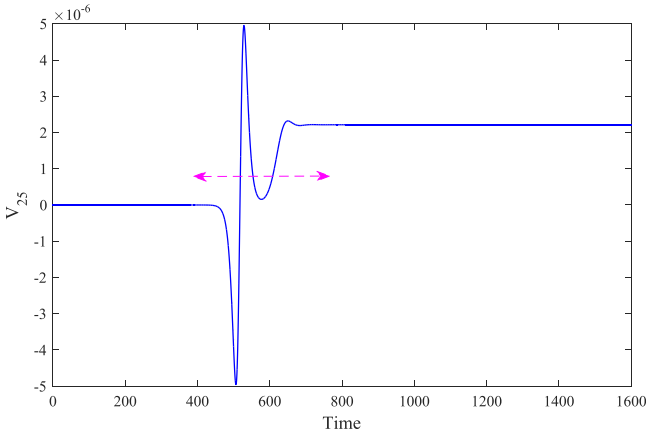

FIG. 13. Local time series of the dynamical unit at location $n = 25$, indicating the refractory period of the lattice found to be approximately 372.1 time units. The parametric conditions are the same as in Fig. 10.

At this point of our numerical analysis, it becomes obvious that our biological system, via its electrical model of microtubule, is resiliently qualified to uphold nonlinear localized waves of excitation. This predisposition to excitability has thoroughly been proven both analytically and numerically.

VI. CONCLUSION

Excitable media are widely spread amid biological systems. They include among others, the heart, the muscular tissues, and the neural networks. In this work, we have studied the capability of the inner part of a microtubule, namely, a protofilament, to behave like an excitable structure. For this purpose, we have proposed an electrical model mimicking the behavior of a microtubule protofilament, with strongly nonlinear resistive elements. Based on this model, we could derive the discrete equation of evolution of the voltage

stimulus urging the calcium ions to flow both within the medium and in between the microtubules. We showed that this equation of motion could be reduced to a *CGLE* describing the dynamics of the amplitude of the ionic wave. An analytical and numerical treatment of this equation indicates that its plane waves solutions are continually unstable, thereby depicting the propensity of our biological milieu to favor the emergence of modulated amplitude waves. These localized modes incorporate both stationary and travelling bright solitons, bi-solitons, and dark solitons. We could equally notice the accessibility of our array of biochemical units to some stationary homogeneous and inhomogeneous spatial patterns.

Microtubule model for excitability was originally proposed for wireless communication in the brain, where microtubules at the axon initial segment may serve as the receiving antennas for converting electromagnetic waves into neuronal excitability.[21] Some investigators hypothesized that reducing the number of microtubules with general anesthetics,[22] colchicine,[23] or other antimitotic drugs[24] suppressed the ability of nerve cells to produce action potentials. In this case, the states of excitability analysed indicate that microtubules possess a high degree of complexity, peculiar to many nonlinear biological systems, and it plays a crucial role in the processes underlying the mechanisms of information processing and transmission in living beings at the subcellular scale.

(Received 25 January 1993)

A model is presented that is intended to provide a realistic physical picture of the energy-transfer mechanism in cell microtubules. A classical ϕ^4 model in the presence of a constant electric field is used as a conceptual basis. It is demonstrated that kinklike excitations arise as a result of the guanosine 5′-triphosphate (GTP) hydrolysis and that an intrinsic electrical force may cause them to propagate along a microtubule. A discussion is given on the possible effects of these excitations on the dynamics of microtubules.

GTP binds to tubulin dimers

I. INTRODUCTION

The interiors of biological cells are structurally and dynamically organized through the presence of networks of interconnected protein polymers. These networks are referred to as the cytoskeleton due to their bonelike structure. Of the various filamentary structures which comprise the cytoskeleton, microtubules (MT's) appear to be the most prominent ones. It can safely be said that MT's are ubiquitous through the entire biology [1].

Parallel-arrayed MT's are interconnected by cross-bridging proteins which are called microtubule-associated proteins (MAP's), as shown in Fig. 1. These interconnections, together with MT's, are believed to be responsible for numerous cellular activities such as growth and division, which are essential for the living state. From the characterization of structure and function, MT's appear very well suited for dynamic information processing [1–3].

MT's represent hollow cylinders formed by protofilaments aligned along their axes (see Fig. 2) and whose lengths may span macroscopic dimensions. In vivo, the cylindrical walls of MT's are assemblies of 13 longitudinal protofilaments, each of which is a series of subunit proteins known as tubulin dimers. Each tubulin subunit is a polar, 8-nm dimer which consists of two slightly different 4-nm monomers with molecular weight of 55 kilodaltons. These two constituent parts are usually called α and β tubulin. Each dimer may be physically viewed as an electric dipole $\mathbf{p}$ whose dipolar character originates from the 18 calcium ions bound within each β monomer. An equal number of negative charges required for the electrostatic balance are localized near the neighboring α monomer. Thus, MT's can be identified as an example of electret substances, i.e., oriented assemblies of dipoles. They are predicted to possess piezoelectric properties that may be quite important in their functions, especially in the very interesting assembly and disassembly behavior [4,5].

A very important role is played by guanosine 5′-triphosphate (GTP), an energy-providing analog of adenosine 5′-triphosphate (ATP) which binds to polymerizing tubulin dimers. It is a very appealing mechanism from the biochemical point of view since the order of magnitude of the energy produced is just right. The chemical reaction involved is [6] the hydrolysis of GTP, which is

$$GTP^{4-}+H_2O \rightarrow GDP^{3-}+HPO_4^{2-}+H^+ ,$$

and under normal physiological conditions approximately 10 kcal/mol (0.42 eV/molecule) of free energy is released in this reaction, where GDP denotes guanosine 5′-disphosphate. It is known that the energy produced during GTP hydrolysis is delivered to assembled MT's,

although a precise manner in which this energy is utilized is still not understood. One possible mechanism for the utilization of this form of energy is the production of coherent lattice vibrations as proposed by Fröhlich [7] and by the scores of other researchers that followed his idea of biological coherence over the past two decades. Although Fröhlich's theory has never been confirmed by experiment, we believe that the basic mechanism proposed by Fröhlich merits continued interest. Our approach in the present paper will not follow Fröhlich's theory but will be influenced to a certain degree by his ideas.

An interesting suggestion was made by Barnett [8] that filamentary cytoskeletal structures may operate much like information strings in analogy to semiconductor word processors. Barnett conjectured that MT's are indeed processing channels along which strings of information bits can move, transferring messages from place to place. In addition, within this context protofilaments could be envisaged as playing the role of parallel-arrayed memory channels. It was also suggested [2,3,9] that conformational states of tubulin dimers present within MT's may be coupled to charge or dipolar states, thereby allowing for cooperative interactions with neighboring tubulin states. Such interactions were modeled in the framework of molecular automata in which the conformational states of individual tubulin subunits represent bits of information that can change under the dynamic influence of the neighbor subunits.

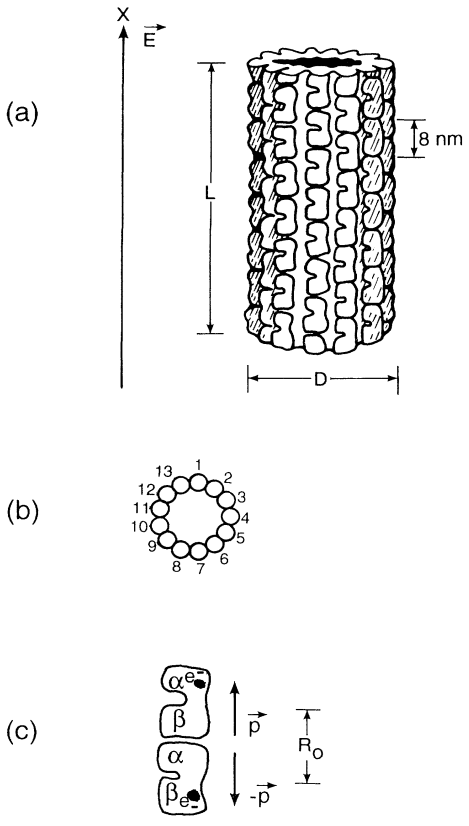

FIG. 2. (a) The structure of a microtubule, (b) its cross section, and (c) two neighboring dimers.

Another intriguing property of MT's is the process of their assembly. Since in solution containing their subunits MT's are not true equilibrium polymers, the process is rather complicated to model. Dark-field microscopy was the technique used to investigate the process experimentally [10]. It was found that when a single MT is monitored, its two ends grow at different rates. The active "+" end grows faster than the inactive "−" end. However, each end independently stops growing in a stochastic manner and then immediately begins to shorten at a high rate. After the shortening period, a microtubule suddenly stops and restarts the growth phase. A very important experimental observation was made that the presence of MAP's significantly suppresses uncorrelated phase conversions and stabilizes MT's in their growth phase.

In this paper we will put forward a theoretical model based on the creation of kinklike excitations in MT's. Their presence will be linked to GTP hydrolysis and the energy released therein. This will offer a plausible explanation of this aspect of the very complex and intriguing MT dynamics. The model proposed in this paper will also provide a starting point for the physical description of a molecular computation system.

II. THE PHYSICAL MODEL

Biological systems in general, and MT's in particular, possess a high degree of order. This is predominantly in the form of functional organization but also, to a large degree, represents spatial arrangement. One basic physical idea concerning the nature of biological order was put forward by Fröhlich [11]. Fröhlich considered an ensemble of molecular dipoles that are capable of high-frequency oscillations that can be subjected to an external electric field and allowed to strongly interact among themselves. He conjectured that, provided the supply of energy to the dipolar system exceeds a critical value, a nonequilibrium metastable state may be formed that is characterized by long-range coherence manifested by a macroscopic occupation of a single mode. An example of such a system could be the dipoles of a cell membrane in the presence of a transmembrane potential [12]. The conditions described above may also apply to the assembly of dimers within a MT which was already described as an electret. The supply of biochemical energy in the form of ATP or GTP hydrolysis may be the source of nonequilibrium excitations.

We believe that the entire MT may be viewed within the context of the Fröhlich model as a regular array of coupled dipole oscillators interacting through resonant (i.e., frequency-specific) long-range forces. Furthermore, coherent vibrations within regions of a MT may take the form of kinklike excitations (KLE's) separating adjacent regions with opposite polarization vectors. The dipole orientation is in the direction of the protofilament axis. It should be mentioned that macroscopic mobile domain structures are of great practical interest due to their potential applications as active components in optical switching and memory devices [13]. It is the number of

KLE's formed and their mobility that determine their most important characteristics, such as the switching time, effective polarization, power dissipation rate, and hysteretic behavior.

In the physical model that is put forward here, the basic argument is that the MT system has a strong uniaxial dielectric anisotropy so that the array of dipole oscillators can be effectively described in terms of only one degree of freedom. In fact, experiments showed [14] that tubulin undergoes a conformational change induced by the GTP-GDP hydrolysis in which one monomer shifts its orientation by 29° from the dimer's vertical axis. Thus, we deduce that the single degree of freedom retained in our description (analogous to Landau's order parameter; see Ref. [15]) is the projection on the MT cylinder's axis of the monomer's displacement from its equilibrium position. The inherent symmetry of a MT enables one to view them as nearly perfect one-dimensional crystals.

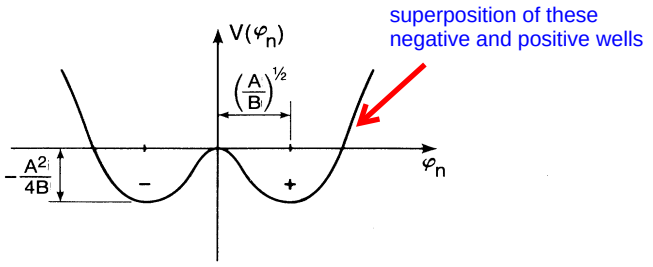
In this paper we intend to describe the nonlinear dynamics of dimer dipoles in one protofilament of a MT in terms of the well-known double-well potential model. This approach has been proven extremely useful in the physics of bistable molecular systems [16]. Its successes in other related areas, for example in the description of dipolar excitations in ferroelectrics [17], are widely acknowledged. The essential argument in favor of introducing the double-well model stems from the fact that the longitudinal projection of the dimer displacement interacts with the rest of the lattice through a mean-field force due to an anharmonic crystal-field potential. A similar inorganic ferroelectric, i.e., antimony sulphoiodide (SbSI), possessing a filamentary structure with parallel filaments [18], has been also analyzed in a similar manner.

The overall effect of the surrounding dipoles on a chosen site n can be qualitatively described by the double-well quartic potential

f(x)=ax^4+bx^3+cx^2+dx+e is a quartic equation

$$V(u_n) = -\tfrac{1}{2}Au_n^2 + \tfrac{1}{4}Bu_n^4 \ , \tag{2.1}$$

where u_n is the longitudinal displacement of the nth dimer, A and B are model parameters such that $B>0$ and is temperature independent, while A is typically a linear function of temperature that may change its sign at an instability temperature T_c, i.e., $A \cong \alpha(T-T_c)$. With $\alpha>0$, below T_c $A>0$ and $u_n=0$ is a maximum of the potential such that $V(0)=0$. Two symmetric local minima exist at $u_n=\pm\sqrt{A/B}$ for which $V_{\min}=-A^2/4B$. This is illustrated in Fig. 3. The anharmonic potential discussed here is meant to approximate the average effect due to the environment when all the neighboring dimers assume their equilibrium positions. As shown in Fig. 4, the mobile electron on each dimer can be localized either more toward the α monomer or more toward the β monomer. The latter possibility is associated with changes in dimer conformation. Experimental evidence indicates [14] that a conformational distortion of 29° from vertical occurs in the β state. We, therefore, identify the variable u_n with the amount of β-state distortion when the latter is projected on the vertical axis.



superposition of these negative and positive wells

FIG. 3. The double-well on-site potential of Eq. (2.1).

This equilibrium being affected by ATP or GTP hydrolysis

In the next step of developing our model, account is taken of the experimental fact that the MT cylinder taken as a whole represents a giant dipole. When the cross section of a MT is viewed using electron microscopy, the outer surfaces of a MT are surrounded by a "clear zone" of several nm which apparently represents the oriented molecules of cytoplasmic water and enzymes [19]. This could be explained by the presence of an electric field produced by a MT. Therefore, we assume that, together with the polarized water surrounding it, a MT generates a nearly uniform intrinsic electric field parallel to its axis (see Fig. 2). Consequently, the additional potential energy due to this electric field and associated with each dipole is

$$V_{\rm el} = -cu_n \ , \quad c=qE \ , \tag{2.2}$$

where q denotes the effective mobile charge of a single dimer and E is the magnitude of the intrinsic electric field.

We are now in a position to write the model Hamiltonian for a microtubule. It can be given as

$$H=\sum_{i=1}^{N}\left[\frac{1}{2}M\left[\frac{du_n}{dt}\right]^2+\tfrac{1}{4}K(u_{n+1}-u_n)^2-\frac{A}{2}u_n^2 + \frac{B}{4}u_n^4-cu_n\right] . \tag{2.3}$$

The first term above represents the kinetic energy associ-

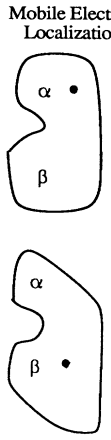


FIG. 4. An illustration of switching between conformational states (α and β) in microtubule dimers.

ated with the longitudinal displacements of constituent dimers, each of which has mass M. The second term arises from the restoring strain forces between adjacent dimers in the protofilament. If the stiffness parameter K is sufficiently large (so that the intersite strain energy exceeds the depth of the on-site potential well: $-A^2/4B$), then it is expected that large-amplitude long-wavelength excitations of the displacement field will be formed. They will be manifested by a slowly varying modulation of u_n along the MT axis.

In order to derive a realistic equation of motion for this system, it is indispensable to include the viscosity of the solvent and introduce the associated damping force. Assuming for simplicity that the solvent is made up of only water molecules, we may infer the following properties [20]:

(i) The dipolar water molecules will have a very significant effect on the long-range electrostatic energy between the dimer dipoles.

(ii) Water will provide a viscous medium that will damp out vibrations of dimer dipoles.

The first effect has already been mentioned, and it can be accounted for by an appropriate choice of the model parameters, especially by an inclusion of the dielectric constant. The second effect can be simply taken into account by adding the viscous force to the equation of motion with

$$F_v=-\gamma\frac{\partial u_n}{\partial t}\ , \tag{2.4}$$

where γ represents the damping coefficient that will be estimated in the next section. We are now in a position to obtain and analyze the relevant equation of motion for the displacement field.

III. THE EQUATION OF MOTION

Based on our assumption that the dipolar oscillations of dimers within a MT form a system that can be classified as displacive ferrodistortive, we can use the continuum approximation whereby

$$u_n(t)\rightarrow u(x,t) \tag{3.1}$$

and

$$u_{n+1}(t)\rightarrow u(x,t)+R_0\frac{\partial u(x,t)}{\partial x}+\tfrac{1}{2}R_0^2\frac{\partial u^2(x,t)}{\partial x^2}+\cdots\ , \tag{3.2}$$

where R_0 represents the equilibrium spacing between adjacent dimers.

An equation of motion for dipolar oscillations can be now derived using the Hamiltonian of Eq. (2.3), applying the continuum limit of Eqs. (3.1) and (3.2) and adding the viscous force of Eq. (2.4) to the thus-obtained Euler-Lagrange equation. We therefore find that

$$M\frac{\partial^2 u}{\partial t^2}-KR_0^2\frac{\partial^2 u}{\partial x^2}-Au+Bu^3+\gamma\frac{\partial u}{\partial t}-qE=0\ . \tag{3.3}$$

Note that the x coordinate is along the protofilament axis. Moreover, for longitudinal sound waves the dispersion relation $\omega=\sqrt{K/M}$ can be used to identify the sound velocity with $v_0=\omega R_0=\sqrt{K/M}R_0$.

We now seek solutions of Eq. (3.3) in the traveling-wave form where the moving coordinate ξ is given by

$$\xi=\left[\frac{|A|}{M(v_0^2-v^2)}\right]^{1/2}(x-vt)=\alpha(x-vt)\ , \tag{3.4}$$

where v denotes the propagation velocity and the coefficient α is, of course,

$$\alpha=\left[\frac{|A|}{M(v_0^2-v^2)}\right]^{1/2}\ . \tag{3.5}$$

Consequently, Eq. (3.3) is reduced to the ordinary differential equation below:

$$M\alpha(v^2-v_0^2)u''-\gamma\alpha u'-Au+Bu^3-qE=0\ , \tag{3.6}$$

where $u'\equiv du/d\xi$. This is an equation for an anharmonic oscillator with linear friction, and a recent paper [21] was devoted to describing is analytical solutions, one of which will be discussed shortly. In addition, Lal [22] discussed a similar problem concerning the existence of kink solutions when friction is present and emphasized its importance in biological applications.

For the sake of convenience we now introduce a normalized displacement field as

$$\psi(\xi)=u(\xi)/\omega\ , \tag{3.7}$$

where the normalizing coefficient $\omega=\sqrt{|A/B|}$ corresponds to the minimum of the double-well potential in Eq. (2.1). The dimensionless equation of motion now takes the form of the ordinary differential equation below:

$$\psi''+\rho\psi'-\psi^3+\psi+\sigma=0\ , \tag{3.8}$$

where we have used the symbols

$$\rho=\gamma v[M(v_0^2-v^2)|A|]^{-1/2} \tag{3.9}$$

and

$$\sigma=q\sqrt{B}\,|A|^{-3/2}E\ . \tag{3.10}$$

It has been shown [17] that Eq. (3.8) has a unique bounded solution which is given by the formula (and illustrated graphically in Fig. 5)

$$\psi(\xi)=a+\frac{b-a}{1+\exp(\beta\xi)}\ , \tag{3.11}$$

where

$$\beta=(b-a)/\sqrt{2} \tag{3.12}$$

and the parameters a, b, and d satisfy the cubic equation

$$(\psi-a)(\psi-b)(\psi-d)=\psi^3-\psi-\sigma\ . \tag{3.13}$$

It is important to note that the above kinklike solution propagates along the protofilament with a fixed velocity

$$v=v_0\left[1+\frac{2\gamma^2}{9d^2Mv_0^2}\right]^{-1/2}\ . \tag{3.14}$$

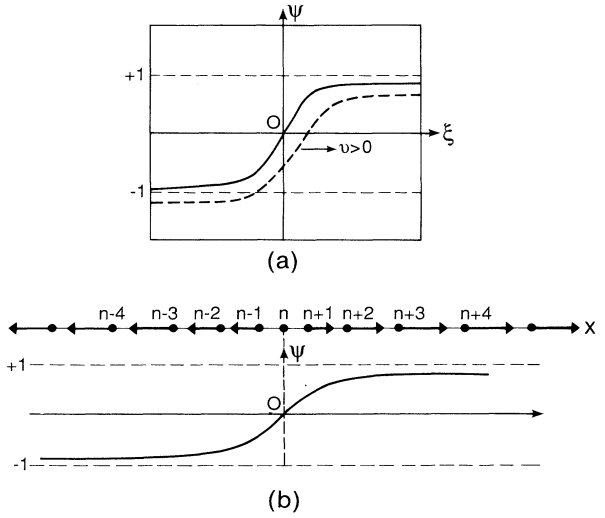

FIG. 5. The form of a kinklike excitation of Eq. (3.11).

This velocity is less than the sound velocity v_0 and it obviously decreases with an increase of the friction coefficient γ. It is clear that v depends on the magnitude of the electric field E through the parameter d. The dependence of d on E is not very simple, since it involves the cubic equation (3.13). However, for $T<T_c$ and large fields E, we know that $d\sim E^{1/3}$, while for small fields $d\sim\psi_0+\lambda E$, where $\psi_0=\pm 1$ is the mean-field solution for $E=0$ and λ is a constant coefficient. In order to gain a more quantitative understanding of this result, we now wish to estimate the magnitude of the intrinsic electric field E in the protofilament. To this end, we assume that the length of a MT, L, is much greater than the diameter D, $L\gg D$. Hence, for points along the protofilament that are sufficiently removed from its ends, the magnitude of the electric field can be approximated simply as

$$E\cong\frac{Q}{4\pi\epsilon_0 r^2}\ , \tag{3.15}$$

where Q represents the effective charge on the ends of the hollow cylinder and r is the distance between the selected point and the end of the protofilament.

Taking, as an example, a moderately long MT consisting of approximately 10^2 dimers gives $L\sim 10^{-6}$ m. Then the effective charge Q consists of 2×13 protofilament end dimers, each of which has a charge of $18\times 2e$ due to the presence of 18 Ca^{2+} ions. Consequently, $Q\cong 26\times 36e\cong 9.4\times 10^2 e$ with $e=1.6\times 10^{-19}$ C. Therefore, the field in the vicinity of the middle point on the protofilament is found to be on the order of $E\sim 4\times 10^6$ V/m. Taking into account the dielectric effects of the surrounding water molecules, this value must be reduced by almost two orders of magnitude to approximately $E\sim 10^5$ V/m. As shown in Fig. 6, the magnitude of the electric field $E(x)$ sharply increases as we approach the end points.

Unfortunately, no reliable experimental data exist at present regarding the values of the potential coefficients

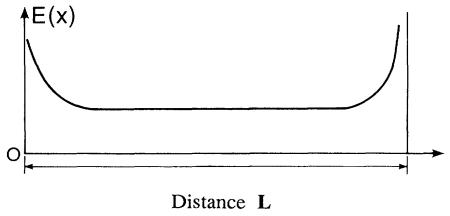

FIG. 6. Plot of the intrinsic electric-field distribution along the MT axis.

A and B or indeed whether the form of our potential is suitable. In principle, at least, neutron-scattering experiments should provide a dynamic structure factor for microtubules which could be used for modeling purposes in a manner similar to that used for ferroelectrics [23]. In the absence of any hard data for MT's we can use some typical values for crystalline ferroelectrics, knowing that they do not vary substantially between different compounds. For example, the well-studied [23] ferroelectric $Pb_5Ge_3O_{11}$ has been demonstrated to support the formation of kinklike domain walls. There, $A(T)=\alpha(T-T_c)$ with $\alpha=10^2$ J m^2 and $B\cong 1.6\times 10^{24}$ J m^{-4}, while $T_c\cong 500$ K. Assuming that the critical temperature T_c for MT's is in the room-temperature range or somewhat above it, we take $T_c\sim 320$ K and estimate that in the room-temperature region

$$A(T=300\text{ K})\cong 200\text{ J m}^{-2}\ ,\quad B\cong 10^{24}\text{ J m}^{-4}\ . \tag{3.16}$$

Thus, with the parameter values obtained in this section we find

$$\sigma\simeq 2\times 10^{-9}E\ . \tag{3.17}$$

It is, therefore, clear that even for very strong electric fields ($E\sim 10^8$ V/m) the inequality $\sigma\ll 1$ holds right up to the protofilament ends. Under these circumstances we can safely approximate the KLE of Eq. (3.11) as

$$\begin{aligned} u(\xi)&=u_0\left[1-\frac{\sigma}{2}-\frac{2}{1+\exp(\sqrt{2}\xi)}\right] \\ &\cong u_0\left[1-\frac{2}{1+\exp(\sqrt{2}\xi)}\right]\ , \end{aligned} \tag{3.18}$$

where the amplitude of the dimer displacement field has the value $u_0=\sqrt{|A|/B}\cong 1.4\times 10^{-11}$ m. Let us now assess other consequences of smallness of the electric field. First, the propagation velocity of a KLE is approximated (for T well below T_c and large values of γ) as

$$v\cong\frac{3v_0}{\gamma|A|}\left[\frac{MB}{2}\right]^{1/2}qE \tag{3.19}$$

and it is generally much smaller than the sound velocity ($v\ll v_0$). Equation (3.19) can be interpreted as a linear response between the propagation velocity v and the magnitude of the electric field E. The coefficient of proportionality in this relationship represents the KLE mobility

$$\mu \cong \frac{3v_0}{\gamma |A|} \left[\frac{MB}{2} \right]^{1/2} q \ . \tag{3.20}$$

In order to evaluate the magnitude of μ we require an estimate of the damping coefficient γ. To do so we will use simple fluid mechanic arguments. First of all, note that each dimer can be roughly viewed as a sphere of mass M. Then, using the well-known result for a sphere of radius R moving through fluid with velocity du/dt, the drag force exerted by the fluid on the sphere is

$$F_d = -6\pi R \eta \frac{du}{dt} = -\gamma \frac{du}{dt} \ , \tag{3.21}$$

where η is the absolute viscosity of the fluid. In our case, the fluid is assumed to be water and its viscosity is temperature dependent. However, at physiological temperatures (~ 300 K) we take

$$\eta \cong 7 \times 10^{-4} \text{ kg m}^{-1} \text{s}^{-1} \ . \tag{3.22}$$

Substituting $R \cong 4 \times 10^{-9}$ m into Eq. (3.21) we obtain

$$\gamma \cong 5.6 \times 10^{-11} \text{ kg s}^{-1} \ . \tag{3.23}$$

The last quantity required in our estimate is the sound velocity v_0. The experimental results [24] of v_0 for DNA produced the value

$$v_0 = 1.7 \times 10^3 \text{ m/s} \ . \tag{3.24}$$

Finally, then, putting $M = (55 \times 10^3) \times (2 \times 10^{-27})$ kg $\cong 1 \times 10^{-22}$ kg and $q = 18 \times 2 \times (1.6 \times 10^{-19})$ C $\cong 6 \times 10^{-18}$ C, Eq. (3.21) yields

$$\mu \cong 2 \times 10^{-5} \text{ m}^2 \text{ V}^{-1} \text{s}^{-1} \ . \tag{3.25}$$

Thus, taking $E = 10^5$ V m^{-1} as a representative average value of the electric field, the propagation velocity of a KLE is on the order of

$$\bar{v} \cong 2 \text{ m/s} \ . \tag{3.26}$$

However, in close proximity of MT ends E may reach 10^7 V m^{-1} and, consequently, the KLE may accelerate up to $v \sim 10^2$ m/s.

Assuming a smooth journey from one end of the protofilament to the other, we estimate the average time of propagation for a single KLE to be

$$\bar{\tau} = L/\bar{v} \cong 5 \times 10^{-7} \text{ s} \ . \tag{3.27}$$

However, increasing the length of the protofilament will increase $\bar{\tau}$ on two accounts: (a) increasing the numerator in Eq. (3.27), and (b) affecting the mean velocity through the dependence of the electric field on L. Indeed, $E \sim L^{-2}$ and hence $\bar{v} \sim L^{-2}$. Consequently,

$$\bar{\tau} \sim L^{+3} \ , \tag{3.28}$$

leading to a rapid increase of $\bar{\tau}$ with L.

While the model presented here is very closely related to the one developed by Collins *et al.* [17] for ferroelectrics, we should mention that the effects of discreteness of the lattice may play an important role. For example, Kimball's analysis [25] of kink dynamics for a discrete lattice indicates that there may exist a threshold value of the external field required to sustain kink motion. Moreover, it appears that fast-propagating kinks are more stable than slow ones. Similar conclusions were obtained by Sánchez and Vázquez [26], who studied the propagation of topological kinks in a stochastically perturbed ϕ^4 model. Their numerical simulations confirmed the conclusion that for all noise strengths studied slow kinks were more affected by the perturbation than fast ones. Finally, in this context, Combs and Yip [27] demonstrated that discreteness of the lattice may be accommodated by continuous equations of the form in Eq. (3.3) by adding higher powers of the time derivative of the field, i.e., terms like $(\partial u/\partial t)^2$. A general discussion on the propagation and stability of kinks and their generalizations in dissipative nonlinear models can be found in Ref. [28].

IV. STATISTICAL PROPERTIES OF THE KLE ENSEMBLE

It is well known that extra energy is required in order to create a kink, since kinks are not solutions of the equation of motion with the lowest energy. Thus, outside the immediate proximity of the critical temperature T_c, kinks are not easily formed. Due to their topological stability, however, they are not readily destroyed once they are formed. An injection of energy into the system in the form of incoherent pulses of electromagnetic radiation is expected to stimulate kink creation. This extra energy can be produced, for example, during the hydrolysis of ATP or GTP, as was already mentioned in this paper. Due to their mutual repulsion over short distances, the number of KLE's formed is limited from above.

In order to formulate a statistical description of an ensemble of KLE's we must first calculate the energy of a single kink. This is found by substituting the displacement field solution of Eq. (3.18) into the model Hamiltonian of Eq. (2.3) so that

$$E = \frac{1}{R_0} \int_{-\infty}^{+\infty} dx \, H(x,t) \ , \tag{4.1}$$

and we find

$$E = \frac{2\sqrt{2}}{3} \frac{A^2}{B} + \frac{\sqrt{2}}{3} K \frac{A}{B} + \frac{1}{2} \left[\frac{4}{3\sqrt{2}} \frac{MA\alpha}{R_0 B} \right] v^2 \ . \tag{4.2}$$

The first term in the formula above represents the well-known binding energy of a KLE. Its magnitude is much greater than that of the remaining two, being on the order of 1 eV. The second term in Eq. (4.2) corresponds to the resonant transfer of energy responsible for the propagation of KLE's along the MT. The third term is the classical kinetic energy of a KLE, which can be expressed as

$$E_k = \tfrac{1}{2} M^* v^2 \ , \tag{4.3}$$

where the effective mass M^* is

$$M^* = \frac{4}{3\sqrt{2}} \frac{MA\alpha}{R_0 B} \ . \tag{4.4}$$

Thus, the total energy can be rewritten more compactly

as

$$E=\Delta+\tfrac{1}{2}M^*v^2 , \tag{4.5}$$

where

$$\Delta=\frac{2\sqrt{2}}{3}\frac{A^2}{B}\left[1+\frac{K}{3A}\right] . \tag{4.6}$$

Using the same set of parameters as before, including the DNA value for K ($=32\ \mathrm{N\,m^{-1}}$), we obtain the following estimates for a MT:

$$\begin{aligned}&\frac{2\sqrt{2}}{3}\frac{A^2}{B}\cong 0.4\times 10^{-19}\ \mathrm{J} ,\\ &\frac{\sqrt{2}}{3}K\frac{A}{B}\cong 0.3\times 10^{-20}\ \mathrm{J} ,\\ &M^*\simeq 5\times 10^{-27}\ \mathrm{kg} .\end{aligned} \tag{4.7}$$

This estimate appears to indicate that thermal energy is insufficient to create a significant number of KLE's. Thus, we must seriously consider the hydrolysis of GTP from the surrounding medium (or injection of energy pulses of another type) as a main potential source of KLE formation. At normal concentrations of attached GTP molecules one expects a few KLE's to be generated so that their mean separation by far exceeds their width. In this regime, KLE's can be viewed as a gas of weakly interacting quasiparticles whose velocities are thermalized.

In the following we provide a more quantitative statistical calculation [29] intended to demonstrate that thermal generation of KLE's is negligibly small. The partition function for a single KLE with a number of available momenta p is

$$Z=\frac{1}{D}\int_0^L dx\int_0^{M^*v_0} dp\,\exp(-\beta E) , \tag{4.8}$$

where D is a normalization constant, $d\Gamma=dx\,dp$ is an element of the phase space, $p=M^*v$ is the momentum of one KLE, and $\beta=(k_BT)^{-1}$, where k_B is the Boltzmann constant and T is the absolute temperature. In order to calculate the mean number of KLE's, we first define the grand partition function Ξ as

$$\Xi\equiv\sum_{i=1}^{\infty}\frac{1}{i!}Z^i\exp(i\beta\mu)=\exp[Z\exp(\beta\mu)] , \tag{4.9}$$

where Z^i is an i-particle partition function and μ is the chemical potential. Then, standard thermodynamic relations give

$$F=-k_BT\ln\Xi , \quad \langle n\rangle=-\frac{\partial F}{\partial\mu} , \tag{4.10}$$

and the mean number of KLE's is found as

$$\langle n\rangle=Z\exp(\beta\mu) . \tag{4.11}$$

The mean density of KLE's in the MT is their number per unit length, i.e.,

$$\begin{aligned}\rho_0&\equiv\frac{\langle n\rangle}{L}\\ &=\frac{1}{D}\left[\frac{M^*}{2\beta}\right]^{1/2}\mathrm{erf}\left[v_0\left[\frac{M^*\beta}{2}\right]^{1/2}\right]\exp\left[\frac{\mu-\Delta}{k_BT}\right] ,\end{aligned} \tag{4.12}$$

where erf( ) denotes the error function which stems from the p integration in Eq. (4.8). However, the most important factor in Eq. (4.12) is $\exp(-\Delta/k_BT)$, since at room temperature $\Delta\simeq 0.2$ eV, $k_BT\cong 0.02$ eV, and the expression for ρ_0 is *reduced* by a factor of e^{10}. This fully supports our earlier predictions and also agrees with the results of Koehler *et al.* [30].

Finally, the thermodynamic equation of state for an ensemble of KLE's on a MT can be found as

$$\lambda L=\left[\frac{Z}{\beta}\right]\exp(\beta\mu)=\langle n\rangle k_BT , \tag{4.13}$$

where λ is the uniaxial stress on the MT. This result takes the form of an ideal-gas equation relating the space occupied by KLE's with the magnitude of the electric field that influences the value of the chemical potential. This is consistent with the emergence of piezoelectric properties of MT's.

V. SUMMARY AND CONCLUSIONS

This paper provided a general biophysical picture regarding the structure and function of microtubules. A physical model has been developed based on nonlinear dipolar excitations. Although this is but a first step in the direction of quantitative modeling of microtubular behavior, we believe that it will be very useful in future investigations. The basis of our model has been the approach due to Collins *et al.* [17] that has proved very useful in ferroelectric and ferroelastic applications. In our model, we have assumed the existence of an intrinsic electric field in MT's and included its interactions with dipolar oscillations in the constituent dimers. Lastly, the presence of the surrounding water molecules has been accounted for by the addition of an effective viscous force that opposes the motion of dimers in an aqueous environment. We have estimated the required model parameters using available experimental data.

Our main result is that a unique kinklike excitation exists which may propagate with a unique velocity that, in the given range of parameters, is proportional to the magnitude of the electric field E. We predict that these excitations may be observed experimentally, for example, through neutron-scattering and polarization experiments. In the past, somewhat similar ferroelectric materials possessing filamentary structure [23] (e.g., Sb-Si) have been precisely analyzed using light-, neutron-, and x-ray-scattering data [31,32].

Although quantitative experimental evidence to support our model appears rather tenuous at present, there are a number of facts that are consistent with the qualitative features of our approach. For example, the observed growth rates of MT's are different at both ends in spite of

an identical concentration of the surrounding monomers. This can be explained on the basis of the following argument. We assume that KLE formation is mainly due to the hydrolysis of GTP into GDP so that one act of hydrolysis corresponds to the conformational change resulting in the formation of a single KLE. However, a KLE is preferentially oriented towards the direction of the intrinsic electric field. The propagation of a KLE will then distribute the energy of hydrolysis at the preferred end of a MT. This energy will then be used to detach dimers from the MT. This picture is in accordance with a hypothesis put forward in a recent paper by Krischner and Mitchison [33], who stated that on-rate (growth) is limited in principle only by the rate of diffusion of the monomer subunits into the MT polymer (i.e., by the concentration of the constituent monomers in solution). On the other hand, the off-rate (depolymerization) can be extremely rapid and the net amount of MT polymer formed can be regulated independently by the hydrolysis of GTP. Our model can be especially useful in the explanation of a peculiar dynamical effect known as "treadmilling." In it, the "+" end grows at the same rate as the "−" end shortens so that the overall length of the MT remains constant under the condition of constant temperature and concentrations. See Fig. 7 for an illustration of this process.

It is reasonable to expect that at the onset of the MT assembly process, when MT's are very short, the formation of KLE's is very unlikely (or even impossible), since for a short chain the displacement field gradient required would be very high and the associated energy to form it prohibitively large. However, when the length of a MT reaches a threshold value, kink formation could become a real possibility. Excitation of kinks, being related to GTP hydrolysis, would become dependent on the GTP concentration. As MT's become longer, KLE propagation becomes an important new factor, and it introduces disassembly at the "−" end, whose rate is proportional to the rate of KLE's arriving per unit time at the "−" end.

It has been emphasized [33] that the existence of a so-called "cap" of dimers containing GTP near the "+" end is a factor stabilizing the growth of GTP. If dimers within this cap do not hydrolyze, the growth of a MT is maintained. However, an intensive hydrolysis of this cap is a trigger mechanism for the disassembly of MT's occurring at *both* ends. We also attribute this instability to the energy transfer through KLE's, since the probability of a growing MT to start shrinking is thought to be governed by the stochastic loss of the fluctuating GTP cap.

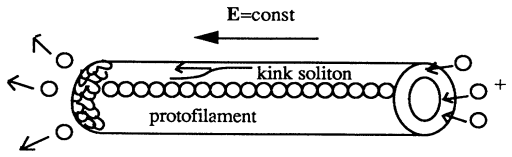

FIG. 7. Schematic representation of the "treadmilling" process involving tubulin dimers of a microtubule which takes place at the (−) end with disassembly and at the (+) end with assembly.

We have seen in our model that the intrinsic electric field governs the rate of propagation of KLE's. By adding an external electric field to the Hamiltonian we can introduce a new control mechanism in the MT dynamics. An applied electric field will result in a faster-moving population of KLE's and thus a greater stability against thermal fluctuations; if, on the other hand, the intrinsic and applied electric fields are oriented in opposite directions, then KLE's motion may be slowed down or stopped altogether. This then can be seen as a basis for treating MT's as artificial information strings. Each KLE within a MT can be viewed as a bit of information whose propagation can be controlled by an external electric field.

Another important experimental fact is that stability of MT's is greatly enhanced by the presence of lateral cross-bridging proteins (MAP's). From the physical point of view, these bridges represent lattice impurities in the MT structure. Interactions between solitonlike pulses and impurities have been studied very extensively in the pst few years. It was demonstrated that impurity modes play an important role in soliton propagation. In particular, kinks may be totally reflected by an attractive impurity if their velocities lie in specific resonance velocity "windows" [34]. Hence, if the velocity of KLE's lies within such a "window," the rate of arrival of KLE's at the "−" end will decrease or even stop as the number of MAP's increases. This mechanism can lead to a significantly reduced rate of MT disassembly. This mechanism together with a control mechanism offered by an external electric field may provide a number of interesting possibilities for information transmission and storage in MT's.

Abstract:

Investigations into the laser–Raman shift spectra of bacterial and mammalian cells have revealed that many Raman lines observed at 4–6 K, do not appear in the spectra of cells held at 300 K. At 300 K, Raman activity, at set frequencies, is observed only when the cells are metabolically active; however, the actual live cell spectrum, between 0 and 3400 cm^{-1}, has been found to alter in a specific way with time as the cells' progress through their life cycles. Lines above 300 cm^{-1}, from *in vivo* Raman active states, appear to shift to higher wave numbers whereas those below 300 cm^{-1} seem to shift to lower ones. The transient nature of many shift lines observed and the intensity of them when present in the spectrum indicates that, *in vivo*, a metabolically induced condensation of closely related states occurs at a set time in the life of a living cell. In addition, the calculated ratio between the intensities of Stokes and anti-Stokes lines observed suggests that the metabolically induced "collective" Raman active states are produced, *in vivo*, by non thermal means. It appears, therefore, that the energetics of the well established cell "time clock" may be studied by laser–Raman spectroscopy; moreover, Raman spectroscopy may yield a new type of information regarding the physics of such biological phenomena as nutrition, virus infection and oncogenesis.

Introduction

Over the past four decades investigations into the working of living cells designed to understand those special properties of matter that constitute life, have been dominated, almost exclusively, by biochemically oriented considerations. Such works, by a large number of dedicated researchers, have (a), increased our knowledge of the chemical composition of life forms; (b), unravelled the chemical structures of some large macromolecules; (c), tracked the pathways by which many components are synthesized and (d), led to the introduction of a mechanism by which the primary structure of proteins *in vivo* may be determined and the required codes handed down from one generation to the next. The sheer number of such investigations and the wealth of information they have provided, however, have tended to overshadow other types of approaches to the problem of life, and to drown the words of caution, issued from time to time, from the voices of those who have walked different paths. It is understandable, therefore, that initial ideas and theory regarding the nature of life were based on chemical concepts and the random collision kinetics of physical chemistry.

In more recent times cell biologists and geneticists have uncovered new facts which reveal the cell to be a highly ordered, dynamic entity in which the chemical events, described by the biochemists, occur in sequences of extreme precision with respect to time, place and accuracy; few mistakes, if any, are made in either of these three parameters. In addition the rates, at which the *in vivo* syntheses of macromolecules occur are several orders of magnitude faster than those performed, in the test tube, by individual components in isolation from the rest of the cell. From the standpoint of statistics and the enormous number of steps performed by a cell, in just one sequence of events, the probability of an error, if it was governed by random collision, would far exceed the small number of errors actually made. Some process exists *in vivo*, therefore, able to direct, in time and space, rapid sequential events with great accuracy, a process accredited by biologists, to the "cell time clock"; giving the phenomenon a name, however, does not provide, in any way, a clue to its mechanism.

The living cell has been found to possess unexpected electrical properties, with membrane potentials 10^7 V/M and dielectric characteristics which alter with time and nutrition, phenomena which have occupied the research efforts of some scientists over many years. It is susceptible also to injury from specific frequencies of electromagnetic radiations of extremely low photon energy, such as microwaves, by mechanisms which appear to be of a non-thermal nature [1, 2, 3, 4]. While the cell is stable and capable of extreme accuracy in its internal manoeuvres, under "normal" thermal conditions, its precision can be seriously impaired by an input of small quantities of electromagnetic energy. The livelihood of the cell thus rests heavily on the specific, yet delicately balanced, physical relationship it creates between its component parts; balances which it is able to generate and maintain sometimes in the presence of excess thermal energy.

The creation of specific states and transitions between them are known vital parts of the life process. Somehow, however, the cell is able to direct, in time and space, the occurrence of these transitions so as to extract configurational energy from its nutrients, with a minimum of loss in the form of heat or the emission of electromagnetic radiation, and produce an entity identical to itself, or one with a limited lifetime but special mission within societies of cells that make up multicellular life forms.

It is clear today that life, even in its simplest form, the cell, does not rest on the independent activities of enzymes, DNA or even membrane potentials but arises from the creation of unique complexes of macromolecules in which the chemical and physical characteristics of the individual molecules are changed and their activities integrated. It is, therefore, a collective phenomenon of enormous complexity as far as the structure and activities of its component parts are concerned, but one

which may be understood more easily perhaps, through the acquisition of knowledge regarding the physics of the phenomenon, as Fröhlich has attempted to do over the years [5, 6]. Much of the enormous effort of biochemists and cell biologists could be wasted, therefore, if physicists do not take up the challenge of ascertaining how the information supplied by these scientists may be collectively viewed in terms of energy, space, time and motion. Any physicist who does try to solve anyone of these problems, however, must keep in mind the limitations of the theories of physics based on "simple" models in which he or she has been schooled. Most, if not all of these amply apply to an individual atom or small collections of them or to collections of identical but small molecules; there is, however, no guarantee that these theories will hold true as far as the life phenomenon is concerned. Indeed, one of the excitements of such explorations is the possibility today of new physical "laws", or phenomena, being discovered via studies of the life process just as they were a century or so ago. Moreover, while it is important that the physicist acquaints himself with the fundamentals and theory of modern biochemistry and cell biology (which may seem, at first, a formidable task, although the essentials, free of intimate details, are not difficult to grasp) it is equally important that he appreciates information acquired much earlier, something which even modern biologists often fail to do. It is essential to recognize, for instance, that ever since chromosomes and the developing embryo were first viewed under a primitive microscope directed and orderly motions of macromolecular complexes and whole cells have been known to be vital parts of the life process; these activities have been given names, such as mitosis and meiosis etc., but the mechanism by which they occur remains neither explained nor covered by popular biological theory. Another feature of the cell is that simply to survive as a life form it requires no use of outside energy, inputs of thermal or electromagnetic energy can be "anti-life" but if these are avoided a cell can retain, for an indefinite period, its ability to renew its life activities if the correct environmental conditions are established. In this state of anabiosis, a condition not understood, the cell possesses, in the form of enzymes, electrical potentials, and so on, all the energy necessary to perform its tasks. It lacks only the ingredients with which to do them. If these are supplied, it simply uses its inherent energy to re-arrange the configurational energy, present in the supplied nutrients, to form a unit just like itself, or to make something other cells require. No one can say how self perpetuating systems, able to re-arrange random energy sources into identical organized systems, evolved, all that can be said today is that they exist and constitute the only method by which energy "packets" with the property of life may be reproduced. Since all the components of "ruptured" cells in a test tube will not reform into cells, it may be said safely that it takes life to create life and it is with life that we must work if we are to understand it.

In the knowledge that the cell is a special form of integrated changes in energy states transformed by metabolic processes into coherent and specific vibrations of large macromolecular complexes and mechanical motions (analogous to the crystals and cogs of a highly accurate watch) some researchers have tried to bring to bear, on the problem of understanding the energy transactions of life, new physical tools such as the laser and Raman spectroscopy. The purpose of this report, therefore, is to describe the difficulties and frustrations encountered in such endeavours and the preliminary successes achieved.

Why laser–Raman spectroscopy?

If life is to be considered a collective phenomenon and to arise from a particular way in which transitions in the states of large macromolecules are integrated then, to understand the life "force", methods must be used which will display not only the energy distribution in isolated molecules but also

how this is affected by the formation of macromolecular complexes and the presence of adjacent ones. In addition, the techniques should permit a determination of those transitions allowed and propagated *in vivo* by living entities. Some form of spectroscopy, therefore, is suggested. Many powerful tools exist such as Nuclear Magnetic (NMR) and Electron Spin Resonance (ESR) but these require, often, the addition to the system of special chemicals toxic to the living cell. The same is true of methods which employ gamma rays, X-rays and ultraviolet light, all have been, and are, invaluable techniques for molecular biology but all are lethal to life processes. To look at life the best techniques are those which do the least harm. Thus visible and infrared light appear to be the preferred probes.

Straight forward absorption spectroscopy in the visible would seem to be insufficient. Only a few biological molecules absorb in the visible and those that do usually have very specialized functions, in vision, photosynthesis and so on, and while vision is a part of some life forms it is not essential to life as such. Photosynthesis in the overall picture is essential to life on earth but it plays no direct role in the organization of animal and other heterotrophic life forms. Thus while valuable information about the above phenomenon has been obtained by such absorption techniques, the procedures have limitations which may prevent them from yielding the type of knowledge sought.

Since it is the allowed transitions in states *in vivo* about which information seems vital, infrared or Raman spectroscopy appear the methods of choice. In accordance with classical electrodynamics any motion of an atomic system involving a change in dipole moment leads to absorption, or emission, of radiation. Any vibrational motion of a molecule may be resolved into a sum of normal vibrations and, as these are simple periodic motions, the frequencies are the ones emitted or absorbed and lie in the near infrared. To be infrared active, the vibrations must be connected with a change in the dipole moment (M), so in the harmonic oscillation approximation only the fundamentals are active. In asymmetric molecules, however, every normal vibration is infrared active, only in symmetrical molecules may the change in dipole moment be zero and thus a motion be infrared inactive.

In order for a fundamental to appear as a Raman shift, the amplitude of M must change. The magnitude of the dipole moment $p = \alpha E$, where E is the electric vector of the incident radiation of frequency ν and α = polarizability. If, therefore, α changes during a vibration with a frequency ν_1, P will change with frequencies $\nu + \nu_1$, $\nu - \nu_1$ and ν. In asymmetrical molecules, all normal vibrations are associated with a periodic change in polarizability and are Raman active. From classical considerations an induced dipole moment will oscillate at frequency ν of the incident radiation (Rayleigh scattering) and at $\nu \pm \nu_1$ (Raman scattering); the vibration ν_1 will appear as a Raman shift, however, only if one of the components of the polarizability α, for the various scattering geometries, differs from zero. From classical theory, therefore, the intensity of the Raman line $\nu - \nu_1$ should equal that of the $\nu + \nu_1$.

From quantum theory the frequencies of infrared absorption and Raman shift bands are determined by the energy difference between the levels of a transition with the selection rule $\Delta\nu = \pm 1$ for each normal vibration. For molecules with a centre of symmetry infrared active transitions can occur only between states of opposite symmetry with respect to the centre of symmetry, i.e. components of M are antisymmetric but Raman active ones can occur only between states of the same symmetry. For all molecules, however, without a centre of symmetry many transitions can be both infrared and Raman active. As far as sublevels are concerned, only those of opposite parity are IR active whereas those of the same parity are Raman active. Rotational transitions follow similar selection rules in the IR, a transition can take place only if there is a permanent dipole moment and positive levels can combine only with negative ones, thus $\Delta J = \pm I$; for Raman active transitions the selection rule is $+ \leftrightarrows +$ and $- \leftrightarrows -$ and $\Delta J = 0 \pm 2$.

From the above it is clear that the wave number of IR and Raman shift bands are equal to the actual

frequencies of the movements, thus from classical and quantum theory the spectra are the same as far as position and occurrence of bands are concerned. There is, however, one important difference, classical theory suggests that the intensity of Raman bands $\nu - \nu_1$ (Stokes lines) and $\nu + \nu_1$ (anti-Stokes lines) are the same, whereas quantum theory predicts that the number of vibrations in the first state of the anti-Stokes line is only $e^{-h\nu/kT}$ times the number of vibrations in the initial state of the Stokes line (e.g. the ground state). Thus anti-Stokes lines are considerably weaker than their Stokes counterpart and are rarely seen at wave numbers above $500\,cm^{-1}$. It is this difference, therefore, that makes Raman spectroscopy more attractive for biological endeavours than infrared.

The large molecules of life systems are, in the main, linear and asymmetrical thus both IR and Raman active. The metabolically induced electronic transitions between them, *in vivo*, moreover, should involve not only changes in dipole moment but in large alterations in their amplitude, and hence polarizability; and, since it is controlled shifts in electron density which seem to control life process, such processes should exhibit Raman activity. A living system, however, it not governed by thermal equilibria as, in order for it to function, it must produce "excited" states at what must be considered to be low temperatures. An amino acid, for instance, may be produced by the chemist on refluxing certain chemicals at temperatures lethal, on microsecond exposures, to all life forms. The cell, however, produces them, at rapid rates, at very low temperatures and it does so by using the "configurational" energy present in its large organic catalysts, namely its enzymes, in place of heat. In general, heat is toxic to life forms and is a waste product of some of their internal processes. The association of even a small molecule, such as H_2O, with a macromolecule can induce enormous shifts in electron cloud densities causing severe alterations in the conformation of the macromolecule. For instance, transitions between the B and A forms of DNA are brought about by the association or disassociation of just a few molecules of H_2O to or from its outer groups [7, 8, 9]. Thus a rhythmic oscillation between the two conformations can be set up physiologically by H_2O exchange with large changes in dipole moments and their amplitudes. For a cell to "live", it has to create unstable states; a cell in thermal equilibrium, therefore, is either dormant, i.e. in an anabiotic state, or dead. The physical mechanism by which life forms perform their activities suggests, therefore, that large rhythmic shifts in the amplitudes of dipole moments of specific frequencies occur which should give rise to Raman shifts of high intensity, moreover, the population of upper states should differ from that arising from normal thermal distribution. Thus, if this is fact, then the ratio between the intensities of Stokes and anti-Stokes lines should differ from the thermal factor and anti-Stokes lines observed at higher Raman shift frequencies. Raman spectroscopy, therefore, appears to offer a greater versatility in the interpretation of the physics of life processes than infrared, although, for a full picture to be seen, both should be performed.

Experimental findings

With the advancements in laser technology laser–Raman spectroscopy has proven a powerful tool for studies in many areas of physics, chemistry and molecular biology, by which new information regarding the structure of small and large molecules has been obtained. The excellent works of experimentalists such as Yu and colleagues on the proteins of the eye [10, 11]; Hartmann [12] and Lord [13] on many proteins and nucleic acids have revealed the spectra of these molecules to be complex, reproducible and specific. Data on the spectra of isolated biomolecules [14–20] and membranes [21–25] now are abundant, but it is not, however, the purpose of this report to describe such information and interested readers are referred to the recent reviews of the subject [14–25]. It was the success of these endeavours,

nevertheless, that led the author to believe that the technique should yield new information about *in-vivo* energy states even though the spectra of whole cells, by expectation, would be extremely complex; work on the subject began, therefore, in our laboratories in 1971.

Stokes spectra

The biological models chosen initially were the microbes *Bacillus megaterium* and *Escherichia coli*, as much is known about their physiology and molecular composition. Following the procedures used by prior investigators with isolated macromolecules the microbial cells were collected and thoroughly washed in 0.85% NaCl (saline) or 0.1 M phosphate buffer (pH 6.9) (Buffer) and then used either as suspensions in saline, Buffer or H_2O or as a wet "paste". The physical equipment consisted of a high resolution Cary 82 spectrometer, a Spectra-Physics argon–ion laser and a PDB 11 minicomputer with a link to an IBM 370. The spectrophotometer possessed a multipass system, by which some ten passes of the laser beam could be focussed on a spot in the sample, and a sample chamber equipped with facilities by which the sample could be maintained at any desired temperature. The available apparatus, therefore, was of a high quality and conducive to immediate success, but this was not the case. For almost a year my colleagues and I worked with "pastes" and cell suspensions varying from 10^3 to 10^9 cells/ml but without success, the only Stokes spectrum obtained, if one could call it a spectrum, was that of water and the suspending medium which, because of its dilute nature produced only a few weak lines (fig. 1). These results were confusing, therefore, and disappointing as, from the standpoint of physics, the spectra seen, or lack of spectra seen, made little sense. The enterprise was given up, therefore, because of the belief that something was wrong with either the equipment or the techniques employed. Repeated publications in the literature of the spectra of large biomolecules prompted, however, a return to the project but again with no success.

It was our custom to discuss our failures each morning over tea and on such a morning, with the usual "Raman" run in operation, we heard a loud whistle from our recorder, a characteristic of it, even though new, when it recorded a strong line. Over the next few minutes it continued to whistle and produce a spectrum the like of which we had not seen before. A hasty reset of the instrument produced a second and a third spectrum then, disappointment, on the fourth time of asking, no lines appeared. Over the next week total failures again were experienced, but, in checking over all procedures, suspending fluids etc. it was discovered, by Mrs. Montgomery, our technician, that on the "successful" morning she had inadvertently placed the cells in a fluid containing glucose; the salts fluid used, therefore, was not a holding one as thought, but one in which the cells were able to grow. This experiment using a growth medium, therefore, was repeated and, up to a point, it was successful.

The cuvettes used were of a special kind in that, for use with the multipass system, set Brewster angles were required and only a 0.5 ml volume of sample could be employed. With any one sample in the cuvette, only two or three spectra with lines could be obtained, after this the recorded spectra became, once again, essentially devoid of lines. In addition, in the two or three runs able to be made and showing lines, the spectra were almost totally different; if aliquots of fresh cells, however, were placed in the cuvettes, renewed Raman activity was seen but again each spectrum obtained differed, in large part, from that of the others. Later experiments revealed that more spectra with lines could be achieved, with a given sample, if the laser power was reduced (but here the lines were much weaker) and also if a given scan of up to 3400 cm^{-1} was conducted as short consecutive scans of 400 cm^{-1} with a 2 minute, dark period, between them. Thus the maximum time the cells could be in a 300 mW laser beam and a spectrum produced was

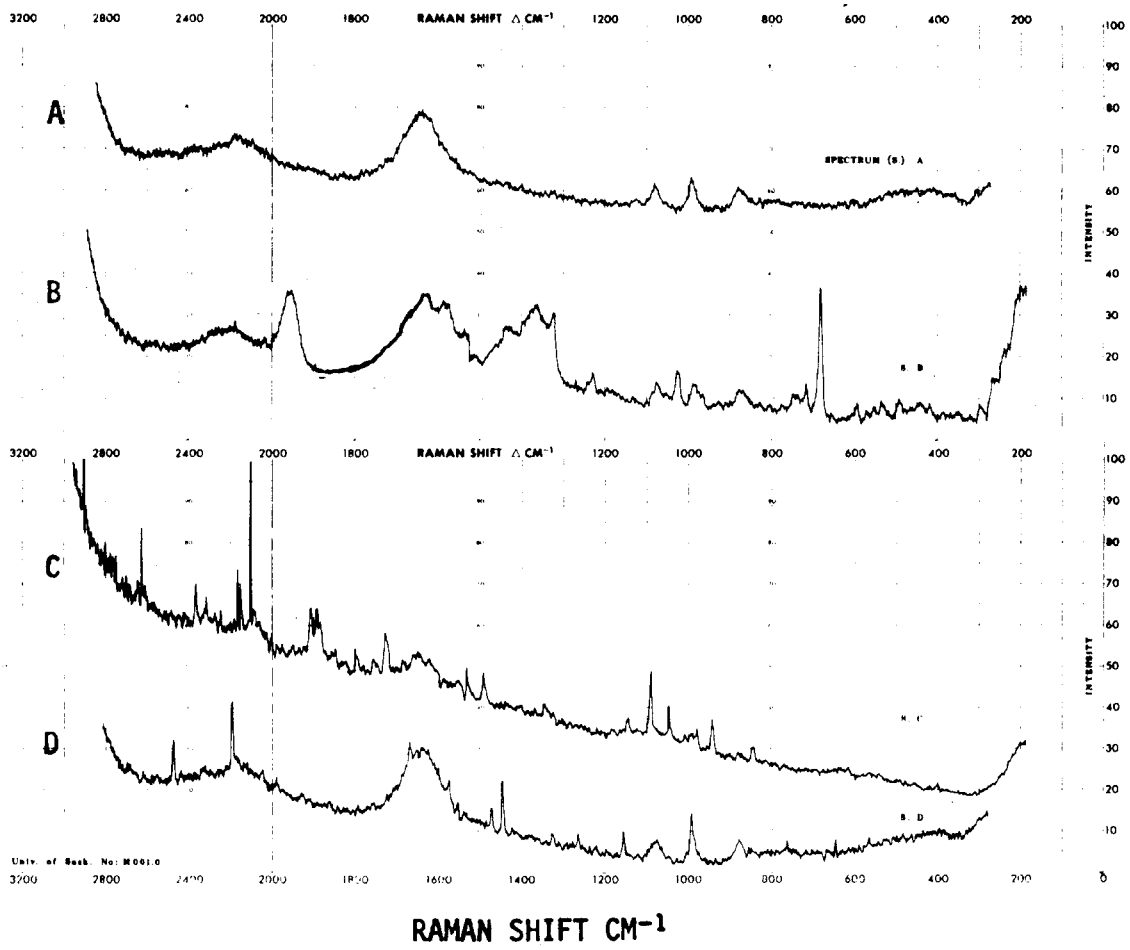

Fig. 1. Examples of initial spectra obtained with washed *B. megaterium* cells in Davis NH_4^+ salts medium. A, without glucose at any incubation time; B, C and D, with glucose at 30, 60 and 90 minutes of incubation respectively. Sensitivity 1×10^4 cps. Band width 5 cm^{-1}; laser 488 nm. Taken from Webb et al. [26].

about 6 minutes. The technique adopted, therefore, was to scan for 3 minutes only and then change to a fresh sample of cells taken from a culture actively growing in a growth medium.

Normal bacteriological growth media, such as the various nutrient broths could not be used because all are highly coloured and hence, in a laser light, they display complex fluorescences. The growth medium of choice, therefore, was the Davis minimal salts medium (MM) which contains only inorganic salts and glucose; if this was used as a 1:3 dilution in H_2O of its normal strength it produced a characteristic Raman shift spectrum with three weak lines at 873 cm^{-1}, 988 cm^{-1} and 1068 cm^{-1} and one stronger peak at 1660 cm^{-1} which was due, in part to water (fig. 1). For cells unable to proliferate in this medium a second one was used which consisted of the MM to which a given amino acid, or group of amino acids, at 1.0 μg/ml was added. At this low concentration no Raman shift lines were produced from these additives and no fluorescence problems were encountered.

Stokes spectra with synchronized populations

Even with the sequential 3 minute scans and the above growth media the spectrum, from 5 to 3200 cm^{-1}, varied from run to run (fig. 1) and, moreover, if the temperature in the sample chamber of the spectrophotometer was held between 15°C and 25°C no lines, except those of the medium were observed. It was clear, by now, that, to obtain Raman shift lines from intact cells, the cells had to be in an active metabolic state which required that they be given a usable carbon (energy) source and environmental temperatures above 25°C. Thus, it was concluded that, if these conditions held, the Raman shift lines observed were due to energy states produced *in vivo* by an active metabolism, and the non-reproducibility of the spectrum was because these states changed, with time, during the lifetime of a given cell. To test this hypothesis synchronized populations of cells next were employed.

Synchronization was achieved by taking cells from a stationary phase culture and first; washing them three times with 0.85% NaCl (saline); second, resuspending them at 10^7 cells/ml in saline and subjecting them to two successive heat and cold shocks, at 40°C and 4°C, for 15 minutes at each temperature; and third, resuspending them at 2×10^7 cells/ml in a fresh medium held at 35°C or 37°C. A second technique was the starvation for 30 minutes, of an auxotrophic strain of *Escherichia coli K12* of a vital nutrient, such as thymine, and then add the nutrient to the medium. Both techniques produced a population of cells in which the metabolic events in each cell were synchronized, to within 3 to 5 minutes, in approximately 70% of the population. After resuspending the synchronized cells in the new medium, new samples were taken every 3 minutes and the shift spectrum between the Rayleigh line and about 3200 cm^{-1} determined. This procedure was carried out only over the first generation (or lag phase) of the cells, which varied from 70 to 180 minutes depending on the growth medium used, at a scan rate of 2.5 cm^{-1}/sec as this gave the best results. Thus a complete spectrum could be obtained every 20 minutes or repeat segments of 450 cm^{-1} run every 3 minutes. For the examination and presentation of the results the abbreviation, MAR, was coined to signify the number of minutes after the cells had been resuspended, in the appropriate growth medium, and at which, a spectral run was started.

The four spectra, obtained over a 90 minute growth period, always differed from one another, only two very broad lines between 1600–1800 cm^{-1} and 2000–2150 cm^{-1} appeared in all but, even here, the fine characteristics of each of these changed (fig. 2). This type of result had been expected, what was not anticipated, however, was the subsequent inability to reproduce, in toto, each of the four spectra in repeat runs: some lines occurred again, others did not and new ones appeared. The reason for this was found to be the inability to reproduce exactly the same characteristics in successive microbial cultures. The lag phase of the cells, after the treatments given, varied by ±5 minutes and apparently this variation, which could not be improved upon, was sufficient to alter the spectral characteristics.

At this time much data had been collected and so some 62 complete spectra were examined; each distinct line seen was tabulated, broad lines of more than 100 cm^{-1} were omitted unless a clear peak appeared on them, as seen in fig. 2A and C at 1225 cm^{-1} or 1620 cm^{-1}. In addition the very narrow "spikes", seen in fig. 1C at 2132 cm^{-1}, were omitted for reasons to be discussed below. When these lines were graphed as a histogram, in terms of the number of times a given line (±2.5 cm^{-1}) was seen, it became clear that the appearance of lines was not random, all the lines occurred over and over again although they were not always present in a given spectrum (fig. 3). The composite, shown in fig. 3, therefore, may be considered as the, in toto, Raman Shift Stokes spectrum of metabolically active *Escherichia coli*. When these lines were histogrammed in terms of the time of their spectral appearance during the life span of the cells they became even more informative. As can be seen from fig. 4 the bulk

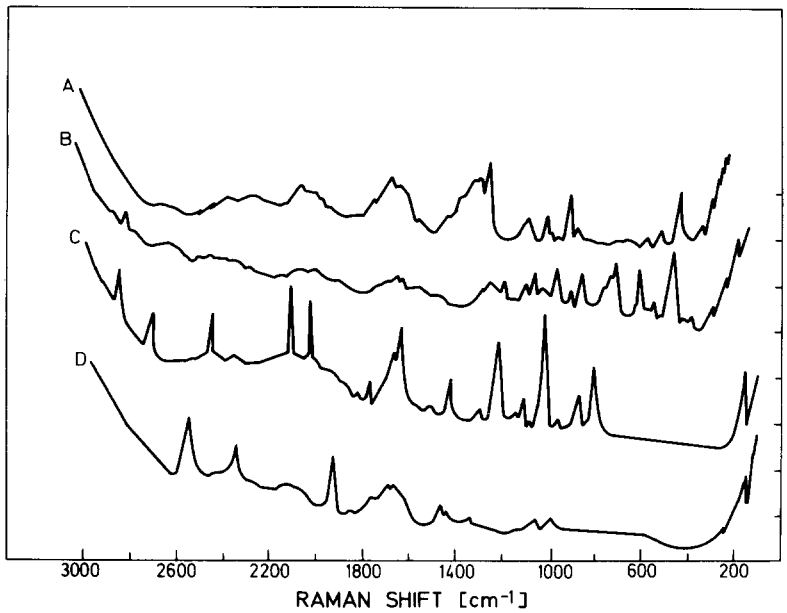

Fig. 2. Examples of spectra obtained with synchronized *Escherichia coli* cells in Davis NH_4^+ salts. A, 0–20 min; B, 20–40 min; C, 40–60 min; D, 65–85 min. Conditions as for fig. 1.

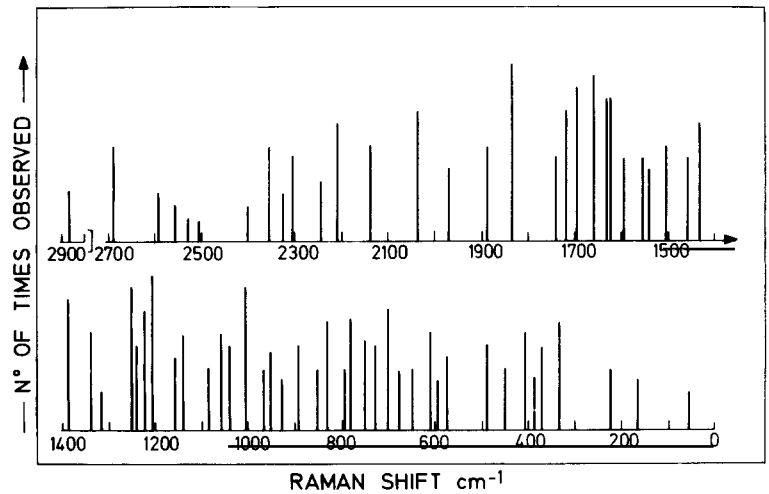

Fig. 3. Composite of all Raman lines observed in the spectra obtained with synchronized populations of *Escherichia coli* cells. Each Raman line seen in a given spectrum, recorded at a set time in the lifetime of the cell, is tabulated along with the number of times each line re-occurred in repeat spectral determinations. The height of the frequency markers, used to scale, the illustration, = two appearances of a line.

of the lines, during the first 30 minutes of the cells' lifetime, occurred between 300 cm^{-1} and 1200 cm^{-1}, from 30 to 60 minutes it was between 800 cm^{-1} and 1900 cm^{-1} and from 60 to 80 minutes between 1400 cm^{-1} and 2600 cm^{-1}. Thus the lines, associated with Raman active metabolic states appeared to shift, with incubation time, to higher wavenumbers; there was, however, an exception to this, the lines below 200 cm^{-1} appeared to move towards lower wavenumbers (both facts apparent from figs. 1, 2, 3, 14). Another interesting finding was that, approximately 10 minutes before cell divisions began, lines at about 2035 cm^{-1} and 2142 cm^{-1} often became very strong (fig. 5).

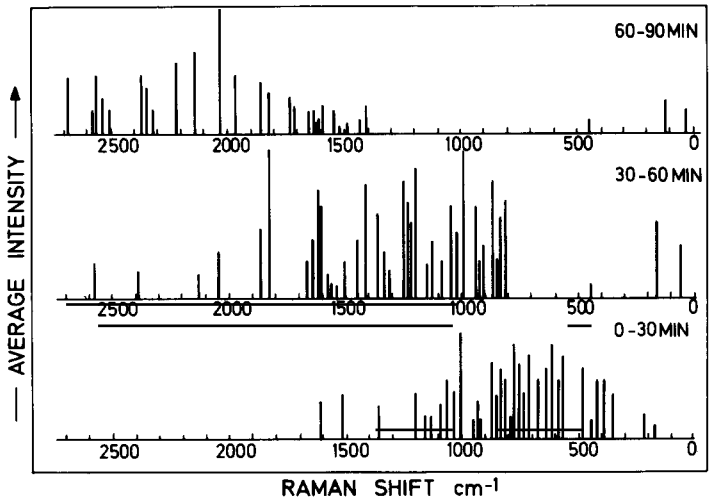

Fig. 4. The timed appearance of Raman lines seen in the spectra of synchronized populations of *Escherichia coli* cells during a 90 minute cell cycle. The times shown represent the time after the cells were placed in a minimal medium and, at which, their Raman shift spectrum was determined. The average intensity of each line is that calculated from two, or more, spectra in which the line appeared and is presented merely to demonstrate the relative intensities of the lines and change in them with time.

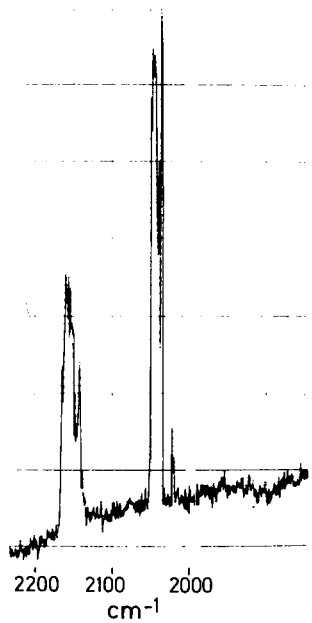

Fig. 5. The strong Raman lines which appeared in the spectrum of *Escherichia coli* just before cell divisions began. Laser 5145 Å, sensitivity 10 K.

Low temperature spectra

The spectra of *Escherichia coli* at 6 K recently obtained is shown in fig. 6. These spectra were produced from a 20 mg, wet weight, paste of 18 hr cells, grown in MM at 33°C, placed on a silvered

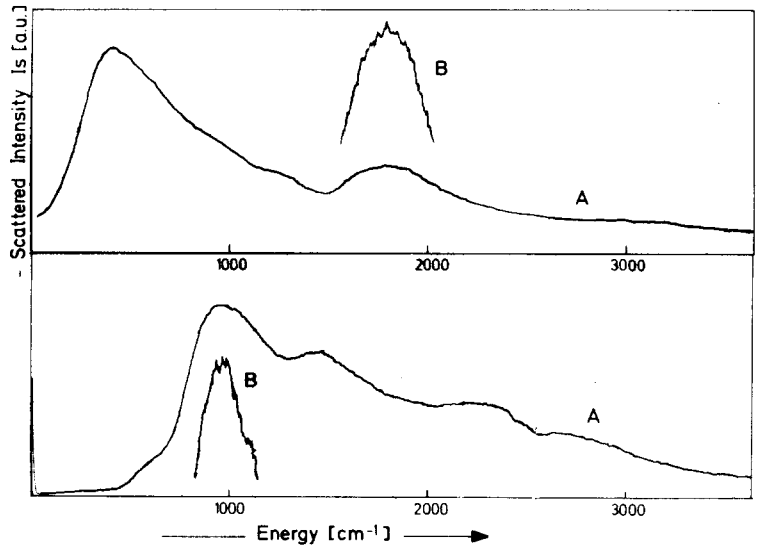

Fig. 6. Low temperature Raman shift spectra of *Escherichia coli* cell pastes obtained at 6 K. Top, laser at 5145 Å; Bottom, laser at 4880 Å. A = sensitivity at 100 K, B = sensitivity at 10 K.

plate. The technical details of the apparatus and procedures may be found in the publication by Drissler and Webb [27]. These spectra are reproduced here for comparison with the lines from time scans of active cells shown in figs. 3 and 4. The low temperature low sensitivity spectrum showed three distinct very broad bands while the high sensitivity scans revealed each of these bands to have a fine structure and thus the broad bands to be a result of the overlapping of many closely related Raman active modes. At low temperatures, this fine structure was completely reproducible. The interesting feature of the low temperature spectra was that the shift frequencies of broad humps appeared to correspond with the peaks in the average intensities and shift frequencies of the lines obtained with active cells (fig. 4). There was, however, one obvious difference in that many more Raman active modes were present in the fine structure of the low temperature humps than in the active cell spectra.

Stokes spectra below 300 cm^{-1}

At this stage of the studies little attention had been paid to shifts below 300 cm^{-1} although it had been noticed that the Rayleigh wings, which were "smooth" with resting cells, always displayed more "noise" when active cells were investigated and, in some cases, definite sharp likes were seen superimposed on these wings. Moreover, the spectra obtained with non-synchronized cells displayed lines below 200 cm^{-1} which were reproducible as far as shift frequencies were concerned but not intensity (fig. 7). These lines below 200 cm^{-1} became of special interest because they did not occur in the published Raman spectra of solutions of isolated macromolecules surveyed by the author, but several groups had reported such lines in the spectra of crystals and other "solid" preparations of natural and synthetic proteins [28, 29, 30]. In our laboratory, moreover, such low frequency lines could not be detected in the spectra of concentrated, but aqueous, lysates of cells produced by bacterophages or chloroform. It seemed, therefore, that the states associated with these lines were peculiar to the intact cell and crystals of biomolecules.

When synchronized cells were studied lines at low frequencies were seen in nearly every spectrum,

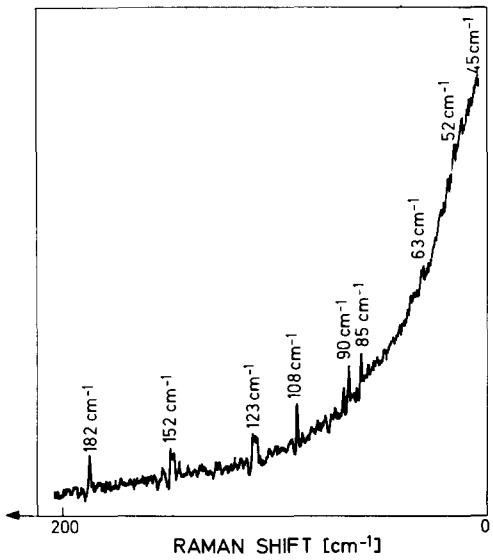

Fig. 7. The Raman shift spectrum, between 30 and 200 cm^{-1} of non-synchronized cultures of *Escherichia coli* in Davis minimal medium. Cell concentrations 5×10^7/ml; laser at 5145 Å and 300 mW; sensitivity 10 K.

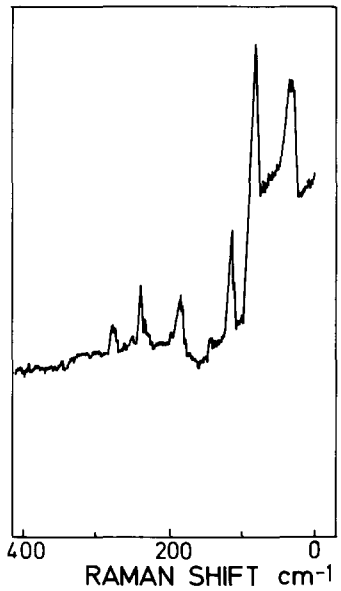

Fig. 8. A low frequency Raman shift spectrum obtained with cultures of *Escherichia coli* in which lines at 45 and 85 cm^{-1} became very strong. Cell concentration 2×10^7/ml; laser at 5145 Å and 300 mW; growth medium Davis minimal medium.

from 0 to 200 cm^{-1}, taken 20 minutes after the start of cell incubation (i.e. 20 MAR). Their intensity varied, however, from appearing as a shoulder on the wings to very strong lines at 45 cm^{-1}, 85 cm^{-1}, 150 cm^{-1} and 186 cm^{-1} (figs. 8, 9). Such lines were seen in the spectra of both *Escherichia coli* and *B. megaterium* and in both cases their exact frequency and detection depended on the MAR time at which the spectrum was obtained. The line at about 150 cm^{-1} appeared to move, as MAR time increased, from 158 cm^{-1}, at the time of its first appearance, to 126 just before cell divisions began. The line at 45 cm^{-1}, which was not detected until after 40 MAR, also moved, but only by a few wavenumbers, to 38 cm^{-1} (see fig. 14). The suggestion that the lines moved came from consecutive scans from 0 to 200 cm^{-1} each taking 80 seconds to run, in which only one predominant line between 126 cm^{-1} and 158 cm^{-1} was seen in any one scan (at least as far as the bacterial cells were concerned) which moved with time a few wavenumbers towards lower frequencies (fig. 10). Such lines at almost the same low wavenumbers have been observed recently in the spectrum of active algal cells and these also seem to change in intensity with time [32]. It is not known at present whether the apparent movement of the line is real or whether it is just another example of the time dependency of given Raman active states which, in this case, arise from a narrow cluster of *in vivo* states.

Time scans

By now at least one thing had been established, this was that the Raman activity of *in vivo* states was a time-dependent phenomenon. It was natural, therefore, that time scanning should follow to ascertain

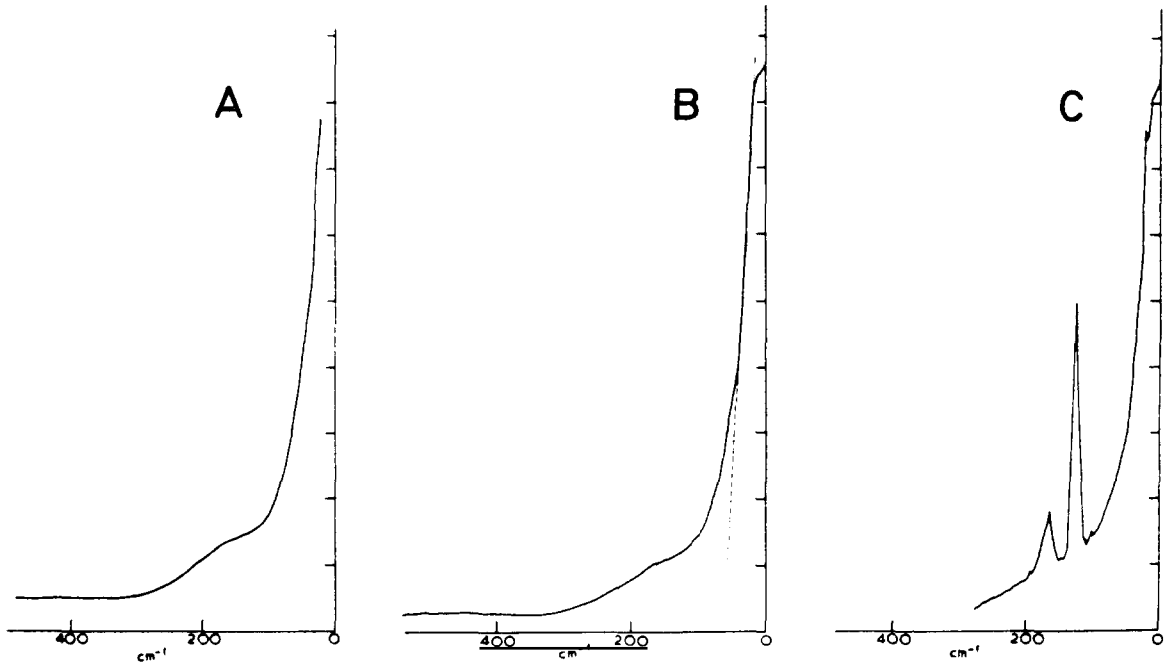

Fig. 9. Low frequency Raman spectra of A, Davis minimal medium; B, resting cells of *Bacillus megaterium*; C, active synchronized cells. Taken from Webb and Stoneham [31].

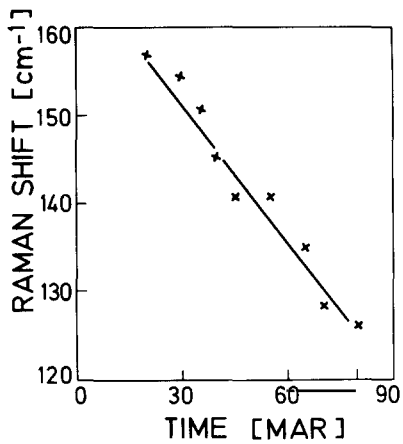

Fig. 10. The change seen in the frequency of a strong line between 126 cm^{-1} and 158 cm^{-1}, as cells of *Escherichia coli* progressed through a 90 minute life cycle.

the time, or times, during one cell cycle at which a given activity occurred. To do this a given shift frequency was chosen, the Raman instrument set on this frequency and a fresh sample of cells placed in the cuvettes every 5 minutes. The results repeated well the observations seen above (fig. 11) in that lines at the lower shift frequencies, but above 300 cm^{-1}, were seen more abundantly early in the life of the cells and a gradual movement to higher frequency shifts took place as the life cycle of the cells progressed. Thus the time phenomenon would have been well established if it was not for a new finding. A given Raman activity at a given frequency certainly occurred at definite times in the life of the cell

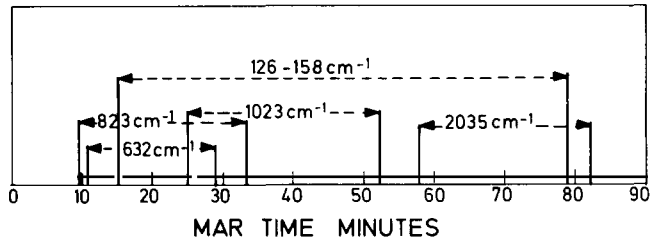

Fig. 11. The times at which set Raman shift lines occurred, in fixed shift frequency time scans, during a 90 minute cycle of synchronized cells of *Escherichia coli* in Davis minimal medium. Cell concentration 3×10^7/ml; laser 5145 Å and 300 mW.

but some of this activity appeared as "bursts" of lines over a 3 to 5 minute period (fig. 12). Since metabolic synchrony could be achieved only within 3–5 minutes a given line should have appeared at a set time and the line traced in amplitude, as a normal Gaussian curve indicating the normal distribution of the effective Raman active state within the 3–5 minute heterogeneity of the population. As seen in fig. 12 this, however, was not the case and so an analysis was made of the intervals of time between the appearance of successive strong lines (Δt) on the spectral traces from many independent scans. The result, histogrammed in fig. 13, revealed that the interval between successive strong lines was not random; Δt's of 15–20 sec and 50–55 sec apparently were the most commonly occurring intervals. The shaded portion of the histogramme represents only the frequency with which the most common time interval occurred when all lines, including very weak ones, seen only in high resolution spectra, were included. It is shown, mainly because the computer analysis revealed its presence but, since many of the lines analysed were extremely weak, it must be viewed with scepticism. The Δt's of the strong lines, which are well under the minimal 3 minute synchrony time, however, seem real and this phenomenon is discussed below.

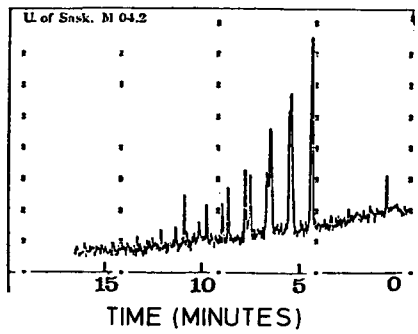

Fig. 12. Bursts of Raman activity which occurred at 1273 cm^{-1} over a 5 minute period and seen in fixed frequency time scans of synchronized cultures of *Escherichia coli*. From Stoneham and Webb [33].

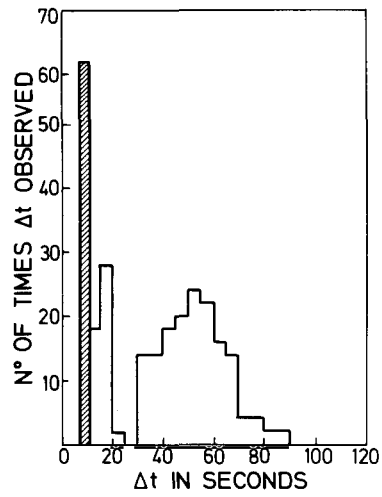

Fig. 13. Histogramme of the intervals of time (Δt) which occurred between the sequential appearance of a line at 1273 cm^{-1} within a 3 to 5 minute period during fixed frequency time scans with synchronized *Escherichia coli* cells.

Anti-Stokes lines

At this stage of the investigations the anti-Stokes spectra had not been explored since it was assumed that the intensity of such lines above $300\,cm^{-1}$ would be too low to be detected. However, the appearance of Stokes lines below $200\,cm^{-1}$ which, at times were of considerable strength, made it reasonable to search for them. Such lines were observed but again their intensity varied from run to run and many appeared as broad bands. At the MAR time when the Stokes line reached its maximum intensity so did the corresponding anti-Stokes line but detailed analysis of their intensity ratio proved difficult because of the need to change the cell sample between successive spectral runs. This required many cultures of cells each started (0 MAR) at various times so that each population could be examined at the same MAR time. The inherent small, but uncontrollable, variation in the time of the cell cycle, from culture to culture, made it impossible to obtain the same absolute intensity of the lines. One of the best sequences observed is shown in fig. 14, but it must be emphasized that this has been selected from many spectra of which most were not of the same quality. To obtain this type of spectrum the sensitivity of the instrument was set at 1×10^5 cps during the first $30\,cm^{-1}$ wavenumbers of the scan past the laser line and then switched through 1×10^4 to 5×10^3 cps. This procedure tended to flatten the wings, result in small "false" lines over the first $35\,cm^{-1}$ and amplify the intensity of real lines between 40 and $60\,cm^{-1}$ which appear on the Rayleigh wings. The line at about $150\,cm^{-1}$, therefore, is a true representation of its Stokes and anti-Stokes intensities, that at $43\,cm^{-1}$, however, must be viewed with caution. This caution kept in mind, it is interesting nevertheless that both Stokes and anti-Stokes at $43\,cm^{-1}$, have almost the same intensity. This type of intensity ratio also held true of the line at $158\,cm^{-1}$ which, as stated above, appeared to move to lower wavenumbers as the MAR time increased. In eight successive spectral runs the anti-Stokes to Stokes ratio of this line was found to vary from a low of 0.73 to a high of 1.08.

As was done with the Stokes lines some time runs were conducted at set anti-Stokes shift frequencies

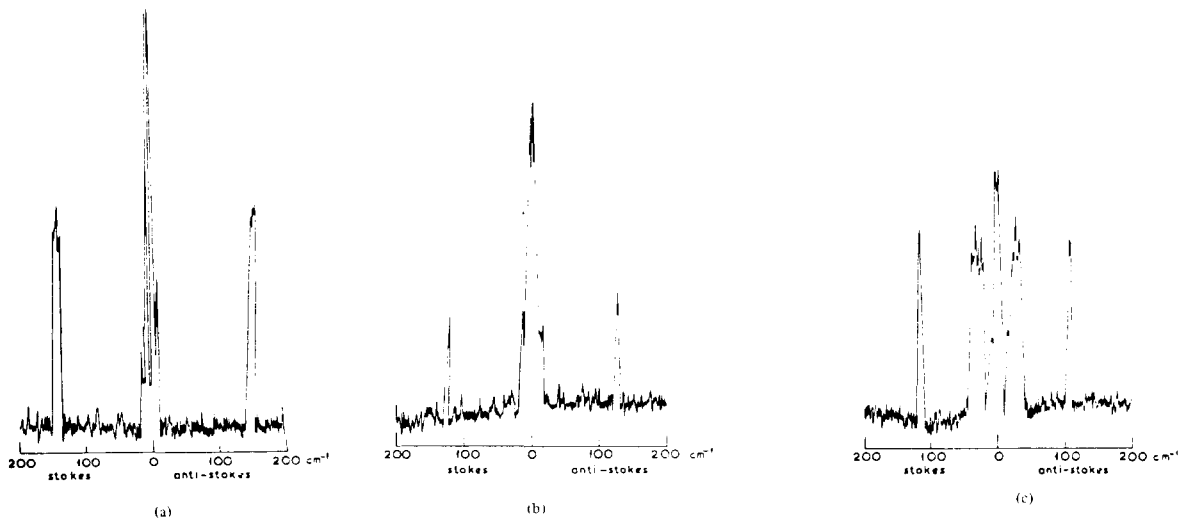

Fig. 14. An example of Stokes and anti-Stokes low frequency spectra of *Escherichia coli* cells obtained at 40, 50 and 60 minutes after resuspension. Taken from Webb et al. [34].

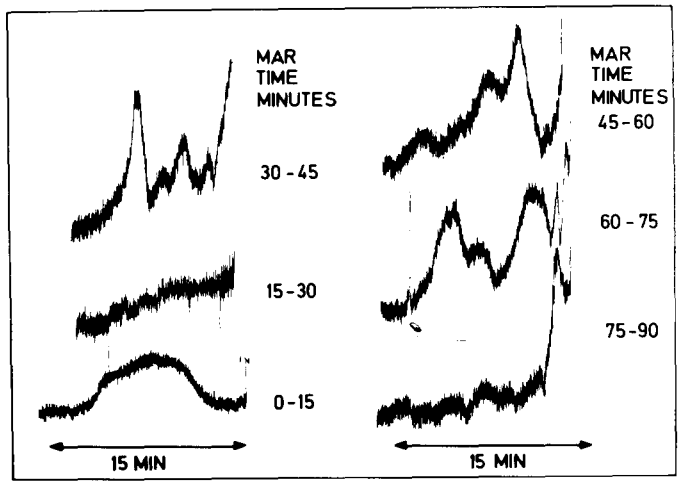

Fig. 15. The changing pattern of anti-Stokes line at 455 cm^{-1} seen during fixed frequency time scans with synchronized cells of *Escherichia coli* MAR TIME = minutes after resuspension over which a 15 minute time scan was conducted. Laser at 5145 Å.

and one line at 455 cm^{-1} so far has been studied. This line was selected because of its relatively low wavenumber and its frequent appearance in normal spectral scans. As can be seen from fig. 15 the characteristics of the line altered considerably with MAR time, also the line did not reappear if a given suspension of cells was left unchanged in the laser light for more than 10–15 minutes, if, at this time, however, a new sample of cells was introduced the line reappeared during the next 15 minute period. Thus this anti-Stokes line behaved in a similar manner to that of many Stokes lines in that its intensity and appearance fluctuated with MAR time and the *in vivo* activity, responsible for the Raman activity, seemingly sensitive to some "bleaching" action of the laser light, if exposure to the light was prolonged. Bleaching was indicated because the length of time, in the laser light, over which the line could be seen, appeared to be inversely proportional to the laser power used.

Cells other than bacteria

In recent times both Stokes and anti-Stokes lines at relatively high shift frequencies have been observed in the spectrum of algal cells exposed for only a millisecond or so to light to activate photosynthesis. The lines, seen at 300 K, however, were those of the carotenoid pigments only, the spectral lines associated with the large chlorophyll molecules were not detected (fig. 16). Chlorophyll lines, however, now have been seen clearly in the spectrum of these algal cells held at low temperatures (fig. 17) and, moreover, in experiments where the temperature has been gradually increased from 6 K to 300 K, these lines have been found to "disappear" from the spectrum at about 273 K, i.e. at the melting point of water. In addition, at 300 K and certain laser frequencies, lines below 200 cm^{-1} which vary greatly in intensity from run to run and with laser wavelength have been observed. A detailed description of these thermal effects will appear shortly in a new publication [37]. The lack of appearance of the chlorophyll lines and indeed other lines, seems to simulate the non appearance of lines in the spectra of resting bacterial cells at 300 K, however, it is possible that some chlorophyll and carotenoid lines overlap.

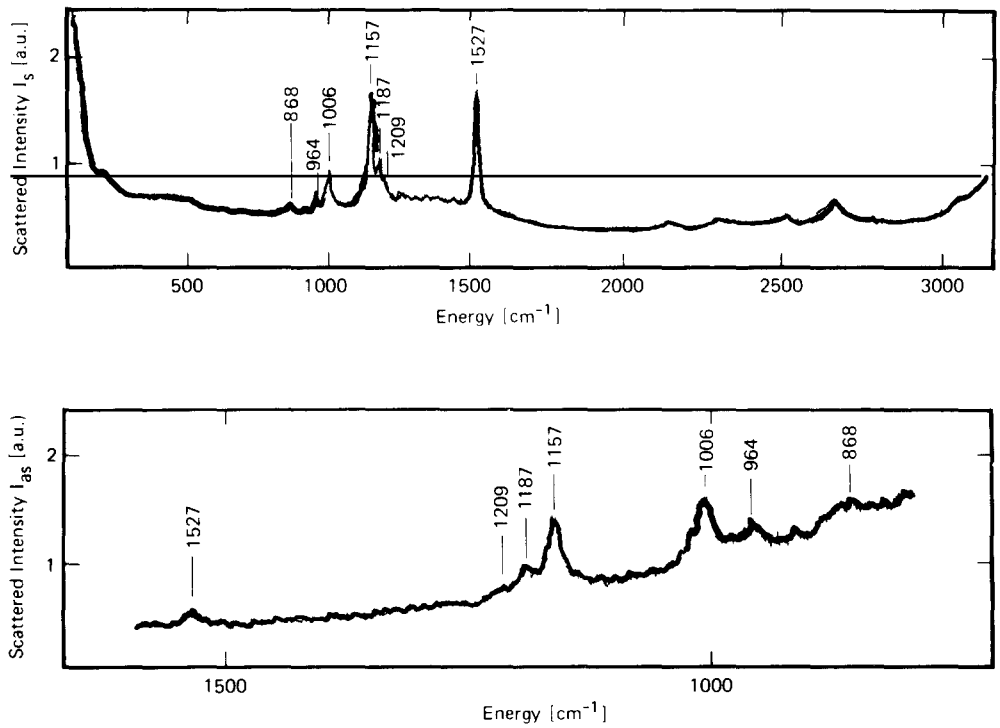

Fig. 16. Raman shift spectra of *Chlorella pyrenoidosa*. Top, Stokes lines; Bottom, anti-Stokes lines. Taken from Drissler and MacFarlane [35]. The Stokes bands shown, have been assigned to vibrational modes of carotenoid molecules by Lutz [34].

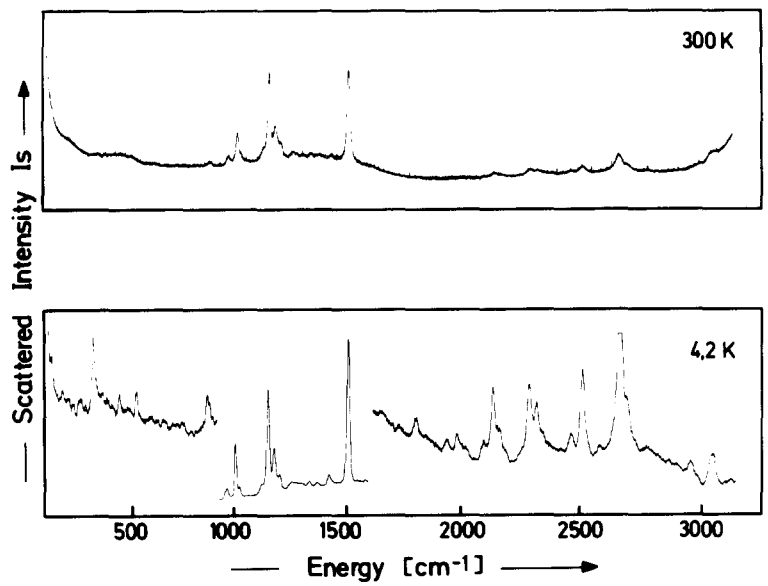

Fig. 17. Stokes spectra of *Chlorella pyrenoidosa* at 300 K (top) and at 4.2 K (bottom). Courtesy of F. Drissler [37].

Normal and tumour animal cells

In fig. 18 are shown some recently determined spectra of "normal" and tumour mammary cells, between 0 and 200 cm^{-1}. These were obtained by taking scraping from the outer regions of freshly removed 2 to 3 diameter mammary carcinomas or pieces of normal tissue [38]. The scrapings, containing pieces of tissue about 1.0 mm in thickness, were washed in Dulbecco's salts solution and then placed in a tissue culture medium similar to that of the commercial 1066 medium. Modifications, however, had to be made in this medium in that dyes and animal serum were omitted because, if present, both produced fluorescences which tended to hinder the characteristics of the spectra obtained. Such cells, if suspended in holding fluids such as Hanks (without dyes) and Dulbecco's basic salt solutions, produced no discernable Raman activity between 0 and 200 cm^{-1} nor did those placed in a tissue culture medium several hours after they had been removed from a patient or subjected previously to "fixing" solutions, only with the fresh tissue was the Raman activity, shown in fig. 17, seen. An interesting feature of these spectra was that the Raman lines from tumour tissue and the "normal" tissue from a diseased patient were broad and double spiked areas whereas the spectral lines from normal tissue, i.e. from a patient found not to be suffering mammary carcinoma, were narrower and sharp. Further studies of this phenomenon seem warranted, therefore, to ascertain whether the pattern of Raman activity seen is characteristic of other tumour cells.

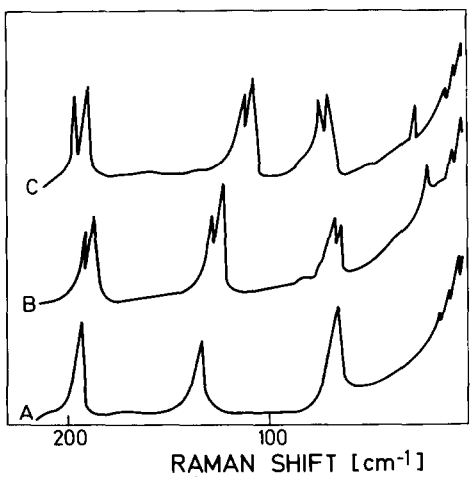

Fig. 18. Low frequency Raman shift spectra of: A, normal mammary tissue; B, "normal" right side tissue; C, left side 2–3 cm diameter mammary carcinoma of a human female. Taken from Webb et al. [38].

Discussion

The studies presented paint a complex picture and pose more questions than answers, a great deal more work will be required, therefore, before any sound conclusions may be made as to what the above findings mean. With this caution in mind, it does appear that at physiological temperatures the resting cell is in a stable condition with few, if any, of its modes Raman active. This stability is thought to be due to the presence and activity of those water molecules which form an intricate lattice *in vivo* in and around macromolecules and their complexes. It may be argued that the Raman lines are not seen in the

spectra of resting cells in suspension is because, at a concentration of 10^7 cells/ml, their total volume is too small. If this was the case, however, no lines would be detected in the spectra of any such suspension but, as demonstrated, the active cell spectra display many lines which often have a very high intensity. If the fine low temperature spectra of *Escherichia coli* is compared with the composite active cell spectra it becomes evident that fewer lines within a given 300 to 400 cm^{-1} band, appear in the active spectra than in the low temperature ones, but because of the small volume of cells used in the former case, the lines in the active spectra are very much stronger. The impression is given then that some form of condensation of closely related states takes place as a result of metabolic activity which gives rise to Raman activity, at a given frequency, of a high amplitude. Thus the Stokes lines in the active cell spectra may arise from a condensation *in vivo* of states excited by metabolic processes as suggested by Fröhlich [5, 6].

An indication that a condensation type of process does take place comes from the ratios of respective Stokes and anti-Stokes lines, and indeed the appearance of anti-Stokes lines above 500 cm^{-1}. Under normal thermal equilibrium conditions the intensity of anti-Stokes lines above 500 cm^{-1} would be too small to be detected while the intensity of those below 200 cm^{-1} would be approximately half that of their Stokes counterpart. As pointed out by Drissler and MacFarlane [35], the intensity ratio R at laser frequency ω is given by:

$$R = \frac{I_{as}^{\omega}}{I_{s}^{\omega}} = A \frac{(\omega - \omega_e - \Omega)^2}{(\omega - \omega_e + \Omega)^2} P[\Omega, T],$$

where A accounts for reabsorption, the second factor, the resonance term (with Ω the vibrational mode frequency) and P the thermal population ratio $(n/(n+1))$ derived from Boltzmann's statistics in which n is the number of vibrators in a particular energy level.

With cells containing a large quantity of molecules which have a strong absorption in the visible at about 480 nm, such as the carotenoids, the anti-Stokes line is nearer resonance with these pigments than is the Stokes line when the laser is set at say 514.5 nm. Near resonance, and in particular for large Ω, R could be influenced, and perhaps dominated, by preferential resonance enhancement in the intensity of the anti-Stokes line due to resonance with the carotenoid absorption band at 480 nm; i.e., mathematically, by the cross sectional factor. In recognition of this the authors [35] attempted to separate resonance factors from the population ratio P by a consideration of the ratio between the Stokes intensity $I_s^{\omega+\Omega}$ (laser at $\omega + \Omega$) and the anti-Stokes intensity I_{as}^{ω} (laser at ω) because under these conditions

$$P = I_{as}^{\omega} / I_{s}^{\omega+\Omega},$$

from which

$$P = \frac{I_{as}^{\omega}}{I_{s}^{\omega+\Omega}} \cdot \frac{I_{s}^{\omega}}{I_{s}^{\omega}} = \frac{I_{as}^{\omega}}{I_{s}^{\omega}} \cdot \frac{I_{s}^{\omega}}{I_{s}^{\omega+\Omega}} = R \frac{I_{s}^{\omega}}{I_{s}^{\omega+\Omega}}.$$

Thus R was measured at a given ω and corrected from a plot of the intensities of the Stokes lines at 868 cm^{-1}, 1157 cm^{-1}, 1006 cm^{-1} and 1527 cm^{-1} found with equal laser power but different wavelengths (fig. 19). With their flow system, in which the cells were exposed to light for only a millisecond or so, they calculated, under these conditions, for the 4 Ω's, population enhancements, over the thermal population factor, of 1.2 to 2.6. They found, however, in preliminary experiments, that, if the cells were exposed to white light for longer periods, the intensity of the Raman lines was increased by approximately 5%; this increase, if proven true would yield a much greater population enhancement

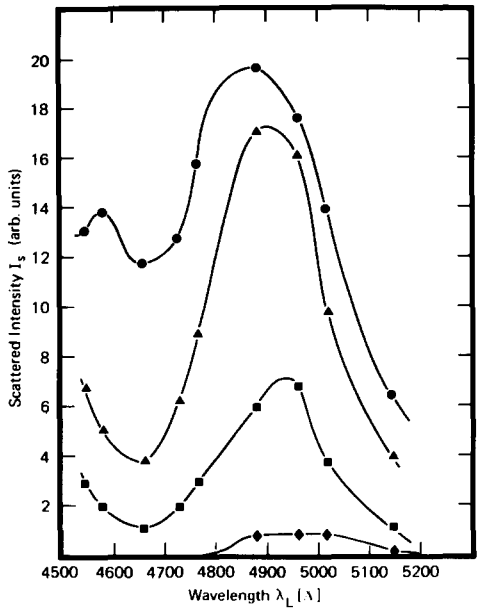

Fig. 19. Intensity dependence of the Stokes shifted bands at 868 cm^{-1} (◆), 1006 cm^{-1} (■), 1157 cm^{-1} (▲) and 1527 cm^{-1} (●) on the wavelength of the incident laser light. Taken from [35].

over the thermal factor. As far as the bacteria studied are concerned the anti-Stokes/Stokes ratio (R) at 150 cm^{-1} had an average value of about 0.8 which, at this frequency, indicates a very large population enhancement over the thermal factor. It is not known, at present, whether resonance enhancements of the above type occur in bacteria able to influence R in the same way. At this time it seems unlikely because they do not possess, in great quantities, the carotenoid pigments present in algal cells and display no absorption in the visible but further work with laser wavelengths other than the 5145 Å and 4880 Å wavelengths used will clarify this point. In any event, in two independent studies the anti-Stokes/Stokes ratios have been found to exceed considerably those predicted by thermal population factors. Thus metabolic processes do appear to excite, and perhaps produce, by non-thermal means specific Raman active modes.

One thing that certainly emerges from the studies presented is the time dependency of the onset of *in vivo* Raman activity at specific frequencies. This suggests that the living cell only allows small "cracks" to occur in its otherwise Raman inactive stable state and somehow controls, in time and frequency, the occurrence of these cracks. It is assumed, therefore, that the great stability and accuracy of function of the living system, which is in a constant state of flux, resides in its ability to confine the occurrence of unstable states, which are required for metabolic activities to take place, to set times in its lifetime. In this way it maintains its dynamic stability by allowing only minute "cracks", or perhaps one crack, to occur at any given time while the rest of the system is held in a stable state. If, as suspected, water molecules are involved in the production of the stable system, then since nearly all *in vivo* metabolic processes involve the addition or subtraction of one or two H_2O molecules to a given molecule, the movement of H_2O at a specific time and place could lead to the "cracks" in the otherwise stable architecture of the cell and lead to Raman activity of the groups with which H_2O directly associates or dissociates. It has been suggested that the known timing and occurrence of events *in vivo* may arise from an overall uniform spiral, or helical motion within the cell which brings together enzymes and their

substrates at specific times. The pitch of this motion, determined by nutritional factors, thus controls when, and if, an event will take place [39, 40, 41, 42]. In recent preliminary studies nutritional factors, both in terms of the type of carbon and nitrogen supplied to the cells, have been found to alter the frequencies and timing of Raman active events but it will take much effort to establish just how each nutritional factor alters the *in vivo* "Raman active time clock".

The Raman lines below 200 cm^{-1} clearly show a different behaviour in time from those above 200 cm^{-1}. First, these lines are present in the spectra over a prolonged period of the cells' life time, even though they may vary in intensity from a mere shoulder on the Rayleigh wings to the strong lines shown in figs. 8, 9, 14 and second, their movement with time appears to be towards lower frequencies. The metabolic process associated with these Raman lines, therefore, seems to be of a different nature from those producing lines at higher shift frequencies. Such low frequency Raman lines have been seen only in the spectra of large crystals of proteins and then it has required special techniques for their presence to be detected. In the living cell enzyme molecules of a given type are known to be clustered together in blocks, thus the lines below 200 cm^{-1} may arise from collective coherent modes peculiar to blocks of proteins, or the cell membrane, which, with time, increase in size as their metabolic synthesis proceeds.

In this report no effort has been made to identify any of the Raman lines with specific metabolic activities, or indeed the particular modes of biosystems. Only in one case has this been attempted by blocking the respiratory chain with carbon monoxide which resulted in severe changes in the characteristics, with time, of a line at 1273 cm^{-1} [33]. To identify each of the lines by the specific inhibition of set metabolic processes obviously will require an enormous amount of work, if the techniques of analysis of many time spectra, used in this study, is employed. What is required is instrumentation capable of displaying simultaneously all the Raman lines present at a given MAR time; such equipment is available but expensive. In addition, there is the danger that the inhibition of one *in vivo* process may affect the behaviour of others, a factor that could lead to falsely identifying a line with a given process. Some method should be found, however, to achieve this goal and perhaps the best one would be to study, as mentioned above, the effects of various types of nutrients on the actual shift frequencies seen and their time of appearance. Much is known about the biochemical and molecular changes induced *in vivo* by nutritional factor and it is possible that this knowledge could be put to use to identify lines.

The "bursts" of lines, seen at set MAR times but occurring within the 3–5 minute synchrony, is a mystery. This pattern could indicate that some sort of metabolic pumping, of modes with frequencies close to the Raman line, occurs over a few seconds which produces a coherent mode of high amplitude. It is difficult to comprehend, however, how this could be seen in the spectra of populations of cells metabolically, "out of phase" by at least 3 minutes. A second possibility is that some sort of resonance enhancement, induced by the laser at the frequencies the phenomenon is seen, takes place and that alternate laser excitation and biologically induced energy transfer produce this type of pattern; perhaps future work will shed some light on the phenomenon.

Time resolved Raman spectroscopy, of time scales from 10^{-1} to 10^{-8} seconds has been achieved with isolated bacteriorhodopsin, a retinal-proteins complex found in some halophilic bacterial cells [43–46]. Such studies have shown changes in the spectrum of the complex within this small timescale, and it may be that the phenomenon has some relationship to "bursts" of lines seen in this study, however, the timescale here is at least one order of magnitude higher.

The very sharp "spikes" with narrow bandwidths, sometimes seen on the tops of weak broad bands, are thought to be monochromatic fluorescences induced by the laser. The emission of virtually monochromatic light by some genera of bacteria and fungi as a result of metabolic activity, is not uncommon. In the present case, however, if the laser light was removed, no such spikes were seen; so they do not appear to arise from the metabolic activities of the cells used in this study.

One other fact that seems to arise from the study presented is that the living cell system appears unique in its ability to control the occurrence of Raman active states. The closest entities to life forms are the viruses and independent studies of aqueous suspension of bacterial [47] and plant [48, 49, 50] viruses have shown them to have a clear reproducible spectra, between 200 cm^{-1} and 3100 cm^{-1} which possess lines of high intensity. These entities are macromolecular complexes of protein and nucleid acid, and much smaller than bacterial cells. The question arises, therefore, as to why viruses display such high Raman activity while resting bacterial cells, in suspension, do not. Locked up in this phenomenon, therefore, may be a key as to why and how viruses are able to infect cells, disrupt and take control of their metabolic activities. Here again studies of the effect of virus infection on the time dependent Raman spectra of cells should prove enlightening and may provide a new tool by which virus infection may be better understood from the standpoint of the physics of the process.

Finally the phenomenon shown as far as the Raman spectra of normal versus tumour cells are concerned [26, 51]. In the one clinical case shown [38], there is a clear difference in the characteristics of the Raman lines below 200 cm^{-1}. It is possible, therefore, that in normal cells degenerate states exist which, as a result of the oncogenic process, becomes resolved and this process produces the broad double spiked peaks seen in the tumour cell spectrum. Should this prove true of other tumour cells, then Raman spectroscopy, and perhaps time dependent spectroscopy, may prove a new method by which tumour, and pretumour, cells may be rapidly identified. Indeed, differences in the Raman spectra of the membranes of such cells already have been reported [52].

The study described, at this stage, has solved very little and has merely confirmed facts cell biologists have uncovered by other means, concerning the existence of an accurate metabolic time clock within living cells. It has introduced nevertheless a different parameter in the form of the physical nature of this clock and a new method by which it may be studied. Clearly, however, the above discussion concerning "why Raman spectroscopy" is grossly inadequate as groundwork for any interpretation to be made here as to the seemingly complex physics governing the observations shown. It is hoped, therefore, that these findings will encourage some theoretical physicists to explore, in detail, their possible meanings. In addition the work seems to have opened a new approach by which a variety of different biological phenomena, such as nutrition, virus infection and oncogenesis may be identified and studied with respect to energetics and time. There is, therefore, much to be done.

Acknowledgements

The author thanks Professor M.E. Stoneham, Dr. F. Drissler and Mrs. Jane Montgomery for their valuable assistance in the acquisition of the spectral data, Professors H. Fröhlich and L. Genzel for their help in the preparation of the manuscript and Professor L. Genzel for providing the place and time for me to prepare the report.

Long Range Coherence and the Action of Enzymes

SOME time ago it was proposed that the energy produced in biological activities is partly stored in various materials through excitation of coherent electrical vibrations (polarization waves). If strong enough, such excitations can be stabilized through non-linear effects leading to various types of deformations[1,2]. R. Ferreira (personal communication) has suggested that such considerations might be of importance for an understanding of the action of enzymes. In fact the properties of a model which I have considered recently (unpublished) seems to support this idea.

The model consists of a system of interacting vibrating electric dipoles suspended in a neutral fluid with whose compressional modes they interact in a non-linear way. This system contains the case treated in appendix I of ref. 1. The electric polarization field P of the dipoles will be (but need not be) restricted to one direction. For weak excitation, this system behaves in the usual way, that is, it exhibits polarization waves whose frequency is very insensitive to the wavelength, and whose energy U is proportional to $\overline{P^2}$, the mean value of P^2. For larger excitations, however, the system shows remarkable properties, the most important being the establishment of a metastable state characterized by a non-vanishing mean value P_+ of P, that is, by a permanent mean displacement as it is found in ferroelectric materials. In the present case, however, this state is metastable; it has a higher energy than the undisplaced ground state though it is stable against small displacements. This metastable state is best reached through excitation of coherent modes which have very different characteristics from non-coherent ones. As a consequence of non-linear properties of the model, excitation of a certain amount of incoherent vibrations in the metastable state will lead as an immediate mechanical consequence to excitation of a coherent mode—quite apart from the further arguments for such excitation given in ref. 2.

Assume now that the model may be applicable to enzyme molecules which would possess metastable excited states in which polar groups are stretched so that the molecule may have a very large dipole moment resembling a ferroelectric case, and in which excitations above this state are partly transformed into coherent vibrational modes. An enzyme molecule so excited will have strong long range interaction with other molecules. This interaction will tend to lift other enzyme molecules into the metastable state, the required energy to be provided from the coherently excited modes. The interaction will also lead to attraction of other types of molecules (substrates) to the excited enzyme molecule, especially when they possess a proper frequency close to that of the coherent modes. It is therefore likely that the total energy of the complex of stretched enzyme and substrate is lower than it would be otherwise and this may facilitate the relevant chemical processes in the substrates.

Some of the properties of our model resemble Koshland's hypothesis of conformational changes[4] but they go much further because they imply a stretching of dipoles throughout the large enzyme molecule rather than a deformation near the active site. A principal consequence is the occurrence of the new long range forces which are likely to dominate the dynamic behaviour.

We thus arrive at the following dynamic picture. Assume the first substrate–enzyme complexes to be formed by fluctuations. The energy liberated by the relevant chemical transformations leaves the enzyme molecules coherently excited near their metastable state; return to the ground state would take a relatively long time. Through the long range forces so established they will (*a*) assist other enzyme molecules to transfer to the metastable state and (*b*) attract further substrates. The energy liberated by the chemical processes so acts as a pumping device. At this first stage the number of activated enzyme molecules—and therefore chemical processes—will consequently increase at an accelerating rate, much as in a chain reaction. This will continue until most enzyme molecules are in the metastable state after which the process will continue in a normal way.

These proposals could be tested in three ways. First, by investigation of the build-up of the reaction rate (first stage; chain-like process) as a function of the enzyme density. Second, by direct observation of the excited coherent modes. These modes are optically inactive. Use of Raman effect would, therefore, be appropriate. Through surface effects weak coherent radiation might, however, be observable. Third, by the detection of increase in the static dielectric constant as a result of the expected large increase in the dipole moment of the enzyme molecules when they are transferred to the metastable state.

G_{M1}-gangliosidosis Types 1 and 2: Enzymatic Differences in Cultured Fibroblasts

G_{M1}-GANGLIOSIDOSIS occurs in two clinical forms[1,2]. Type 1 resembles Hurler's syndrome somatically, but its psychomotor aspect is apparent from birth and progresses rapidly to cause death by 2 years of age. Type 2 presents no Hurler signs and its psychomotor course, though similar to that in type 1, is neither congenital nor is rapidly progressive; death occurs about 5 years of age. In addition to the accumulation of G_{M1}-ganglioside in neural, and to a lesser extent in extraneural, tissues both types share a profound, generalized deficiency of lysosomal β-galactosidase, with storage and excretion of modified keratin sulphates. Although the clinical and biochemical definition of the type 2 form is very recent[3], failure to observe both clinical types within single sibships is sufficient to suggest that each is caused by a different mutant gene. To test this hypothesis we have examined the gangliosides, glycosaminoglycans and residual β-galactosidase activities in fibroblast cell strains derived from skin in the deltoid area of patients with each type of G_{M1}-gangliosidosis. This communication deals only with the last focus of interest.

1. – Introduction.

The great success of molecular biology arises from the discovery of the detailed structure of biomolecules such as DNA and enzymes. No systematic spacial order was found, and it was concluded that these molecules do not possess a physical order. Physical order, however, does not express itself in spacial order only. Thus superfluid helium, or the electrons in a superconductor exhibit an order that might be termed « motional order ». This type of order is connected with the existence of macroscopic wave functions, which implies the existence of certain quantum phase correlations over macroscopic distances or the existence of coherent states.

Other correlations connected with the phase of oscillating systems rather than with those of macroscopic wave functions are also well known when those systems are lifted from their thermal equilibrium. A well-known example are laser systems which need not exhibit a spacial order as, *e.g.*, in the case of gas lasers.

Many other types of physical order may be imposed on certain systems

(*) Based on lectures delivered at the Symposium on « Interdisciplinary Aspects of Modern Physics », in Parma, Italy, May 3-7, 1976.

when they are lifted from their thermal-equilibrium state even though they are spacially disordered. This does not hold, however, for all systems, and no general criterium has been found, so far, which when satisfied permits particular systems to exhibit some type of order when energy is supplied to them. Most systems, however, simply raise their temperature.

Biological materials, when they exhibit typical biological properties, must be « fed », *i.e.* energy passes through them. This energy may arise from chemical processes, or it may be supplied by the Sun.

It seems rash, therefore, to conclude from the absence of spacial order —obtained from structural analysis—that no physical order exists in biological systems. On the contrary, it has been suggested several years ago that they belong to those systems in which the supply of energy imposes a characteristic order [1, 2].

In approaching these questions from the point of view of theoretical physics it must be realized that, in contrast to most materials usually treated in physics, biological materials have been selected through long evolutionary processes. As a consequence, they often show quite extraordinary properties, and, rather than ask whether some material properties seem likely, one should ask whether they are possible. Clearly, in the first place, the role of theoretical physics must be to decide what questions should be asked; subsequent developments should then work in close contact with experiments.

It has often been thought that exact knowledge of the atomic structure of a system will provide all answers at least in principle. This is already a basic mistake [3], even in the case of the physics of simple systems. Thus, for example, the above-mentioned concept of macroscopic wave function refers to the whole assembly of particles, *i.e.* it is a collective property which cannot in a simple way be reduced to properties of individual particles.

2. – General.

In looking for a striking material property common to most biological systems one will, no doubt, choose their dielectric properties [1, 2, 4]. Biological systems are, of course, not uniform, but composed of many different such systems. In ordinary physics, one would then extract each subsystem, *e.g.* a certain type of molecule, and determine its dielectric properties, *e.g.* its dipole moment. In solution this dipole moment, say μ_i, would be slightly different from the moment μ_v in vacuum owing to polarization effects. Such a procedure would be highly misleading in the biological case, say for water-soluble proteins. Their conformation is largely dominated by the interaction of their charged groups with the surrounding water and ions which thus form an integral part of the structure and hence of the measured dipole moment. Under these circumstances, very high internal electric fields may exist in such systems.

Most striking, of course, are the fields in cell membranes which have average values of the order of 10^5 V/cm, which in ordinary materials would require great precautions to avoid breakdown. Inhomogeneous regions, *e.g.* through proteins dissolved in the membrane, might lead to much higher local fields. These fields play a basic role in nerve conduction, but here weaker fields could fulfil the same purpose. Their role in the membranes of other cells is unknown.

One notices that the energy difference of a unit electronic charge across the membrane (about 10^{-6} cm) would, at room temperature T, amount to about $3kT$. This suggests that the transport of single charges obtains a significance against thermal noise.

Also in a field $F \sim 10^5$ V/cm the energy μF is larger than kT when μ is the dipole moment of a small protein, say $\mu \sim 300$ Debye units. This suggests that proteins dissolved in membranes are oriented by the field.

In addition, however, the whole membrane system is strongly polarized by the field. As a consequence, an oscillation of a section of the membrane—or of certain proteins dissolved in it—is connected with a corresponding electric vibration, so that the longest electric wave usually yields an electric-dipole vibration. According to one of our main suggestions, such vibrations are very strongly, coherently, excited in biological systems when they are active, *i.e.* when metabolic energy is available.

Now it must be realized that the displacement of a single ion by 10^{-6} cm produces a very large dipole moment of the order of 500 Debye units. It would be wrong, however, to neglect other processes arising from such displacements, for the change of electric field arising from this displacements may substantially alter the polarization in the neighbourhood of the ion (note that the electric field at a $3 \cdot 10^{-7}$ cm distance from the electronic charge is of the order of 10^6 V/cm) and cause other ions to move. Under these circumstances, one would expect such displacements to become stabilized, and our second principal suggestion states that biological systems have metastable states with very high electric polarization.

How can one support theoretically such general statements referring to a variety of complicated materials? It is already clear from the above that we are dealing with strongly nonlinear effects. This provides possibilities only occasionally contemplated in ordinary physics. Our method will be to formulate simple, but general models which do show the required properties. General conditions required in these models then impose corresponding conditions on the respective biological systems. If experiments confirm the theoretical predictions, then we can conclude that the molecular evolution has led to the selection of materials with the required properties. This does not imply that other systems do not exist which do not have the required properties, though from a structural point of view they could be very similar to the systems which

do have these properties. The difference between the two would then rest in their nonlinear behaviour, *i.e.* in properties of certain excited states which would not be revealed in structural analysis.

3. – The vibrational model.

Any system containing charged particles is capable of long-wave electrical vibrations. Such a system need not be homogeneous. One of the characteristics of these vibrations is the existence of a lowest frequency $\omega_1/2\pi$, different from zero. Our system is assumed to possess such modes, $\omega_1, \omega_2, \ldots, \omega_z$. They are considered not to interact with each other, but to be strongly coupled to the surroundings, *i.e.* to the other modes of the systems which will be treated as a heat bath at temperature T. Let n_k be the number of quanta $\hbar\omega_k$ in the mode ω_k. Then, through first-order processes, single quanta $\hbar\omega_k$ may be emitted to or absorbed from the heat bath, so that the rate of change $\dot{n}_{k,1}$ of n_k due to these processes is [2, 5]

$$\dot{n}_{k,1} = -\varphi\big(n_k \exp[\beta\hbar\omega_k] - (n_k + 1)\big)\,, \tag{3.1}$$

where $\beta = 1/kT$, and φ will depend on T and, in general, also on ω_k. For simplicity we shall neglect the ω_k-dependence. The ratio of emission to absorption processes is governed by detailed balance.

Similarly, for second-order processes we find

$$\dot{n}_{k,2} = -\chi \sum_j \big(n_k(1 + n_j) \exp[\beta\hbar\omega_k] - n_j(1 + n_k) \exp[\beta\hbar\omega_j]\big)\,. \tag{3.2}$$

Again, apart from depending on T, the transition probability χ could depend on k and j, but we shall neglect this. This will greatly simplify the calculations, but should have no influence on the main results.

We note that, on this choice,

$$\sum_k \dot{n}_{k,2} = 0\,, \tag{3.3}$$

i.e. such processes lead to interchange of quanta $\hbar\omega_k$ without alteration of their total number.

Now we consider that energy is supplied at the rate s_k to the mode ω_k. We then find, for the total rate of change $\dot{n}_k$,

$$\dot{n}_k = s_k - \varphi\big(n_k \exp[\beta\hbar\omega_k] - (n_k + 1)\big) - \\ - \chi \sum_j \big(n_k(1 + n_j) \exp[\beta\hbar\omega_k] - n_j(1 + n_k) \exp[\beta\hbar\omega_j]\big)\,. \tag{3.4}$$

We wish to solve this equation for the stationary case, *i.e.* when

$$\dot{n}_k = 0 \,. \tag{3.5}$$

We may derive the general behaviour of n_k in a simple manner, though it would be difficult to solve this system of quadratic equations exactly.

Summation over k with the definition

$$S = \sum s_k \tag{3.6}$$

yields

$$S = \varphi \sum_k \left(n_k \exp\left[\beta\hbar\omega_k\right] - (n_k + 1)\right) . \tag{3.7}$$

Introducing the total number of quanta N,

$$N = \sum n_k \,, \tag{3.8}$$

we find with

$$\omega_1 \leqslant \omega_k \leqslant \omega_z \tag{3.9}$$

that $\left(\text{note } \sum_k 1 = z\right)$

$$N\left(\exp\left[\beta\hbar\omega_z\right] - 1\right) > S/\varphi + z > N\left(\exp\left[\beta\hbar\omega_1\right] - 1\right) . \tag{3.10}$$

This means that N must increase proportional to S if the supply S is sufficiently large.

Now define μ by

$$\exp\left[-\beta\mu\right] = \frac{\varphi + \chi \sum (1 + n_j)}{\varphi + \chi \sum n_j \exp\left[\beta k\omega_j\right]} , \tag{3.11}$$

so that

$$1 - \exp\left[-\beta\mu\right] = \frac{\chi \sum \left(n_j \exp\left[\beta\hbar\omega_j\right] - (1 + n_j)\right)}{\varphi + \chi \sum n_j \exp\left[\beta\hbar\omega_j\right]} . \tag{3.12}$$

From (3.7) it then follows that

$$\mu \geqslant 0 \tag{3.13}$$

and

$$1 - \exp\left[-\mu\beta\right] = \frac{\chi}{\varphi} \frac{S}{\varphi + \chi \sum n_j \exp\left[\beta\hbar\omega_j\right]} \geqslant 0 . \tag{3.14}$$

Equation (3.4) with (3.5) can thus be formally solved by

$$n_k = \left(1 + \frac{\varphi}{\chi} \frac{s_k}{S} \left(1 - \exp\left[-\beta\mu\right]\right)\right) \frac{1}{\exp\left[\beta(\hbar\omega_k - \mu)\right] - 1} , \tag{3.15}$$

and $n_k \geqslant 0$ together with (3.13) yields

$$\hbar\omega_1 > \mu \geqslant 0 \,. \tag{3.16}$$

This inequality permits the establishment of an upper limit for N although μ is a complicated function of all the n_k. For (3.15) then yields

$$N = \sum n_k < \left(1 + \frac{s_m(1 - \exp[-\beta\hbar\omega_1])\,\varphi}{\chi S}\right) \sum_k \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,, \tag{3.17}$$

where s_m is the largest of the s_k.

Clearly, if the sum in (3.17) can be replaced by an integral, then for $\mu \sim \hbar\omega_1$ a value independent of the s_k will be reached. Moreover, always $s_m/S \leqslant 1$, so that an upper limit for N independent of S is obtained. This contradicts the conclusion drawn from (3.10), according to which N must increase proportional to S if S is sufficiently large. This situation is the same as normally found in Einstein condensation of a Bose gas. Thus the replacement of the sum by an integral is incorrect; μ takes a value close to $\hbar\omega_1$ such that n_1 becomes very much larger that all the other n_k.

It follows then that a single mode ω_1 gets very strongly (coherently) excited when the energy supply is larger than a critical one.

As special cases we may consider that all s_k are equal. Then

$$s_k/S = 1/z \tag{3.18}$$

and (3.15) becomes

$$n_k = \left(1 + \frac{\varphi}{\chi_z}\left(1 - \exp[-\beta\mu]\right)\right) \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,. \tag{3.19}$$

As another extreme consider that all s_k vanish except for $k = k_0$.

Then

$$s_k = S\delta_{k,k_0}\,, \qquad s_{k_0} = S \tag{3.20}$$

and

$$n_k = \left(1 + \delta_{k,k_0}(1 - \exp[-\beta\mu])\,\frac{\varphi}{\chi}\right) \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,. \tag{3.21}$$

To understand qualitatively these conclusions, we notice first of all that the case $\chi = 0$ leads to a completely trivial result, namely

$$n_k = \left(1 + \frac{s_k}{\varphi}\right) \frac{1}{\exp[\beta\hbar\omega_k] - 1}\,, \qquad \text{if } \chi = 0\,, \tag{3.22}$$

i.e. to a modified thermal-equilibrium Planck distribution. It will be noticed from (3.11) that $\chi = 0$ in fact entails $\mu = 0$ and thus eliminates the occurrence of Bose condensation. Thus the nonlinear terms χ arising from a strong interaction with the heat bath tend to force the system into a thermal-equilibrium distribution making use of a chemical potential μ.

A main difference from ordinary condensation of a Bose gas in thermal equilibrium should also be noted. There the ordered (condensed) state is reached by lowering the temperature. In our case, the ordered state is reached by supplying sufficient external energy to the system. Quite a similar situation prevails with respect to the second of our concepts (sect. **4**).

The above model, naturally, is a very simplified version of any actual situation. It has a very general consequence which might not depend on modifications required in particular cases, namely the coherent excitation of a polar mode when energy supply exceeds a critical magnitude.

Which frequencies should we anticipate? Roughly speaking, if a polarized system of linear dimensions l carries out long-wave elastic vibrations (*e.g.* breathing vibrations), then the electric polarization of the system implies coexistence of an electric-polarization vibration with the same frequency

$$\nu \sim v/l\,, \tag{3.23}$$

where v depends on the elastic constants and can formally be expressed as a velocity of sound. Thus $l = 10^{-6}$ cm and $v = 10^5$ cm/s would yield $\nu = 10^{11}$ Hz, but $l = 3 \cdot 10^{-7}$ cm (small protein) with $v = \frac{1}{3} 10^5$ cm/s yields, of course, the same value. The band of polarization waves ω_k would then consist of the interacting vibrations of such units, and also of higher vibrational states of the same unit. It must be emphasized again that the existence of long polarization waves does not require homogeneous material.

A further condition is the absence of unduly high friction, which probably will mean that surfaces facing water should not move. This does not hold, however, for structured water, which is to be considered as an integral part of the particular biological unit. Most likely, these conditions are satisfied by proteins in or near membranes. Thus, if $\Delta\nu$ is the frequency width, we have in this case

$$\nu \sim 10^{11}\ \mathrm{Hz}\,, \qquad \frac{\Delta\nu}{\nu} \ll 1\,, \qquad s > s_0 \tag{3.24}$$

as condition for the excitation of coherent vibrations. Here s is an appropriate average over the rate of energy supply and s_0 is the threshold value for Bose condensation.

It should be emphasized that other frequencies, both higher and lower, are well feasible. Thus larger units such as DNA-protein complexes might

well possess lower frequencies. Higher ones, on the other hand, may be based on a combination of the various rotational and vibrational subgroups of relevant molecules.

4. – The high-polarization model.

Consider [6] a polarizable material, polarization P. Its mean « self-energy » can then be written as $\frac{1}{2}a^2\overline{P^2}$, where the bar indicates an appropriate average and the positive a^2 depends on the polarizability, including size and shape of the material. These definite size and shape imply the elastic energy of the material to be a minimum relative to small deformations. If these are measured in terms of a deformation parameter η, then on deformation the elastic energy increases by $\frac{1}{2}\eta^2\varepsilon$, where $\varepsilon > 0$ depends on the elastic properties. In the case of a sphere, for instance, the deformation could produce an ellipsoid with eccentricity η. Now the polarizability in general is not an extremum at $\eta = 0$, so that a^2 would have to be replaced by $a^2(1 + c\eta)$, where c may be positive or negative. The total contribution to the free energy thus amounts to

$$U = \tfrac{1}{2}a^2(1 + c\eta)\,\overline{P^2} + \tfrac{1}{2}\eta^2\varepsilon\,. \tag{4.1}$$

Minimizing with regard to η at fixed $\overline{P^2}$ yields

$$\eta = -\frac{1}{2}\frac{ca^2}{\varepsilon}\,\overline{P^2}, \tag{4.2}$$

so that

$$U = \frac{1}{2}a^2\,\overline{P^2}\left(1 - \frac{1}{4}\frac{c^2}{\varepsilon}a^2\,\overline{P^2}\right). \tag{4.3}$$

Thus increasing $\overline{P^2}$ ultimately may lead to decreasing U. At this stage, the linear approximation η and the quadratic one in P will probably have become invalid. Higher-order terms may thus reverse this trend and lead to a minimum of U at a certain $\overline{P^2}$. If U at this value is negative, then the material would acquire a spontaneous dipole moment. If U is positive, then a metastable state with spontaneous polarization exists.

These conclusions are of a very general nature. They follows from the shape dependence of the polarizability and require the material to be sufficiently soft, *i.e.* ε should be sufficiently small.

They can be extended to a dynamical model composed of a polarization field $\boldsymbol{P}$ and an elastic (acoustic) field $\boldsymbol{A}$. Let ω_0 be the circular frequency of long-wave polarization waves in the absence of any interaction with the elastic field, then with such an interaction the density of potential energy has the

form

$$W = \tfrac{1}{2}\omega_0^2 \boldsymbol{P}^2 + \left(\tfrac{1}{2}v^2(\operatorname{div}\boldsymbol{A})^2 + c\boldsymbol{P}^2 \operatorname{div}\boldsymbol{A}\right)(1 - d^2\boldsymbol{P}^2)\,, \tag{4.4}$$

where v is the velocity of sound, d^2P^2 is an *ad hoc* term introduced to achieve stabilization for high P^2.

Note that, for long waves,

$$\varrho = \operatorname{div}\boldsymbol{A} \tag{4.5}$$

may be introduced as change in density. The static case requires minimization of (4.4) with regard to ϱ and P^2, so that for homogeneous displacements

$$\varrho = -\frac{cP^2}{v^2}\,, \tag{4.6}$$

yielding

$$W = \frac{1}{2}\omega_0^2 P^2 - \frac{1}{2}\frac{c^2}{v^2}(1 - d^2P^2)\,. \tag{4.7}$$

Apart from the different notation, this result corresponds to (4.3) except that the d^2P^2 term leads to a stabilization at high P^2.

Now we can introduce the density of kinetic energy

$$K = \tfrac{1}{2}(\dot{\boldsymbol{P}}^2 + \dot{\boldsymbol{A}}^2) \tag{4.8}$$

and hence from the Lagrangian density L obtain the equations of motion in the usual way,

$$\delta\int L\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}t = \delta\int (K - W)\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}t = 0\,, \tag{4.9}$$

where $\boldsymbol{r}$ is the space vector and t the time. The assumption that acoustic phonons are absent then permits the elimination of the $\boldsymbol{A}$-field and yields an equation of motion of the form

$$\ddot{\boldsymbol{P}} + \frac{\partial V(P)}{\partial \boldsymbol{P}} = 0\,. \tag{4.10}$$

The effective potential $V(P)$ has the form

$$V(P) = A + BP^2 + CP^4\,, \tag{4.11}$$

apparently a harmless anharmonic oscillator. This is misleading, however, for the coefficients A, B, C depend on the mean square amplitude

$$p = \overline{P^2}\,, \tag{4.12}$$

such that

$$A = \frac{1}{2}\frac{c^2}{v^2}p^2, \tag{4.13}$$

$$B = \frac{1}{2}\left(\omega_0^2 - 2\frac{c^2}{v^2}p - \frac{d^2c^2}{v^2}p^2\right), \tag{4.14}$$

$$C = \frac{c^2d^2}{v^2}p\,. \tag{4.15}$$

For small p clearly the CP^4 term is negligible and B becomes $\omega_0^2/2$, so that an harmonic oscillation with frequency ω_0 is obtained.

For increasing p, however, the magnitude of B decreases, *i.e.* the mode softens. For appropriate values of the parameters it is then found that a metastable state with permanent polarization $\pm P_0$ exists and that the system has two branches of oscillation: one around $P = 0$ and another with limited amplitude around $\pm P_0$. In this case, the effective potential $V(P)$ has a maximum at $P = 0$ and two minima at $P = \pm P_0$. The value of P_0 is found by minimizing (4.7), which yields

$$P_0^2 = p_0 = \frac{1}{3d^2}\left(1 + \sqrt{1-\lambda}\right), \tag{4.16}$$

where

$$\lambda = \frac{3v^2d^2\omega_0^2}{c^2}. \tag{4.17}$$

Thus $\lambda < 1$ is a necessary condition for the existence of a P_0, and it can be shown that this state is metastable, *i.e.* has positive energy when

$$\frac{3}{4} < \lambda < 1\,. \tag{4.18}$$

For $\lambda < \frac{3}{4}$ its energy is negative, *i.e.* it becomes the (ferroelectric) ground state.

We notice again that small v^2, *i.e.* softness of the material, favours the establishment of a polarized state. We also note that in many ferroelectric materials the effective potential has a minimum at $P = 0$ at high temperatures. The mode softens as we decrease the temperature towards the Curie point and below we find two minima at $P \pm P_0$.

In our case $V(P)$ has its minimum at $P = 0$ at low energies, but supply of energy may establish the quasi-ferroelectric state with minima at $P = \pm P_0$. Thus here as in the case of sect. **3** a long-range order—coherent vibrations, or permanent polarization—is established through the supply of energy.

Clearly actual biological materials will behave in a much more complex way than discussed in this simple model. We should recall in this case that structured water and various ions are to be considered as an integral part of the system.

This implies considerably higher nonlinear effects than discussed above. While these will have to be treated case by case, it seems that they usually will contribute to the stabilization of our metastable state. Thus a polarized molecule will shift mobile ions so that its energy is lowered; in turn, this will, of course, affect the magnitude of polarization.

5. – General consequences.

The two types of excitation discussed in sect. **3** and **4** can have far-reaching biological consequences. First of all, it should be noticed that they require supply of energy, *i.e.* activation. Both can then lead to forces which were absent before activation, and to storage and transport of energy.

Cell water contains considerable amounts of small ions which tend to screen any static electric charges at short range. Hence a system activated to a high dipole moment (sect. **4**), *e.g.* a protein, may exert considerable forces in water-free regions, but will be screened for long-range interaction. This screening does not hold, however, for an oscillating field at frequencies of the order of 10^{11} Hz (sect. **3**). Thus, if the coherently excited vibration represents an oscillating giant dipole, then long-range forces may be activated. They will be shown to be frequency selective.

Consider two oscillating giant dipoles at distance R with frequencies ω_e and ω_s, respectively, in the absence of interaction [4, 7]. At sufficient distance, their interaction is essentially dipolar, since other interactions decrease much more rapidly with R. The combined system then has two normal modes ω_+, ω_-, where

$$\omega_\pm^2 = \tfrac{1}{2}(\omega_e^2 + \omega_s^2)\left(1 \pm (q^2 + Q^2)^{\frac{1}{2}}\right). \tag{5.1}$$

Here (by assuming $\omega_e^2 \geqslant \omega_s^2$)

$$q = \frac{\omega_e^2 - \omega_s^2}{\omega_e^2 + \omega_s^2} > 0 \tag{5.2}$$

and Q essentially is the ratio of the interaction energy between the two giant dipoles and their internal potential energies.

It thus depends on the distance as $1/R^3$.

In the particular case that the giant-dipole oscillations in the two molecules consist in correlated oscillations of, respectively, z_e and z_s elastically bound ions of charge e and of equal mass M, then

$$Q = \gamma e^2 (z_e z_s)^{\frac{1}{2}} / M R^3 (\omega_e^2 + \omega_s^2), \tag{5.3}$$

where γ is a numerical constant.

Clearly the expression for ω_-^2 holds only when $\omega_-^2 > 0$; at short distance thus mode softening occurs.

The interaction energy I is defined as the difference of the free energy F at distance R from its value at $R \to \infty$. Now consider the case that the state with the lower frequency has been coherently excited (n_- quanta) so that the contribution of ω_+ to F can be neglected. Then

$$I = F(R) - F(\infty) = n_- \hbar(\omega_-(R) - \omega_-(\infty)) = \tag{5.4}$$

$$= \frac{1}{\sqrt{2}} n_- \hbar(\omega_e^2 + \omega_s^2)^{\frac{1}{2}} \left\{(1 - \sqrt{q^2 + Q^2})^{\frac{1}{2}} - (1 - q)^{\frac{1}{2}}\right\}.$$

This energy is always negative, *i.e.* attractive. Furthermore, if $\omega_e \neq \omega_s$, then at sufficient distance $Q^2 < q^2$ and we find, after development,

$$I = -\frac{\hbar n_-}{4\sqrt{2}} (\omega_e^2 + \omega_s^2)^{\frac{1}{2}} \frac{Q^2}{q(1-q)^{\frac{1}{2}}} \propto -\frac{1}{R^6}. \tag{5.5}$$

If, however, $\omega_e^2 \simeq \omega_s^2$ and $Q^2 \gg q^2$, $q^2 \ll 1$, then

$$I \simeq -\frac{\hbar n_-}{\sqrt{2}} (\omega_e^2 + \omega_s^2)^{\frac{1}{2}} Q = -\frac{\hbar n_-}{\sqrt{2}} \frac{\gamma e^2 (z_e z_s)^{\frac{1}{2}}}{M(\omega_e^2 + \omega_s^2)^{\frac{1}{2}}} \frac{1}{R^3} \propto -\frac{1}{R^3}. \tag{5.6}$$

In this case of near resonance, the always attractive interaction has very long range. Roughly, if

$$U = \hbar n_- \omega_e \tag{5.7}$$

is the energy of excitation, using $\omega_e \simeq \omega_s$, we have

$$I \simeq -U \frac{e^2 (z_e z_s)^{\frac{1}{2}}}{M \omega_e^2 R^3}. \tag{5.8}$$

While thus activation of coherent vibrations may lead to long-range, frequency-selective interaction, activation of the polar state leads to short-range nonselective forces which might facilitate transport of ions within the particular material, or across it.

Long-range selective forces may lead to selective transportation of molecules like enzymes and thus initiate a particular trend of chemical events. It might also be relevant for the transportation of larger units.

It has been suggested that these properties are an essential feature in the high catalytic power of enzymes [4, 6, 8]. Thus the high internal fields arising from the strongly polarized state could reduce activation energies, while excitation of coherent modes could be used for the transport of energy.

Independently [9], the same conclusion has been reached from an analysis of a great variety of enzymatic reactions.

In [10] it has been suggested that the selective long-range interaction (sect. **3**) may be responsible for the attraction of a homologous pair of chromosomes in meiosis—an interaction which according to [11] has till then remained « a great mystery ».

A number of other possible consequences has been discussed elsewhere [1, 2, 4, 12].

Selective long-range interaction in conjunction with the existence of highly polar metastable states may also be decisive for the establishment of the well-known low-frequency electric vibrations in the brain, whose biological significance is only now being explored [13]. It has been shown that the long-range coherent interaction (based on the 10^{11} Hz coherent vibrations) could in an enzyme-substrate system lead to collective enzymatic reactions resulting in slowly varying (periodic) excitation and de-excitation of the system of enzymes from the only slightly polar ground state into the highly polar metastable state. Thus a slow chemical oscillation is connected with a corresponding electric vibration. The strong electric interaction between the highly polar states in conjunction with the considerable damping of electric currents then imposes on them a limit cycle condition, which recently has been investigated [14]. This model requires large regions to oscillate coherently as has actually been found [15].

6. – Experimental evidence.

In active biological systems experimental evidence for the existence of coherent electric oscillations in the 10^{11} Hz region would require methods which have not yet been fully developed (cf., however, Note added in proofs). Evidence does exist, however, that radiation in this frequency region may have very strong effects on such systems. The most comprehensive report on such effects has been presented in a meeting of the USSR Academy of Science [16]. Properties of a great variety of objects have been found to be strongly influenced by coherent electromagnetic waves in the $(5 \div 7)$ mm (vacuum) wave-length region. Almost all experimental results have in common:

i) That they very strongly depend on frequency in a region in which the optical constants have the appearance of broad bands; often the biological effects showed typical resonance character.

ii) The dependence on intensity exhibits a threshold below which no biological effects occur and above which they are nearly independent of intensity.

To interpret these results [17], we assume that these biological effects are initiated by a first step which is sensitive to a radiation followed by a chain of other possibly very complicated effects which are insensitive to it. The

first step might be connected with a long-range interaction arising from coherent excitation of a molecule, *e.g.* an enzyme which could be attracted to its substrate. Let the time required for this be $t_1(s)$, where s represents the radiative supply of energy to it. According to sect. **3**, excitation of the coherent mode requires a threshold s_0. With growing s ($> s_0$) the time $t_1(s)$ will decrease, so that the total time for the whole process

$$t = t_1(s) + t_2 \to t_2 \tag{6.1}$$

will approach the s-independent time t_2 required for the s-independent chain of further biological steps. Thus in these experiments we find

$$\nu \sim \frac{1}{2} 10^{11}\,\mathrm{Hz}\,, \qquad \frac{\Delta\nu}{\nu} \ll 1\,, \qquad s > s_0\,, \tag{6.2}$$

as predicted in (3.24).

We note that the resonancelike frequency dependence in a region in which the optical constants show little frequency dependence is the best proof that we are not dealing with thermal effects.

The magnitude of s_0 has been estimated theoretically [18] from calculations using methods of laser physics and found of the order 0.04 mW/cm², which agrees with some of the experimental results (*).

The Russian experiments range from various effects on bacteria, growth of yeast cultures, influence on human and animal cells to effects on various genetic properties. Depending on the type of process stimulated by the radiation, a certain biological activity might be increased or decreased. Independently, on a smaller scale and without extensive frequency resolution, biological effects near $0.7 \cdot 10^{11}$ Hz and $1.4 \cdot 10^{11}$ Hz have been found by other investigators [19, 20].

In some of the Russian experiments [21], the biological resonance has been found as narrow as $2 \cdot 10^8$ Hz. This can be understood on the assumption that the only broadening of the excited giant-dipole vibration arises from its electric coupling to the thin layers of structured water whose dielectric absorption lies in this region [22, 23]. The remarkable absence of other frictional effects reminds one, of course, of the various suggestions of the existence of room temperature superconductive regions in biological systems. So far no definite experimental proof for their existence has been found. These narrow resonances are most likely to occur when the level which is excited by the radiation is identical with the level which is strongly populated in Bose condensation,

(*) It should be mentioned that in [18] the presentation of a quadratic Hamiltonian is misleading, though the results are correct. For, as required, the authors do use the influence of a heat bath which in terms of a Hamiltonian would require at least 4th order terms to obtain their eq. (8*a*)—as can be seen from our eq. (3.2) which is responsible for the occurrence of a chemical potential μ.

i.e. when in (3.21) this is the level K_0. Broader bands must be expected when this is not the case.

In experiments of this type, one must be prepared for unexpected non-linear effects of the imposed radiation. Thus, within the range in which the radiation is absorbed, in the first place coherent excitation of some molecules is expected. If the same type of molecules is present at greater depth, then they in turn may become excited by transfer of the excitation energy from the outside molecules. Thus the excitation may be expected to move beyond the penetration depth of the imposed radiation.

Now, in turning to the excitation of the strongly polar metastable state, one would, of course, attempt to excite this state by bringing the molecule in question into a strong electric field. It should be of interest in this context that investigations on nerve membranes have led to the conclusion that the electric field in the membrane makes it nearly impermeable to Na^+ and K^+ ions, whereas the absence of the field leads to a much higher permeability presumably through proteins dissolved in the membrane; it is suggestive to attribute these two different properties to the two states in the proteins.

More direct evidence for conformational changes of certain molecules in membranes due to changes of the electric field is available [24].

A number of other possibilities has been discussed in [4], including results found with the electret method [25] and with laser-induced stimulation of enzyme activity at very high dilution [26].

Thus, while experiments available at present seem to support the theoretical predictions, in a general way much greater refinement of the experimental methods is desirable to obtain more specific experimental results. This in turn should stimulate theoretical investigations of a more specific nature.

7. – Cancer.

The problem of cancer is one of the control of cell division. While bacterial cells under appropriate conditions keep on dividing, cells in a fully grown differentiated tissue or organ divide relatively rarely, though they divide more rapidly in growing tissues and organs. We shall assume that a controlling agency belonging to the whole organ, *i.e.* a collective property, exists and that individual cells respond to it.

The nuclei of these cells contain a DNA-protein complex, whose detailed structure is not well known, though it seems reasonable to assume that its spacial arrangement differs in different organs and depends on the type of differentiation that has taken place. Now we shall assume that these materials are capable of electric vibrations which can be excited coherently in the sense of our model (cf. sect. **3**). Thus metabolic energy would be used to excite these vibrations at a well-defined frequency (or frequencies) which would be char-

acteristic for the particular organ or tissue. Note that experiments discussed in sect. **6** confirm the existence of such vibrations in some biological materials.

This then implies that a coherent electric vibration carried collectively by the individual nuclei extends through the whole tissue (organ), and that the vibrations of each individual cell respond to it and are thus held in the appropriate phase, such that the total electric energy is a minimum. In general, this vibrating polarization field will form a complicated spacial pattern.

Now, preceding cell division, the DNA-protein complex of the nucleus of a cell must unfold and may then be expected to change some of its physical characteristics, such that it looses its resonance with the collective mode. This implies that its energy of interaction with the collective mode is increased, *i.e.* energy has to be spent to perform this change (apart from changes in the internal energy). This energy may not always be available and, as a consequence, the interaction of an individual cell with the collective mode acts as an inhibition on cell division. The strength of this inhibition depends on the magnitude of excitation of the collective mode. This excitation may well depend on the size of the tissue because of the long range of the interactions as discussed in sect. **5**. The possibility of a size-dependent inhibition on cell division thus exists.

A situation thus prevails which in some respects corresponds to order in physical systems described in terms of an order parameter as, for instance, in lasers (cf. also [27]). In our case, the collective vibration represents the order parameter. It is built up of the contributions of the relevant vibrations of the individual cells, and they in turn obey the instruction of the order parameter, namely not to divide.

Now assume that changes have taken place in a particular cell such that its frequency is altered. This cell no longer contributes to the coherent collective vibration, whose intensity will thus be slightly reduced, nor does this cell obey the instruction of the coherent mode, *i.e.* the inhibition to divide disappears. The slight reduction of intensity of the coherent mode due to the change of property of a single cell should have a minute effect on other cells. A critical intensity should exist, however, below which the control of cell division no longer is effective. It is feasible, therefore, that something like a phase transition takes place from the controlled to the uncontrolled state once a critical number of cells has been affected.

Such an approach requires that—while the controlling vibration is strong enough—a cell in the tissue will be induced to transfer into the correctly vibrating state provided it possesses such a state, for only thus can the system exhibit stability.

This may have two types of consequences:

i) Differentiation may be expected to consist in rearrangements of the DNA-protein complex, such that it obtains relevant frequencies assumed

absent before differentiation. Under the influence of the coherently excited mode(s) of the particular tissue (organ), this transition is energetically favourable and hence is stimulated [28]. The differentiated cell then gets subjected to the control.

ii) Mutations which lead to alterations in the relevant frequency(cies) are energetically less favourable than those which do not alter them and which thus still respond to the control and are, therefore, statistically less likely.

Thus, in our model, the sufficiently excited collective vibration exerts an influence on individual cells which inhibits both cell division and « unfavourable » mutations (which would not react to control) and, at the same time, tends to bring cells which do not respond to the control into states in which they do react to it.

If by external influences some cells are changed such that their relevant frequencies are altered, then *a*) these cells no longer respond to the control and *b*) the strength of the controlling vibration is reduced. Both these effects are rectified by the above-mentioned stabilizing influence provided they are not too large. If, however, the number of altered cells is so large that the excitation of the collective mode is reduced below a critical value, then the control becomes ineffective. As a consequence, all cells divide more frequently, and simultaneously « unfavourable » mutations (having « wrong » frequencies) become possible, *i.e.* a phase transition from order to disorder (cancer) has taken place.

It should be noted here that the frequencies of the changed cells will differ from each other; thus no collective mode with sharp frequency will arise: the ordered state has a sharp frequency, the disordered one a broad frequency band.

Which are the external influences that can lead to a change in frequencies? It has been shown [2] that supply of unattached electrons could have such an influence. Such electrons might occur in the conduction band of various molecules. They are then capable of long-wave electric vibrations, plasma waves, whose frequencies increase proportional to the square root of the electron density. These vibrations will interact with the coherent vibrations of our system and under appropriate circumstances can significantly alter the frequency.

Such electrons might be supplied by excitation through ultraviolet light. Or they might be supplied by foreign molecules which are electron donors. A change of frequency might, of course, also arise from an invasion by foreign molecules into the relevant DNA-protein complex.

Other possibilities may arise, however, if we assume that the frequency sharpness found in some of the experiments discussed in sect. **6** is a feature of the proposed collective vibrations. It has been previously indicated that electric coupling with structured water would account for the measured frequency width indicating absence of all other types of friction. Some structural

changes might be sufficient to eliminate this property and with it the effectiveness of control. The affected cells could then still have frequencies in the region of the nonaffected one, but exhibit greater width.

The model described here can without difficulty be presented in mathematical form by using well-known techniques developed, *e.g.*, in connection with laser physics [29]. Even without doing so, it will be noticed that the term « collective mode » might be given a different physical interpretation from the one suggested here, provided individual cells have selective properties which enable them to react to the collective mode and which could be destroyed by external influences.

If the interpretation of the collective mode as a vibration is correct, then one would wish to know the order of magnitude of relevant frequencies. The 10^{11} Hz region is, of course, a first candidate both for theoretical and experimental reasons (sect. **3** and sect. **6**). It might well be, however, that quite different frequency regions are also of importance, and it will in the first place be a task for experiments to find these frequencies.

Most desirable would, of course, be experiments which measure the excitations of the biological material *in vivo*. For frequencies near or above 10^{12} Hz laser Raman effect would be suitable. For frequencies near or below 10^{11} Hz, this becomes inefficient because of the broadening of the primary line through water. Thus the frequencies for which selective biological effects have been discovered (sect. **6**) are beyond the available range. New methods (corresponding to Brillouin scattering) are being developed, but must still be adapted for use in biological materials.

It should be emphasized in this context that vibrations in this frequency range may very sensitively depend on details of the arrangements and on the conformation of relevant molecules including structured water and ions, which must both be considered an integral part of the system. Investigations on molecules, *e.g.* proteins, outside their natural surroundings may but need not give relevant results. Something similar holds of the measurement of absorption of electromagnetic waves by the biological material. We have mentioned above that the excited collective mode might have a complicated spacial pattern. This will probably not be optically active. Optically active modes are, however, to be expected in the neighbourhood of each « relevant » frequency; they would show up as a band rather than as the relatively sharp line we expect from the collective mode, except in cases in which the spacial pattern is homogeneous in the range of penetration of the electromagnetic wave—as might hold for thin layers of the material. It should be emphasized in this context that some of the experiments mentioned in sect. **6** exhibit extremely sharp frequency response for biological effects, whereas broad bands are found in optical measurements. Nevertheless changes found in the optical spectra would certainly indicate major changes and could thus provide valuable information.

One might in particular wish to measure the changes arising from the excitation of electrons into the conduction bands discussed above. It must be pointed out in this context that plasma waves are not optically active except through the influence of surfaces. The same is likely to hold of the collective mode with which they interact. For optical detection, therefore, one would use biological samples which are small compared with the wavelength of the electromagnetic radiation with the relevant frequency. When using a thin layer, then the electric vector should have a component perpendicular to the surface. Internal surfaces may, however, also be effective which to some extent may relax these conditions.

Finally biological effects of the electromagnetic radiation are most likely to provide significant results. If we can learn from the experiments mentioned in sect. **6**, then we might expect sharp frequency resonances in the biological response. As a consequence, a tunable source will be required.

In the first place, we would expect the naturally excited mode to be in its most favourable state. External excitation of modes with the same frequency, though probably with different spacial pattern, would thus interfere with the efficiency of the collective controlling mode. In a grown material this would then increase the rate of cell division, while in a growing system it should decrease it.

Finally, when under the influence of external agencies a sufficient number of cells have undergone changes in frequency to the extent that the controlling collective mode has become ineffective, then a stronger externally imposed vibration of the correct frequency (though possibly with different spacial pattern) might still be able to restore the original order. This, of course, would be the most startling influence of electromagnetic waves on biological systems.

Note added in proofs on 27/9/1977.

Conclusive evidence for the metabolic excitation of vibrational states in bacteria has now been obtained by Raman effect. WEBB and STONEHAM (*Phys. Lett.*, **60** A, 267 (1977)) show that, while resting bacteria exhibit only bands in the (100÷200) cm^{-1} region, active bacteria show strong lines. Moreover (S. J. WEBB, M. E. STONEHAM and H. FRÖHLICH: *Phys. Lett.*, A, in print), the intensity ratio of anti-Stokes to Stokes lines in thermal equilibrium should be about 0.5, whereas it is found close to 1.0, evidence for strong nonthermal excitation.

Long-Range Coherence and Energy Storage in Biological Systems

H. FRÖHLICH
Department of Theoretical Physics, University of Liverpool, Liverpool, England

Abstracts

Biological systems are expected to have a branch of longitudinal electric modes in a frequency region between 10^{11} and 10^{12} sec^{-1}. They are based on the dipolar properties of cell membranes; of certain bonds recurring in giant molecules (such as H bonds) and possibly on pockets of non-localized electrons. In Section 2 it is shown quite generally that if energy is supplied above a certain mean rate to such a branch, then a steady state will be reached in which a single mode of this branch is very strongly excited. The supplied energy is thus not completely thermalized but stored in a highly ordered fashion. This order expresses itself in long-range phase correlations; the phenomenon has considerable similarity with the low-temperature condensation of a Bose gas. General consequences and proposals of experiments are discussed in Section 3.

Dans les systèmes biologiques on peut présumer une branche de modes électriques longitudinaux dans une région de fréquences entre 10^{11} et 10^{12} sec^{-1}. Ceux-ci peuvent être associés à des propriétés dipolaires de membranes cellulaires, de certaines liaisons récurrentes dans les molécules géantes (telles que des liaisons d'hydrogène) et peut-être de poches d'électrons non localisés. Dans le Section 2 on montre d'une façon toute générale, que si l'on fournit de l'énergie à une telle branche à une certaine vitesse, un état stationnaire sera atteint, dans lequel un seul mode de cette branche est très fortement excité. L'énergie ainsi fournie n'est donc pas complètement thermalisée, mais reste emmagasinée d'une manière bien ordonnée. Cet ordre apparaît dans les corrélations de phase à longue portée. Le phénomène a une similarité considérable à la condensation d'un gaz de Bose aux basses températures. Dans le Section 3 on discute des conséquences générales et on propose des expériences.

Man kann erwarten dass biologische Systeme einen Zweig von longitudinalen elektrischen Schwingungen in einem Frequenzbereich zwischen 10^{11} und 10^{12} sec^{-1} haben. Diese sind auf Dipolareigenschaften von Zellmembranen, von gewissen Bindungen in Riesenmolekülen (z. B. Wasserstoffbindungen) und vielleicht von Taschen von nichtlokalisierten Elektronen gegründet. In Sektion 2 wird im allgemeinen gezeigt, dass wenn Energie mit mehr als einer gewissen Durchschnittsrate einem solchen Zweig zugeführt wird, wird ein stationärer Zustand erreicht, in welchem eine einzige Schwingung dieses Zweigs sehr stark angeregt ist. Die zugeführte Energie ist also nicht vollständig thermalisiert, sondern wird in einer höchst geordnetenr Weise gespeichert. Diese Ordnung zeigt sich in Phasenkorrelationen mit langer Reichweite. Das Phänomen hat beträchtlicle Ähnlichkeiten mit der Kondensation eines Bosegases bei tiefen Temperaturen. Allgemeine Folgerungen und Vorschläge von Experimenten werden in Sektion 3 diskutiert.

1. General

The present paper arises from development and clarification of ideas presented by myself [1] in the opening talk of the recent Versailles conference on Theoretical Physics and Biology. In the past decades biology has been highly successful in the correlation of biological properties with the structure and properties of relevant molecules. This stage of development might be compared with the correlation of the physical and chemical properties of materials with the structure and properties of the atoms and molecules of which the material is composed. These properties modified by interaction with their neighbours account for many features of the substance. Some of the most interesting properties in the physics of materials, however, can be understood in terms of the collective (cooperative) behaviour of a great number of these constituents only, usually associated with some kind of long-range order. Most frequently this order is described in terms of a definite spatial pattern. A much more subtle type of long-range order is found in superfluid helium, and in superconductors. This order is connected with the concept of long-range phase correlation (coherence). Superfluids (and superconductors) undergo at very low temperatures a phase transition. The simplest model available for this transition is the Einstein condensation of a Bose gas in which—with decreasing temperature—more and more particles "condense" into a single quantum state.

At first thought one might consider the order exhibited in these low-temperature phenomena to be quite irrelevant for Biology. Stimulated by a different attitude, however, I have been able to show [2] that under appropriate conditions a phenomenon quite similar to Bose condensation may occur in substances which possess longitudinal electric modes. If energy is fed into these modes and thence transferred to other degrees of freedom of the substance then a stationary state will be reached in which the energy content of the electric modes is larger than in thermal equilibrium. This excess energy is found to be channelled into a single mode—exactly as in Bose condensation—provided the energy supply exceeds a critical value. Under these circumstances a random supply of energy is thus not completely thermalized but partly used in maintaining a coherent electric wave in the substance.

The original reason for considering longitudinal electric modes lay in the extraordinary dielectric properties of biological systems. Furthermore living systems though relatively stable are in some respects far from thermal equilibrium; also they may be expected to exhibit some order of a non-trivial nature. From a very general point of view of physics, three observations may thus be made about living systems.

[1]. They are relatively stable yet in some respects far from thermal equilibrium.

[2]. They probably exhibit some kind of order typical for them yet not of an obvious spatial nature.

[3]. Cells and many of the relevant giant molecules have quite extraordinary dielectric properties.

In connection with (3) it should be remembered that cells have a membrane of about 10^{-6} cm thickness which maintains a very strong dipolar layer. In the (from the point of view of physics) complicated shape of a cell surface, local vibrations of a part of the cell membrane are feasible such that the positive and the negative part of a particular section of the membrane vibrate against each other leading to an oscillating electric dipole. Its frequency is of the order 10^{11}–10^{12} sec^{-1} if a sound velocity in the layer of order 10^{5}–10^{6} cm/sec perpendicular to the surface is assumed.

The giant molecules occurring in biological systems also have extraordinary dipolar properties largely in view of the frequently occurring hydrogen bonds. Careri [3] has pointed out that in the α helix they may be expected to exhibit collective dipolar oscillations in the same frequency region.

Other sources for dipolar oscillations in the same frequency region might exist. They would arise, for instance, from the presence of "non-localized" electrons in some regions of a cell.

Dielectric systems of the type described here are capable of longitudinal electric oscillations extending over the whole material. The existence of such oscillations follows directly from Maxwell's equations though little use has been made of this possibility in physics. They can have a certain range of macroscopic wavelengths depending only weakly on frequency.

Certain processes in living systems involving the cell membrane, or the hydrogen bonds of molecules, or other dipolar constituents, may be expected to feed energy locally to the particular dipolar oscillations. The long-range Coulomb interaction then causes this energy to be shared with other dipoles. The situation thus is exactly as assumed in the above-mentioned model, so that the dipoles will tend to oscillate coherently provided the energy supply is sufficiently large compared with the energy loss. Non-linear effects are likely to reduce this loss with increasing excitation and effectively transfer the system into a metastable state in which the energy supplied locally to dipolar constituents is channelled into a single longitudinal mode which exhibits long-range phase correlations.

It should be remarked that the present model fits the general conditions for the stability of "dissipative structures" presented by Prigogine [4] at the Versailles conference.

Furthermore the channelling of randomly supplied energy into a single mode—described above—should be considered as a special case of long-range quantum-mechanical phase correlations as pointed out in [1]. Such phase correlations are a common property of superfluids and superconductors as described by Yang [5]. They also may be expected to arise in certain forms of chemical bond as has been emphasized by Löwdin [6].

2. Coherent Excitations

Consider a suspension of a large number Z of units in a substance which will be treated as a heat bath. Each unit is assumed capable of electric dipole oscillations with a certain frequency ω_0. Long-range Coulomb interaction between these individual oscillators then gives rise to a branch of Z longitudinal electric modes in a frequency range say

$$\omega_1 \leqq \omega \leqq \omega_2 \tag{1}$$

which may be shifted considerably from ω_0 but is relatively narrow. The modes of this branch describe longitudinal electric waves in the material as a whole. Oscillations of single units can then be described by appropriate superposition of these waves. Assume that energy is supplied locally to each unit at a mean rate s. This is equivalent with a supply of energy at the same rate s to each mode. Assume furthermore that each unit can exchange energy locally with the surrounding heat bath; this can again be expressed in terms of an exchange of energy in quanta $\hbar\omega$ with the modes of the branch at a rate which is nearly independent of ω. The net rate of loss L_{1l} of the mode with frequency ω_l (containing n_l quanta) can then be written in the form

$$L_{1l} = \phi(T)(n_l e^{\hbar\omega_l/KT} - (1 + n_l)) \tag{2}$$

where $\phi(T)$ may depend on temperature T. In a higher order individual units could exchange two, or more quanta with the heat bath but never a fraction of a quantum. The long-range Coulomb interaction between units gives rise, however, to the whole range (1) of frequencies. In second order, therefore, absorption of a quantum $\hbar\omega_l$ in conjunction with emission of a quantum $\hbar\omega_j$, or vice versa, permits an exchange of energy between the branch of electric modes, and the heat bath in a range

$$0 < \hbar\,|\omega_l - \omega_j| \leqq \hbar(\omega_2 - \omega_1) \tag{3}$$

The net range of loss L_{2l} of the mode ω_l due to such processes can be written in the form

$$L_{2l} = \chi(T) \sum_j (n_l\,(1 + n_j) e^{\hbar(\omega_e - \omega_j)/KT} - n_j(1 + n_l)) \tag{4}$$

The general forms of (2) and (4) are dictated by the requirement that in the absence of energy supply, $s = 0$, thermal equilibrium ($L_{1l} = 0$, $L_{2l} = 0$) requires a Planck distribution n_{lT} for n_l,

$$n_{lT} = \frac{1}{e^{\hbar\omega_l/KT} - 1} \tag{5}$$

Note that χ may depend on temperature. A slightly more general form of L_{2l} would permit explicit dependence of χ on ω_l and ω_j.

The condition for stationarity requires for each l,

$$s = L_{1l} + L_{2l} \tag{6}$$

With the notations

$$N = \sum n_j\,, \qquad S(T) = s \sum e^{-\hbar\omega_j/KT} \tag{7}$$

one finds

$$S(T) = \phi \sum (n_j - (1 + n_j)e^{-\hbar\omega_j/KT}) \tag{8}$$

independent of χ, and

$$n_l = \left(1 + \frac{s}{\phi + \chi N}\right) \frac{1}{Ae^{\hbar\omega_l/KT} - 1} \tag{9}$$

where

$$A = \frac{\phi + \chi \sum (1 + n_j)e^{-\hbar\omega_j/KT}}{\phi + N\chi} > 0 \tag{10}$$

or making use of (8),

$$A = 1 - \frac{\chi}{\phi + N\chi} \frac{S(T)}{\phi} \leqq 1 \tag{11}$$

Clearly $s = 0$ leads to $A = 1$ and (9) becomes the thermal equilibrium distribution (5). However, $\chi = 0$ also leads to $A = 1$ even if $s \neq 0$ though in this case n_l no longer represents a Planck distribution.

Inequality (11) together with the condition $n_l \geqq 0$ leads to

$$A = e^{-\mu/KT} \quad \text{where} \quad \hbar\omega_1 > \mu \geqq 0 \tag{12}$$

Clearly a Bose type of condensation into the lowest mode ω_1 will take place when μ approaches $\hbar\omega_1$ very closely. We shall show in the high temperature limit

$$kT \gg \hbar\omega_1 \tag{13}$$

that this will occur when s exceeds a critical value s_0. In this approximation one has from (9) and (12),

$$n_l = \left(1 + \frac{s}{\phi + \chi N}\right) \frac{kT}{\hbar w_l - \mu} + \cdots \tag{14}$$

Let $D(\omega)\, d\omega$ be the number of modes in $d\omega$. Then if no condensation has taken place $D(\omega_l)n_l$ may be considered a continuous function. Let N_n be the total

number of quanta in this case. From the inequality of (12) one then finds an upper limit for N_n, for then

$$N_n = \left(1 + \frac{s}{\phi + \chi N_n}\right) kT \int_{\omega_1}^{\omega_2} \frac{D\, d\omega}{\hbar\omega - \mu} < \left(1 + \frac{s}{\phi + \chi N_n}\right) N_0 \tag{15}$$

or

$$\frac{N_n(\phi + \chi N_n)}{\phi + \chi N_n + s} < N_0 \tag{16}$$

where

$$N_0 = \frac{kT}{\hbar} \int_{\omega_1}^{\omega_2} \frac{D\, d\omega}{\omega - \omega_1} \tag{17}$$

Now the total number N of quanta is quite generally determined by s and ϕ, and may well exceed the maximum of "non-condensed" quanta N_n imposed by (16). For an introduction of the excess number m_l of quanta in ω_l over the number in thermal equilibrium,

$$m_l = n_l - n_{l,T}; \qquad \sum m_l = N - N_T \tag{18}$$

where N_T is the total number of quanta in thermal equilibrium, one finds from (8), (5), and (13),

$$S(T) = \phi \sum m_l (1 - e^{-\hbar\omega/KT}) \simeq \phi \sum m_l \frac{\hbar\omega_l}{kT} = \phi \frac{\hbar\bar{\omega}}{kT} (N - N_T) \tag{19}$$

Here $\bar{\omega}$ must have the range

$$\omega_1 \lessapprox \bar{\omega} \lessapprox \omega_2 \tag{20}$$

Also in approximation (13) one has $S(T) \simeq Zs$, so that

$$N = N_T + \frac{sZ}{\phi} \frac{kT}{\hbar\bar{\omega}} \tag{21}$$

Now $\bar{\omega}$ is limited by (20) and may therefore vary only slightly with s. Hence according to (21) N is linearly increasing with s. A value s_0 of s therefore exists above which $N = N_n$ can no longer hold because (16) can no longer be satisfied. In this case

$$N = n_1 + N_n = \frac{kT}{\hbar\omega_1 - \mu} + N_n \tag{22}$$

where μ approaches $\hbar\omega_1$ very closely. Its actual value follows from (21) and (22). Condensation into the mode ω_1 thus takes place.

It is now of great interest to note that apart from the relatively small variations permitted for $\bar{\omega}$, the excess $N - N_T$ is entirely determined by Zs/ϕ. The smaller ϕ, therefore, the smaller is the critical value s_0 required for condensation. Compared with other processes like energy transfer from acoustic (low frequency) vibrations the processes L_1 (cf.(2)) may indeed be expected to be rather slow (i.e. ϕ relatively small) because they must occur in quanta $\hbar\omega$. The processes L_2 (4), on the other hand, which can transfer smaller amounts contribute only in a higher order, $(\hbar\omega/kT)^2$, which is considered negligible in view of (13).

Assume now that condensation into the mode ω_1 has been established, so that a coherent longitudinal electric vibration exists in the substance. Non-linear effects associated with this excitation are then expected to lead to its further stabilization as pointed out for a simple model in Appendix I of [1], though the argument used there is very general. Roughly speaking the free energy associated with the vibration can be decreased if the system is permitted to undergo deformations. If these deformations are measured in terms of parameters, say η, then for small η the elastic energy associated with a deformation will be proportional to η^2 because in the absence of the vibrations the system was elastically in equilibrium. The energy associated with the electric polarization will, however, be linear in η—for small η. Hence a new equilibrium is established in which η is proportional to P^2, the mean square of the polarization. The total free energy then consists of a positive term proportional to P^2, and a negative one proportional to P^4, thus pointing to an instability at sufficiently large P^2. This may indicate a rupture or else stabilization under the influence of higher order terms in η and P^2. In the latter case a metastable state will be reached, and ϕ will then be very small. Further supply of energy s should then lead to instabilities at a later stage.

3. Discussion and Proposal of Experiments

Biological systems contain components capable of electric dipole oscillations. These interact through long-range Coulomb forces and thus establish a branch (or several branches) of longitudinal electric modes probably in a frequency range of 10^{11}–10^{12} sec^{-1}. The relevant components may be connected with certain regions in the cell membrane, with certain chemical bonds in particular with hydrogen bonds, or with regions containing non-localized electrons. If energy is supplied locally to one component (or removed from there) then in view of the long-range interaction this energy change is shared by all the components which establish the branch of electric modes. If the rate of energy supply is sufficiently large then, as shown in Section 2, the energy gets channelled into a single mode which then presents a strongly excited coherent longitudinal electric vibration. Its wavelength depends on details of the geometrical arrangement of the components. A certain fraction of the supplied energy, therefore, is not thermalized but stored in a single mode which then exhibits long-range phase correlations. With respect to the electric modes the system is thus maintained

through a flux of energy in a state of high order far from thermal equilibrium. In this excited state the mean value P^2 of the square of the electric polarization may be large and hence lead to deformations (and stresses) in the material. This in turn may lead to a relative stabilization of the excitation so that a relatively small supply of energy is required to maintain it. Continued energy supply of a higher magnitude must then ultimately lead to an instability.

If established the phenomenon proposed here should have a profound influence on biological properties like cell division which may involve relatively extensive regions. Thus it has been suggested in [1] that the deformations connected with the excitation should stimulate cell division. This stimulus would increase with increasing size of the cell. It would be partly due to the vibrations inside the cell under consideration, but partly it would arise from the electric fields based on the dipolar oscillations in other cells. This latter influence would disappear, however, when cells are densely packed for then deformations in the cell membrane no longer influence the dielectric response. Such an influence of packing has actually been observed; it is known as "contact inhibition".

Formation of certain bonds as required in the synthesis of giant molecules will feed energy into the branch if the particular bonds belong to the components which establish the electric modes. The coherent excitation, on the other hand, presents a reservoir of energy in a highly ordered form available for various uses.

Observations by Szent-Györgyi [7] may be of considerable relevance in this connection. He concludes that "cellular activities, like cell division or protein synthesis are dominated, to a great extent, by the electronic charges of the system", and he indicates that some of these electrons may be in non-localized states. Such electrons will take part in the proposed electric vibrations and reinforce them provided their density is not too high. Hence if cell division or protein synthesis are stimulated by our vibrations then additional (electronic) sources for it will increase these effects. A change must be expected, however, when the electron density becomes so high (larger than $10^{15}\,\mathrm{cm}^{-3}$) that their proper frequency exceeds ω_1. In this case the reaction on the original vibrations can no longer be neglected. This then may lead to a qualitative change in such cell activities as depend on our vibrations. It is suggestive, of course, to propose that this change characterizes cancer which accordingly would be caused by an excessive density of non-localized electrons in some region of a cell (e.g. in certain giant molecules). Carcinogenic molecules must then have the ability of transferring electrons to the relevant regions of a cell. This hypothesis could possibly be checked if ionizing radiation exists which produces "non-localized" electrons.

Such specific questions must, of course, be studied in detail in connection with the particular structures and processes. Most important in the first place, however, would be experimental establishment of the existence of the coherent vibrations in living systems. The magnitude of the electric polarization should be fairly high, but direct measurement seems difficult in view of the expected high frequency. A very interesting suggestion has been made, however, by

Palma [8]. He proposes investigation of the spectral distribution of scattered light of laser beams. One then deals essentially with Raman-like scattering and thus from the frequency shift obtains the frequency of the longitudinal vibrations. One would have to work with low intensities, of course, so as not to kill the organism.

Careri [9] proposes to investigate the infrared properties of biological systems. The oscillations considered here are of course longitudinal, and hence optically not active. Nevertheless they should be expected to produce a certain amount of radiation through surface effects. Also the deformations associated with the establishment of the proposed oscillations would influence the transverse (optical) resonance frequencies.

More indirect methods would work with the proposed biological effects of the electric vibrations. Thus the stimulus on a cell arising from the dipolar oscillations of other cells could be screened with the appropriate use of absorbers or otherwise altered with the use of filters or reflectors.

The proposals discussed in this paper are speculative. The derivation given in Section 2 in conjunction with the striking dielectric properties of biological systems seems to point definitely, however, to the possibility of the storage of supplied energy in a highly ordered form.

Note added in proof

I have now found that absorption of light ($\hbar\omega \gg kT$) may also lead to energy storage in a single state. This may be relevant to photosynthesis.

1. – Introduction.

The great success of molecular biology arises from the discovery of the detailed structure of biomolecules such as DNA and enzymes. No systematic spacial order was found, and it was concluded that these molecules do not possess a physical order. Physical order, however, does not express itself in spacial order only. Thus superfluid helium, or the electrons in a superconductor exhibit an order that might be termed « motional order ». This type of order is connected with the existence of macroscopic wave functions, which implies the existence of certain quantum phase correlations over macroscopic distances or the existence of coherent states.

Other correlations connected with the phase of oscillating systems rather than with those of macroscopic wave functions are also well known when those systems are lifted from their thermal equilibrium. A well-known example are laser systems which need not exhibit a spacial order as, *e.g.*, in the case of gas lasers.

Many other types of physical order may be imposed on certain systems

(*) Based on lectures delivered at the Symposium on « Interdisciplinary Aspects of Modern Physics », in Parma, Italy, May 3-7, 1976.

when they are lifted from their thermal-equilibrium state even though they are spacially disordered. This does not hold, however, for all systems, and no general criterium has been found, so far, which when satisfied permits particular systems to exhibit some type of order when energy is supplied to them. Most systems, however, simply raise their temperature.

Biological materials, when they exhibit typical biological properties, must be « fed », *i.e.* energy passes through them. This energy may arise from chemical processes, or it may be supplied by the Sun.

It seems rash, therefore, to conclude from the absence of spacial order —obtained from structural analysis—that no physical order exists in biological systems. On the contrary, it has been suggested several years ago that they belong to those systems in which the supply of energy imposes a characteristic order [1, 2].

In approaching these questions from the point of view of theoretical physics it must be realized that, in contrast to most materials usually treated in physics, biological materials have been selected through long evolutionary processes. As a consequence, they often show quite extraordinary properties, and, rather than ask whether some material properties seem likely, one should ask whether they are possible. Clearly, in the first place, the role of theoretical physics must be to decide what questions should be asked; subsequent developments should then work in close contact with experiments.

It has often been thought that exact knowledge of the atomic structure of a system will provide all answers at least in principle. This is already a basic mistake [3], even in the case of the physics of simple systems. Thus, for example, the above-mentioned concept of macroscopic wave function refers to the whole assembly of particles, *i.e.* it is a collective property which cannot in a simple way be reduced to properties of individual particles.

2. – General.

In looking for a striking material property common to most biological systems one will, no doubt, choose their dielectric properties [1, 2, 4]. Biological systems are, of course, not uniform, but composed of many different such systems. In ordinary physics, one would then extract each subsystem, *e.g.* a certain type of molecule, and determine its dielectric properties, *e.g.* its dipole moment. In solution this dipole moment, say μ_i, would be slightly different from the moment μ_v in vacuum owing to polarization effects. Such a procedure would be highly misleading in the biological case, say for water-soluble proteins. Their conformation is largely dominated by the interaction of their charged groups with the surrounding water and ions which thus form an integral part of the structure and hence of the measured dipole moment. Under these circumstances, very high internal electric fields may exist in such systems.

Most striking, of course, are the fields in cell membranes which have average values of the order of 10^5 V/cm, which in ordinary materials would require great precautions to avoid breakdown. Inhomogeneous regions, *e.g.* through proteins dissolved in the membrane, might lead to much higher local fields. These fields play a basic role in nerve conduction, but here weaker fields could fulfil the same purpose. Their role in the membranes of other cells is unknown.

One notices that the energy difference of a unit electronic charge across the membrane (about 10^{-6} cm) would, at room temperature T, amount to about $3kT$. This suggests that the transport of single charges obtains a significance against thermal noise.

Also in a field $F \sim 10^5$ V/cm the energy μF is larger than kT when μ is the dipole moment of a small protein, say $\mu \sim 300$ Debye units. This suggests that proteins dissolved in membranes are oriented by the field.

In addition, however, the whole membrane system is strongly polarized by the field. As a consequence, an oscillation of a section of the membrane—or of certain proteins dissolved in it—is connected with a corresponding electric vibration, so that the longest electric wave usually yields an electric-dipole vibration. According to one of our main suggestions, such vibrations are very strongly, coherently, excited in biological systems when they are active, *i.e.* when metabolic energy is available.

Now it must be realized that the displacement of a single ion by 10^{-6} cm produces a very large dipole moment of the order of 500 Debye units. It would be wrong, however, to neglect other processes arising from such displacements, for the change of electric field arising from this displacements may substantially alter the polarization in the neighbourhood of the ion (note that the electric field at a $3 \cdot 10^{-7}$ cm distance from the electronic charge is of the order of 10^6 V/cm) and cause other ions to move. Under these circumstances, one would expect such displacements to become stabilized, and our second principal suggestion states that biological systems have metastable states with very high electric polarization.

How can one support theoretically such general statements referring to a variety of complicated materials? It is already clear from the above that we are dealing with strongly nonlinear effects. This provides possibilities only occasionally contemplated in ordinary physics. Our method will be to formulate simple, but general models which do show the required properties. General conditions required in these models then impose corresponding conditions on the respective biological systems. If experiments confirm the theoretical predictions, then we can conclude that the molecular evolution has led to the selection of materials with the required properties. This does not imply that other systems do not exist which do not have the required properties, though from a structural point of view they could be very similar to the systems which

do have these properties. The difference between the two would then rest in their nonlinear behaviour, *i.e.* in properties of certain excited states which would not be revealed in structural analysis.

3. – The vibrational model.

Any system containing charged particles is capable of long-wave electrical vibrations. Such a system need not be homogeneous. One of the characteristics of these vibrations is the existence of a lowest frequency $\omega_1/2\pi$, different from zero. Our system is assumed to possess such modes, $\omega_1, \omega_2, \ldots, \omega_z$. They are considered not to interact with each other, but to be strongly coupled to the surroundings, *i.e.* to the other modes of the systems which will be treated as a heat bath at temperature T. Let n_k be the number of quanta $\hbar\omega_k$ in the mode ω_k. Then, through first-order processes, single quanta $\hbar\omega_k$ may be emitted to or absorbed from the heat bath, so that the rate of change $\dot{n}_{k,1}$ of n_k due to these processes is [2, 5]

$$\dot{n}_{k,1} = -\varphi\big(n_k \exp[\beta\hbar\omega_k] - (n_k + 1)\big)\,, \tag{3.1}$$

where $\beta = 1/kT$, and φ will depend on T and, in general, also on ω_k. For simplicity we shall neglect the ω_k-dependence. The ratio of emission to absorption processes is governed by detailed balance.

Similarly, for second-order processes we find

$$\dot{n}_{k,2} = -\chi \sum_j \big(n_k(1 + n_j)\exp[\beta\hbar\omega_k] - n_j(1 + n_k)\exp[\beta\hbar\omega_j]\big)\,. \tag{3.2}$$

Again, apart from depending on T, the transition probability χ could depend on k and j, but we shall neglect this. This will greatly simplify the calculations, but should have no influence on the main results.

We note that, on this choice,

$$\sum_k \dot{n}_{k,2} = 0\,, \tag{3.3}$$

i.e. such processes lead to interchange of quanta $\hbar\omega_k$ without alteration of their total number.

Now we consider that energy is supplied at the rate s_k to the mode ω_k. We then find, for the total rate of change $\dot{n}_k$,

$$\dot{n}_k = s_k - \varphi\big(n_k \exp[\beta\hbar\omega_k] - (n_k + 1)\big) - \\ - \chi \sum_j \big(n_k(1 + n_j)\exp[\beta\hbar\omega_k] - n_j(1 + n_k)\exp[\beta\hbar\omega_j]\big)\,. \tag{3.4}$$

We wish to solve this equation for the stationary case, *i.e.* when

$$\dot{n}_k = 0 \,. \tag{3.5}$$

We may derive the general behaviour of n_k in a simple manner, though it would be difficult to solve this system of quadratic equations exactly.

Summation over k with the definition

$$S = \sum s_k \tag{3.6}$$

yields

$$S = \varphi \sum_k \left(n_k \exp\left[\beta\hbar\omega_k\right] - (n_k + 1)\right) . \tag{3.7}$$

Introducing the total number of quanta N,

$$N = \sum n_k \,, \tag{3.8}$$

we find with

$$\omega_1 \leqslant \omega_k \leqslant \omega_z \tag{3.9}$$

that $\left(\text{note } \sum_k 1 = z\right)$

$$N\left(\exp\left[\beta\hbar\omega_z\right] - 1\right) > S/\varphi + z > N\left(\exp\left[\beta\hbar\omega_1\right] - 1\right) . \tag{3.10}$$

This means that N must increase proportional to S if the supply S is sufficiently large.

Now define μ by

$$\exp\left[-\beta\mu\right] = \frac{\varphi + \chi \sum (1 + n_j)}{\varphi + \chi \sum n_j \exp\left[\beta k\omega_j\right]} , \tag{3.11}$$

so that

$$1 - \exp\left[-\beta\mu\right] = \frac{\chi \sum \left(n_j \exp\left[\beta\hbar\omega_j\right] - (1 + n_j)\right)}{\varphi + \chi \sum n_j \exp\left[\beta\hbar\omega_j\right]} . \tag{3.12}$$

From (3.7) it then follows that

$$\mu \geqslant 0 \tag{3.13}$$

and

$$1 - \exp\left[-\mu\beta\right] = \frac{\chi}{\varphi} \frac{S}{\varphi + \chi \sum n_j \exp\left[\beta\hbar\omega_j\right]} \geqslant 0 . \tag{3.14}$$

Equation (3.4) with (3.5) can thus be formally solved by

$$n_k = \left(1 + \frac{\varphi}{\chi} \frac{s_k}{S} \left(1 - \exp\left[-\beta\mu\right]\right)\right) \frac{1}{\exp\left[\beta(\hbar\omega_k - \mu)\right] - 1} , \tag{3.15}$$

and $n_k \geqslant 0$ together with (3.13) yields

$$\hbar\omega_1 > \mu \geqslant 0 \,. \tag{3.16}$$

This inequality permits the establishment of an upper limit for N although μ is a complicated function of all the n_k. For (3.15) then yields

$$N = \sum n_k < \left(1 + \frac{s_m(1 - \exp[-\beta\hbar\omega_1])\,\varphi}{\chi S}\right) \sum_k \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,, \tag{3.17}$$

where s_m is the largest of the s_k.

Clearly, if the sum in (3.17) can be replaced by an integral, then for $\mu \sim \hbar\omega_1$ a value independent of the s_k will be reached. Moreover, always $s_m/S \leqslant 1$, so that an upper limit for N independent of S is obtained. This contradicts the conclusion drawn from (3.10), according to which N must increase proportional to S if S is sufficiently large. This situation is the same as normally found in Einstein condensation of a Bose gas. Thus the replacement of the sum by an integral is incorrect; μ takes a value close to $\hbar\omega_1$ such that n_1 becomes very much larger that all the other n_k.

It follows then that a single mode ω_1 gets very strongly (coherently) excited when the energy supply is larger than a critical one.

As special cases we may consider that all s_k are equal. Then

$$s_k/S = 1/z \tag{3.18}$$

and (3.15) becomes

$$n_k = \left(1 + \frac{\varphi}{\chi_z}(1 - \exp[-\beta\mu])\right) \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,. \tag{3.19}$$

As another extreme consider that all s_k vanish except for $k = k_0$.

Then

$$s_k = S\delta_{k,k_0}\,, \qquad s_{k_0} = S \tag{3.20}$$

and

$$n_k = \left(1 + \delta_{k,k_0}(1 - \exp[-\beta\mu])\frac{\varphi}{\chi}\right) \frac{1}{\exp[\beta(\hbar\omega_k - \mu)] - 1}\,. \tag{3.21}$$

To understand qualitatively these conclusions, we notice first of all that the case $\chi = 0$ leads to a completely trivial result, namely

$$n_k = \left(1 + \frac{s_k}{\varphi}\right) \frac{1}{\exp[\beta\hbar\omega_k] - 1}\,, \qquad \text{if } \chi = 0\,, \tag{3.22}$$

i.e. to a modified thermal-equilibrium Planck distribution. It will be noticed from (3.11) that $\chi = 0$ in fact entails $\mu = 0$ and thus eliminates the occurrence of Bose condensation. Thus the nonlinear terms χ arising from a strong interaction with the heat bath tend to force the system into a thermal-equilibrium distribution making use of a chemical potential μ.

A main difference from ordinary condensation of a Bose gas in thermal equilibrium should also be noted. There the ordered (condensed) state is reached by lowering the temperature. In our case, the ordered state is reached by supplying sufficient external energy to the system. Quite a similar situation prevails with respect to the second of our concepts (sect. **4**).

The above model, naturally, is a very simplified version of any actual situation. It has a very general consequence which might not depend on modifications required in particular cases, namely the coherent excitation of a polar mode when energy supply exceeds a critical magnitude.

Which frequencies should we anticipate? Roughly speaking, if a polarized system of linear dimensions l carries out long-wave elastic vibrations (*e.g.* breathing vibrations), then the electric polarization of the system implies coexistence of an electric-polarization vibration with the same frequency

$$\nu \sim v/l\,, \tag{3.23}$$

where v depends on the elastic constants and can formally be expressed as a velocity of sound. Thus $l = 10^{-6}$ cm and $v = 10^5$ cm/s would yield $\nu = 10^{11}$ Hz, but $l = 3 \cdot 10^{-7}$ cm (small protein) with $v = \frac{1}{3} 10^5$ cm/s yields, of course, the same value. The band of polarization waves ω_k would then consist of the interacting vibrations of such units, and also of higher vibrational states of the same unit. It must be emphasized again that the existence of long polarization waves does not require homogeneous material.

A further condition is the absence of unduly high friction, which probably will mean that surfaces facing water should not move. This does not hold, however, for structured water, which is to be considered as an integral part of the particular biological unit. Most likely, these conditions are satisfied by proteins in or near membranes. Thus, if $\Delta\nu$ is the frequency width, we have in this case

$$\nu \sim 10^{11}\ \mathrm{Hz}\,, \qquad \frac{\Delta\nu}{\nu} \ll 1\,, \qquad s > s_0 \tag{3.24}$$

as condition for the excitation of coherent vibrations. Here s is an appropriate average over the rate of energy supply and s_0 is the threshold value for Bose condensation.

It should be emphasized that other frequencies, both higher and lower, are well feasible. Thus larger units such as DNA-protein complexes might

well possess lower frequencies. Higher ones, on the other hand, may be based on a combination of the various rotational and vibrational subgroups of relevant molecules.

4. – The high-polarization model.

Consider [6] a polarizable material, polarization P. Its mean « self-energy » can then be written as $\frac{1}{2}a^2\overline{P^2}$, where the bar indicates an appropriate average and the positive a^2 depends on the polarizability, including size and shape of the material. These definite size and shape imply the elastic energy of the material to be a minimum relative to small deformations. If these are measured in terms of a deformation parameter η, then on deformation the elastic energy increases by $\frac{1}{2}\eta^2\varepsilon$, where $\varepsilon > 0$ depends on the elastic properties. In the case of a sphere, for instance, the deformation could produce an ellipsoid with eccentricity η. Now the polarizability in general is not an extremum at $\eta = 0$, so that a^2 would have to be replaced by $a^2(1 + c\eta)$, where c may be positive or negative. The total contribution to the free energy thus amounts to

$$U = \tfrac{1}{2}a^2(1 + c\eta)\,\overline{P^2} + \tfrac{1}{2}\eta^2\varepsilon\,. \tag{4.1}$$

Minimizing with regard to η at fixed $\overline{P^2}$ yields

$$\eta = -\frac{1}{2}\frac{ca^2}{\varepsilon}\,\overline{P^2}, \tag{4.2}$$

so that

$$U = \frac{1}{2}a^2\,\overline{P^2}\left(1 - \frac{1}{4}\frac{c^2}{\varepsilon}a^2\,\overline{P^2}\right). \tag{4.3}$$

Thus increasing $\overline{P^2}$ ultimately may lead to decreasing U. At this stage, the linear approximation η and the quadratic one in P will probably have become invalid. Higher-order terms may thus reverse this trend and lead to a minimum of U at a certain $\overline{P^2}$. If U at this value is negative, then the material would acquire a spontaneous dipole moment. If U is positive, then a metastable state with spontaneous polarization exists.

These conclusions are of a very general nature. They follows from the shape dependence of the polarizability and require the material to be sufficiently soft, *i.e.* ε should be sufficiently small.

They can be extended to a dynamical model composed of a polarization field $\boldsymbol{P}$ and an elastic (acoustic) field $\boldsymbol{A}$. Let ω_0 be the circular frequency of long-wave polarization waves in the absence of any interaction with the elastic field, then with such an interaction the density of potential energy has the

form

$$W = \tfrac{1}{2}\omega_0^2 \boldsymbol{P}^2 + \left(\tfrac{1}{2}v^2(\operatorname{div}\boldsymbol{A})^2 + c\boldsymbol{P}^2 \operatorname{div}\boldsymbol{A}\right)(1 - d^2\boldsymbol{P}^2)\,, \tag{4.4}$$

where v is the velocity of sound, d^2P^2 is an *ad hoc* term introduced to achieve stabilization for high P^2.

Note that, for long waves,

$$\varrho = \operatorname{div}\boldsymbol{A} \tag{4.5}$$

may be introduced as change in density. The static case requires minimization of (4.4) with regard to ϱ and P^2, so that for homogeneous displacements

$$\varrho = -\frac{cP^2}{v^2}\,, \tag{4.6}$$

yielding

$$W = \frac{1}{2}\omega_0^2 P^2 - \frac{1}{2}\frac{c^2}{v^2}(1 - d^2P^2)\,. \tag{4.7}$$

Apart from the different notation, this result corresponds to (4.3) except that the d^2P^2 term leads to a stabilization at high P^2.

Now we can introduce the density of kinetic energy

$$K = \tfrac{1}{2}(\dot{\boldsymbol{P}}^2 + \dot{\boldsymbol{A}}^2) \tag{4.8}$$

and hence from the Lagrangian density L obtain the equations of motion in the usual way,

$$\delta\int L\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}t = \delta\int (K - W)\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}t = 0\,, \tag{4.9}$$

where $\boldsymbol{r}$ is the space vector and t the time. The assumption that acoustic phonons are absent then permits the elimination of the $\boldsymbol{A}$-field and yields an equation of motion of the form

$$\ddot{\boldsymbol{P}} + \frac{\partial V(P)}{\partial \boldsymbol{P}} = 0\,. \tag{4.10}$$

The effective potential $V(P)$ has the form

$$V(P) = A + BP^2 + CP^4\,, \tag{4.11}$$

apparently a harmless anharmonic oscillator. This is misleading, however, for the coefficients A, B, C depend on the mean square amplitude

$$p = \overline{P^2}\,, \tag{4.12}$$

such that

$$A = \frac{1}{2}\frac{c^2}{v^2}p^2, \tag{4.13}$$

$$B = \frac{1}{2}\left(\omega_0^2 - 2\frac{c^2}{v^2}p - \frac{d^2c^2}{v^2}p^2\right), \tag{4.14}$$

$$C = \frac{c^2d^2}{v^2}p\,. \tag{4.15}$$

For small p clearly the CP^4 term is negligible and B becomes $\omega_0^2/2$, so that an harmonic oscillation with frequency ω_0 is obtained.

For increasing p, however, the magnitude of B decreases, *i.e.* the mode softens. For appropriate values of the parameters it is then found that a metastable state with permanent polarization $\pm P_0$ exists and that the system has two branches of oscillation: one around $P = 0$ and another with limited amplitude around $\pm P_0$. In this case, the effective potential $V(P)$ has a maximum at $P = 0$ and two minima at $P = \pm P_0$. The value of P_0 is found by minimizing (4.7), which yields

$$P_0^2 = p_0 = \frac{1}{3d^2}\left(1 + \sqrt{1-\lambda}\right), \tag{4.16}$$

where

$$\lambda = \frac{3v^2d^2\omega_0^2}{c^2}. \tag{4.17}$$

Thus $\lambda < 1$ is a necessary condition for the existence of a P_0, and it can be shown that this state is metastable, *i.e.* has positive energy when

$$\frac{3}{4} < \lambda < 1\,. \tag{4.18}$$

For $\lambda < \frac{3}{4}$ its energy is negative, *i.e.* it becomes the (ferroelectric) ground state.

We notice again that small v^2, *i.e.* softness of the material, favours the establishment of a polarized state. We also note that in many ferroelectric materials the effective potential has a minimum at $P = 0$ at high temperatures. The mode softens as we decrease the temperature towards the Curie point and below we find two minima at $P \pm P_0$.

In our case $V(P)$ has its minimum at $P = 0$ at low energies, but supply of energy may establish the quasi-ferroelectric state with minima at $P = \pm P_0$. Thus here as in the case of sect. **3** a long-range order—coherent vibrations, or permanent polarization—is established through the supply of energy.

Clearly actual biological materials will behave in a much more complex way than discussed in this simple model. We should recall in this case that structured water and various ions are to be considered as an integral part of the system.

This implies considerably higher nonlinear effects than discussed above. While these will have to be treated case by case, it seems that they usually will contribute to the stabilization of our metastable state. Thus a polarized molecule will shift mobile ions so that its energy is lowered; in turn, this will, of course, affect the magnitude of polarization.

5. – General consequences.

The two types of excitation discussed in sect. **3** and **4** can have far-reaching biological consequences. First of all, it should be noticed that they require supply of energy, *i.e.* activation. Both can then lead to forces which were absent before activation, and to storage and transport of energy.

Cell water contains considerable amounts of small ions which tend to screen any static electric charges at short range. Hence a system activated to a high dipole moment (sect. **4**), *e.g.* a protein, may exert considerable forces in water-free regions, but will be screened for long-range interaction. This screening does not hold, however, for an oscillating field at frequencies of the order of 10^{11} Hz (sect. **3**). Thus, if the coherently excited vibration represents an oscillating giant dipole, then long-range forces may be activated. They will be shown to be frequency selective.

Consider two oscillating giant dipoles at distance R with frequencies ω_e and ω_s, respectively, in the absence of interaction [4, 7]. At sufficient distance, their interaction is essentially dipolar, since other interactions decrease much more rapidly with R. The combined system then has two normal modes ω_+, ω_-, where

$$\omega_\pm^2 = \tfrac{1}{2}(\omega_e^2 + \omega_s^2)\left(1 \pm (q^2 + Q^2)^{\frac{1}{2}}\right). \tag{5.1}$$

Here (by assuming $\omega_e^2 \geqslant \omega_s^2$)

$$q = \frac{\omega_e^2 - \omega_s^2}{\omega_e^2 + \omega_s^2} > 0 \tag{5.2}$$

and Q essentially is the ratio of the interaction energy between the two giant dipoles and their internal potential energies.

It thus depends on the distance as $1/R^3$.

In the particular case that the giant-dipole oscillations in the two molecules consist in correlated oscillations of, respectively, z_e and z_s elastically bound ions of charge e and of equal mass M, then

$$Q = \gamma e^2 (z_e z_s)^{\frac{1}{2}} / M R^3 (\omega_e^2 + \omega_s^2), \tag{5.3}$$

where γ is a numerical constant.

Clearly the expression for ω_-^2 holds only when $\omega_-^2 > 0$; at short distance thus mode softening occurs.

The interaction energy I is defined as the difference of the free energy F at distance R from its value at $R \to \infty$. Now consider the case that the state with the lower frequency has been coherently excited (n_- quanta) so that the contribution of ω_+ to F can be neglected. Then

$$I = F(R) - F(\infty) = n_- \hbar(\omega_-(R) - \omega_-(\infty)) = \tag{5.4}$$

$$= \frac{1}{\sqrt{2}} n_- \hbar(\omega_e^2 + \omega_s^2)^{\frac{1}{2}} \left\{(1 - \sqrt{q^2 + Q^2})^{\frac{1}{2}} - (1 - q)^{\frac{1}{2}}\right\}.$$

This energy is always negative, *i.e.* attractive. Furthermore, if $\omega_e \neq \omega_s$, then at sufficient distance $Q^2 < q^2$ and we find, after development,

$$I = -\frac{\hbar n_-}{4\sqrt{2}} (\omega_e^2 + \omega_s^2)^{\frac{1}{2}} \frac{Q^2}{q(1-q)^{\frac{1}{2}}} \propto -\frac{1}{R^6}. \tag{5.5}$$

If, however, $\omega_e^2 \simeq \omega_s^2$ and $Q^2 \gg q^2$, $q^2 \ll 1$, then

$$I \simeq -\frac{\hbar n_-}{\sqrt{2}} (\omega_e^2 + \omega_s^2)^{\frac{1}{2}} Q = -\frac{\hbar n_-}{\sqrt{2}} \frac{\gamma e^2 (z_e z_s)^{\frac{1}{2}}}{M(\omega_e^2 + \omega_s^2)^{\frac{1}{2}}} \frac{1}{R^3} \propto -\frac{1}{R^3}. \tag{5.6}$$

In this case of near resonance, the always attractive interaction has very long range. Roughly, if

$$U = \hbar n_- \omega_e \tag{5.7}$$

is the energy of excitation, using $\omega_e \simeq \omega_s$, we have

$$I \simeq -U \frac{e^2 (z_e z_s)^{\frac{1}{2}}}{M \omega_e^2 R^3}. \tag{5.8}$$

While thus activation of coherent vibrations may lead to long-range, frequency-selective interaction, activation of the polar state leads to short-range nonselective forces which might facilitate transport of ions within the particular material, or across it.

Long-range selective forces may lead to selective transportation of molecules like enzymes and thus initiate a particular trend of chemical events. It might also be relevant for the transportation of larger units.

It has been suggested that these properties are an essential feature in the high catalytic power of enzymes [4, 6, 8]. Thus the high internal fields arising from the strongly polarized state could reduce activation energies, while excitation of coherent modes could be used for the transport of energy.

Independently [9], the same conclusion has been reached from an analysis of a great variety of enzymatic reactions.

In [10] it has been suggested that the selective long-range interaction (sect. **3**) may be responsible for the attraction of a homologous pair of chromosomes in meiosis—an interaction which according to [11] has till then remained « a great mystery ».

A number of other possible consequences has been discussed elsewhere [1, 2, 4, 12].

Selective long-range interaction in conjunction with the existence of highly polar metastable states may also be decisive for the establishment of the well-known low-frequency electric vibrations in the brain, whose biological significance is only now being explored [13]. It has been shown that the long-range coherent interaction (based on the 10^{11} Hz coherent vibrations) could in an enzyme-substrate system lead to collective enzymatic reactions resulting in slowly varying (periodic) excitation and de-excitation of the system of enzymes from the only slightly polar ground state into the highly polar metastable state. Thus a slow chemical oscillation is connected with a corresponding electric vibration. The strong electric interaction between the highly polar states in conjunction with the considerable damping of electric currents then imposes on them a limit cycle condition, which recently has been investigated [14]. This model requires large regions to oscillate coherently as has actually been found [15].

6. – Experimental evidence.

In active biological systems experimental evidence for the existence of coherent electric oscillations in the 10^{11} Hz region would require methods which have not yet been fully developed (cf., however, Note added in proofs). Evidence does exist, however, that radiation in this frequency region may have very strong effects on such systems. The most comprehensive report on such effects has been presented in a meeting of the USSR Academy of Science [16]. Properties of a great variety of objects have been found to be strongly influenced by coherent electromagnetic waves in the $(5 \div 7)$ mm (vacuum) wave-length region. Almost all experimental results have in common:

i) That they very strongly depend on frequency in a region in which the optical constants have the appearance of broad bands; often the biological effects showed typical resonance character.

ii) The dependence on intensity exhibits a threshold below which no biological effects occur and above which they are nearly independent of intensity.

To interpret these results [17], we assume that these biological effects are initiated by a first step which is sensitive to a radiation followed by a chain of other possibly very complicated effects which are insensitive to it. The

first step might be connected with a long-range interaction arising from coherent excitation of a molecule, *e.g.* an enzyme which could be attracted to its substrate. Let the time required for this be $t_1(s)$, where s represents the radiative supply of energy to it. According to sect. **3**, excitation of the coherent mode requires a threshold s_0. With growing s ($> s_0$) the time $t_1(s)$ will decrease, so that the total time for the whole process

$$t = t_1(s) + t_2 \to t_2 \tag{6.1}$$

will approach the s-independent time t_2 required for the s-independent chain of further biological steps. Thus in these experiments we find

$$\nu \sim \frac{1}{2} 10^{11}\,\mathrm{Hz}\,, \qquad \frac{\Delta\nu}{\nu} \ll 1\,, \qquad s > s_0\,, \tag{6.2}$$

as predicted in (3.24).

We note that the resonancelike frequency dependence in a region in which the optical constants show little frequency dependence is the best proof that we are not dealing with thermal effects.

The magnitude of s_0 has been estimated theoretically [18] from calculations using methods of laser physics and found of the order 0.04 mW/cm², which agrees with some of the experimental results (*).

The Russian experiments range from various effects on bacteria, growth of yeast cultures, influence on human and animal cells to effects on various genetic properties. Depending on the type of process stimulated by the radiation, a certain biological activity might be increased or decreased. Independently, on a smaller scale and without extensive frequency resolution, biological effects near $0.7 \cdot 10^{11}$ Hz and $1.4 \cdot 10^{11}$ Hz have been found by other investigators [19, 20].

In some of the Russian experiments [21], the biological resonance has been found as narrow as $2 \cdot 10^8$ Hz. This can be understood on the assumption that the only broadening of the excited giant-dipole vibration arises from its electric coupling to the thin layers of structured water whose dielectric absorption lies in this region [22, 23]. The remarkable absence of other frictional effects reminds one, of course, of the various suggestions of the existence of room temperature superconductive regions in biological systems. So far no definite experimental proof for their existence has been found. These narrow resonances are most likely to occur when the level which is excited by the radiation is identical with the level which is strongly populated in Bose condensation,

(*) It should be mentioned that in [18] the presentation of a quadratic Hamiltonian is misleading, though the results are correct. For, as required, the authors do use the influence of a heat bath which in terms of a Hamiltonian would require at least 4th order terms to obtain their eq. (8*a*)—as can be seen from our eq. (3.2) which is responsible for the occurrence of a chemical potential μ.

i.e. when in (3.21) this is the level K_0. Broader bands must be expected when this is not the case.

In experiments of this type, one must be prepared for unexpected non-linear effects of the imposed radiation. Thus, within the range in which the radiation is absorbed, in the first place coherent excitation of some molecules is expected. If the same type of molecules is present at greater depth, then they in turn may become excited by transfer of the excitation energy from the outside molecules. Thus the excitation may be expected to move beyond the penetration depth of the imposed radiation.

Now, in turning to the excitation of the strongly polar metastable state, one would, of course, attempt to excite this state by bringing the molecule in question into a strong electric field. It should be of interest in this context that investigations on nerve membranes have led to the conclusion that the electric field in the membrane makes it nearly impermeable to Na^+ and K^+ ions, whereas the absence of the field leads to a much higher permeability presumably through proteins dissolved in the membrane; it is suggestive to attribute these two different properties to the two states in the proteins.

More direct evidence for conformational changes of certain molecules in membranes due to changes of the electric field is available [24].

A number of other possibilities has been discussed in [4], including results found with the electret method [25] and with laser-induced stimulation of enzyme activity at very high dilution [26].

Thus, while experiments available at present seem to support the theoretical predictions, in a general way much greater refinement of the experimental methods is desirable to obtain more specific experimental results. This in turn should stimulate theoretical investigations of a more specific nature.

7. – Cancer.

The problem of cancer is one of the control of cell division. While bacterial cells under appropriate conditions keep on dividing, cells in a fully grown differentiated tissue or organ divide relatively rarely, though they divide more rapidly in growing tissues and organs. We shall assume that a controlling agency belonging to the whole organ, *i.e.* a collective property, exists and that individual cells respond to it.

The nuclei of these cells contain a DNA-protein complex, whose detailed structure is not well known, though it seems reasonable to assume that its spacial arrangement differs in different organs and depends on the type of differentiation that has taken place. Now we shall assume that these materials are capable of electric vibrations which can be excited coherently in the sense of our model (cf. sect. **3**). Thus metabolic energy would be used to excite these vibrations at a well-defined frequency (or frequencies) which would be char-

acteristic for the particular organ or tissue. Note that experiments discussed in sect. **6** confirm the existence of such vibrations in some biological materials.

This then implies that a coherent electric vibration carried collectively by the individual nuclei extends through the whole tissue (organ), and that the vibrations of each individual cell respond to it and are thus held in the appropriate phase, such that the total electric energy is a minimum. In general, this vibrating polarization field will form a complicated spacial pattern.

Now, preceding cell division, the DNA-protein complex of the nucleus of a cell must unfold and may then be expected to change some of its physical characteristics, such that it looses its resonance with the collective mode. This implies that its energy of interaction with the collective mode is increased, *i.e.* energy has to be spent to perform this change (apart from changes in the internal energy). This energy may not always be available and, as a consequence, the interaction of an individual cell with the collective mode acts as an inhibition on cell division. The strength of this inhibition depends on the magnitude of excitation of the collective mode. This excitation may well depend on the size of the tissue because of the long range of the interactions as discussed in sect. **5**. The possibility of a size-dependent inhibition on cell division thus exists.

A situation thus prevails which in some respects corresponds to order in physical systems described in terms of an order parameter as, for instance, in lasers (cf. also [27]). In our case, the collective vibration represents the order parameter. It is built up of the contributions of the relevant vibrations of the individual cells, and they in turn obey the instruction of the order parameter, namely not to divide.

Now assume that changes have taken place in a particular cell such that its frequency is altered. This cell no longer contributes to the coherent collective vibration, whose intensity will thus be slightly reduced, nor does this cell obey the instruction of the coherent mode, *i.e.* the inhibition to divide disappears. The slight reduction of intensity of the coherent mode due to the change of property of a single cell should have a minute effect on other cells. A critical intensity should exist, however, below which the control of cell division no longer is effective. It is feasible, therefore, that something like a phase transition takes place from the controlled to the uncontrolled state once a critical number of cells has been affected.

Such an approach requires that—while the controlling vibration is strong enough—a cell in the tissue will be induced to transfer into the correctly vibrating state provided it possesses such a state, for only thus can the system exhibit stability.

This may have two types of consequences:

i) Differentiation may be expected to consist in rearrangements of the DNA-protein complex, such that it obtains relevant frequencies assumed

absent before differentiation. Under the influence of the coherently excited mode(s) of the particular tissue (organ), this transition is energetically favourable and hence is stimulated [28]. The differentiated cell then gets subjected to the control.

ii) Mutations which lead to alterations in the relevant frequency(cies) are energetically less favourable than those which do not alter them and which thus still respond to the control and are, therefore, statistically less likely.

Thus, in our model, the sufficiently excited collective vibration exerts an influence on individual cells which inhibits both cell division and « unfavourable » mutations (which would not react to control) and, at the same time, tends to bring cells which do not respond to the control into states in which they do react to it.

If by external influences some cells are changed such that their relevant frequencies are altered, then *a*) these cells no longer respond to the control and *b*) the strength of the controlling vibration is reduced. Both these effects are rectified by the above-mentioned stabilizing influence provided they are not too large. If, however, the number of altered cells is so large that the excitation of the collective mode is reduced below a critical value, then the control becomes ineffective. As a consequence, all cells divide more frequently, and simultaneously « unfavourable » mutations (having « wrong » frequencies) become possible, *i.e.* a phase transition from order to disorder (cancer) has taken place.

It should be noted here that the frequencies of the changed cells will differ from each other; thus no collective mode with sharp frequency will arise: the ordered state has a sharp frequency, the disordered one a broad frequency band.

Which are the external influences that can lead to a change in frequencies? It has been shown [2] that supply of unattached electrons could have such an influence. Such electrons might occur in the conduction band of various molecules. They are then capable of long-wave electric vibrations, plasma waves, whose frequencies increase proportional to the square root of the electron density. These vibrations will interact with the coherent vibrations of our system and under appropriate circumstances can significantly alter the frequency.

Such electrons might be supplied by excitation through ultraviolet light. Or they might be supplied by foreign molecules which are electron donors. A change of frequency might, of course, also arise from an invasion by foreign molecules into the relevant DNA-protein complex.

Other possibilities may arise, however, if we assume that the frequency sharpness found in some of the experiments discussed in sect. **6** is a feature of the proposed collective vibrations. It has been previously indicated that electric coupling with structured water would account for the measured frequency width indicating absence of all other types of friction. Some structural

changes might be sufficient to eliminate this property and with it the effectiveness of control. The affected cells could then still have frequencies in the region of the nonaffected one, but exhibit greater width.

The model described here can without difficulty be presented in mathematical form by using well-known techniques developed, *e.g.*, in connection with laser physics [29]. Even without doing so, it will be noticed that the term « collective mode » might be given a different physical interpretation from the one suggested here, provided individual cells have selective properties which enable them to react to the collective mode and which could be destroyed by external influences.

If the interpretation of the collective mode as a vibration is correct, then one would wish to know the order of magnitude of relevant frequencies. The 10^{11} Hz region is, of course, a first candidate both for theoretical and experimental reasons (sect. **3** and sect. **6**). It might well be, however, that quite different frequency regions are also of importance, and it will in the first place be a task for experiments to find these frequencies.

Most desirable would, of course, be experiments which measure the excitations of the biological material *in vivo*. For frequencies near or above 10^{12} Hz laser Raman effect would be suitable. For frequencies near or below 10^{11} Hz, this becomes inefficient because of the broadening of the primary line through water. Thus the frequencies for which selective biological effects have been discovered (sect. **6**) are beyond the available range. New methods (corresponding to Brillouin scattering) are being developed, but must still be adapted for use in biological materials.

It should be emphasized in this context that vibrations in this frequency range may very sensitively depend on details of the arrangements and on the conformation of relevant molecules including structured water and ions, which must both be considered an integral part of the system. Investigations on molecules, *e.g.* proteins, outside their natural surroundings may but need not give relevant results. Something similar holds of the measurement of absorption of electromagnetic waves by the biological material. We have mentioned above that the excited collective mode might have a complicated spacial pattern. This will probably not be optically active. Optically active modes are, however, to be expected in the neighbourhood of each « relevant » frequency; they would show up as a band rather than as the relatively sharp line we expect from the collective mode, except in cases in which the spacial pattern is homogeneous in the range of penetration of the electromagnetic wave—as might hold for thin layers of the material. It should be emphasized in this context that some of the experiments mentioned in sect. **6** exhibit extremely sharp frequency response for biological effects, whereas broad bands are found in optical measurements. Nevertheless changes found in the optical spectra would certainly indicate major changes and could thus provide valuable information.

One might in particular wish to measure the changes arising from the excitation of electrons into the conduction bands discussed above. It must be pointed out in this context that plasma waves are not optically active except through the influence of surfaces. The same is likely to hold of the collective mode with which they interact. For optical detection, therefore, one would use biological samples which are small compared with the wavelength of the electromagnetic radiation with the relevant frequency. When using a thin layer, then the electric vector should have a component perpendicular to the surface. Internal surfaces may, however, also be effective which to some extent may relax these conditions.

Finally biological effects of the electromagnetic radiation are most likely to provide significant results. If we can learn from the experiments mentioned in sect. **6**, then we might expect sharp frequency resonances in the biological response. As a consequence, a tunable source will be required.

In the first place, we would expect the naturally excited mode to be in its most favourable state. External excitation of modes with the same frequency, though probably with different spacial pattern, would thus interfere with the efficiency of the collective controlling mode. In a grown material this would then increase the rate of cell division, while in a growing system it should decrease it.

Finally, when under the influence of external agencies a sufficient number of cells have undergone changes in frequency to the extent that the controlling collective mode has become ineffective, then a stronger externally imposed vibration of the correct frequency (though possibly with different spacial pattern) might still be able to restore the original order. This, of course, would be the most startling influence of electromagnetic waves on biological systems.

Note added in proofs on 27/9/1977.

Conclusive evidence for the metabolic excitation of vibrational states in bacteria has now been obtained by Raman effect. WEBB and STONEHAM (*Phys. Lett.*, **60** A, 267 (1977)) show that, while resting bacteria exhibit only bands in the (100÷200) cm^{-1} region, active bacteria show strong lines. Moreover (S. J. WEBB, M. E. STONEHAM and H. FRÖHLICH: *Phys. Lett.*, A, in print), the intensity ratio of anti-Stokes to Stokes lines in thermal equilibrium should be about 0.5, whereas it is found close to 1.0, evidence for strong nonthermal excitation.

The neuronal cytoskeleton has been hypothesized to play a role in higher cognitive functions including learning, memory and consciousness. Experimental evidence suggests that both microtubules and actin filaments act as biological electrical wires that can transmit and amplify electric signals via the flow of condensed ion clouds. The potential transmission of electrical signals via the cytoskeleton is of extreme importance to the electrical activity of neurons in general. In this regard, the unique structure, geometry and electrostatics of microtubules are discussed with the expected impact on their specific functions within the neuron. Electric circuit models of ionic flow along microtubules are discussed in the context of experimental data, and the specific importance of both the tubulin C-terminal tail regions, and the nano-pore openings lining the microtubule wall is elucidated. Overall,

these recent results suggest that ions, condensed around the surface of the major filaments of the cytoskeleton, flow along and through microtubules in the presence of potential differences, thus acting as transmission lines propagating intracellular signals in a given cell. The significance of this conductance to the functioning of the electrically active neuron, and to higher cognitive function is also discussed.

Keywords: Cytoskeleton; ionic conduction; cognitive function.

1. Introduction

The cytoskeleton is a web of filamentous protein polymers that define the structure of all eukaryotic cells. Composed of microtubules (MTs), actin filaments (AFs), and intermediate filaments (IFs), such as neurofilaments and keratin, the cytoskeleton provides architectural support for the cell, giving rise to its name, as well as facilitating cargo transport via motor proteins. Additionally, MTs perform specific functions relevant to cell motility, when composed as part of cilia or flagella, and to cell division, when forming the mitotic spindle. MTs have been discovered to play a role in the communication between the cell exterior and the cell nucleus, although the exact molecular mechanism of this process is not yet fully understood [1–3]. In recent years, it has been proposed that the AF and MT elements act as transmission lines to support the propagation of electrical signals within the cell [4–7].

Within axons and dendrites, the neuronal cytoskeleton displays a dense concentration of MTs stabilized by MT associated proteins (MAPs), specifically MAP-tau and MAP2, in polarized (axon), and mixed-polarity (dendrite) orientation. This is linked to the AF structures lining the walls of axons with specific MT architectures characterizing the presynaptic terminal [8]. In dendrites, the MT network connects to AF structures which enter into the postsynaptic density forming a highly elaborate framework. The IFs known as neurofilaments are the most abundant cytoskeletal components of large myelinated axons, although less is known about them compared to MTs and AFs. As such, due to the unique structure and function of the cytoskeleton in neurons, AFs and MTs play a major role in neuronal development, e.g., differentiation and synaptic generation, and neuronal plasticity.

The role of the neuronal cytoskeleton does not appear to be simply one of architecture or transport either. The functioning of the $GABA_A$ receptor, a key target for the action of anesthetics, appears to rely on the microtubular cytoskeleton as its destruction has been shown to cause a 78% rundown in receptor currents [9]. Additionally, hypoxia-induced cytoskeletal re-ordering has been shown to be responsible for suppression of fast sodium channels in brainstem respiratory neurons [10], while drug-induced modifications of MTs altered the activity of calcium-dependent inactivation of calcium channels in isolated rat hippocampal neurons [11–14]. These results suggest that the neuronal cytoskeleton may mediate ion channel responses.

The specialized neuronal cytoskeletal architecture and function, and the inherently electric nature of neurons, point to the importance of the potential function of the cytoskeleton as a transmitter of electric signals. It is this potential electric

signaling function of the MT cytoskeleton that will be explored within the present article. Accordingly, the remainder of this article will be presented in the following manner: Sec. 2 discusses the involvement of the MT cytoskeleton in higher cognitive functions of learning, memory and consciousness, Sec. 3 will present the current experimental evidence for ionic conduction and theoretical models of these phenomena, Sec. 4 describes the link between cytoskeletal networks, the neuronal membrane, and neuron function, Sec. 5 discusses the particular importance of the C-terminal region and the enzymatic regulation of intracellular signaling, and finally Sec. 6 provides discussion and conclusions.

2. The Microtubule Cytoskeleton in Learning, Memory and Consciousness

J. Integr. Neurosci. 2010.09:103-122. Downloaded from www.worldscientific.com
by AUSTRALIAN NATIONAL UNIVERSITY on 03/13/15. For personal use only.

While there is, as yet, no direct experimental confirmation that the role of the MT cytoskeleton includes electrical signal conduction in neurons, there is a large amount of experimental evidence supporting a role for MTs in higher cognitive function and by extension, neuronal signaling. The role of the neuronal cytoskeleton in learning and memory has been previously reviewed [4, 5, 15]. While in most tissues MTs exhibit growth, catastrophe (shrinkage) and tread-milling movement, they are less dynamic in neurons, largely because of the stabilizing effect of MAPs. However, rearrangement of the MT cytoskeleton does take place during learning. Learning has been shown to correlate with an increase in MTs [16], and to be impaired by the MT polymerization inhibitor colchicine [17–20], indicating that learning relies on dynamic MTs.

Correlations have been shown between learning and an increase in MAP2 [21], a MT cross-linking and stabilizing protein found mainly in dendrites [22, 23]. The converse is also true. Cerebral hypoperfusion, a condition which impairs learning, correlates with decreased MAP2 [24], and mice that exhibit learning and memory deficits also expresses less cortical MAP2 [25]. However, fear conditioning has been shown to produce significant changes in MAP2 immuno-histochemical staining [26–28], suggesting MAP2 breakdown during learning. This apparent contradiction is clarified when taken in the context of memory consolidation, the conversion of short-term memory into long-term memory. To reorganize the MT matrix in memory formation, the stabilizing protein MAP2 must first be broken down before reorganization can occur, and then reproduced to stabilize the new matrix. In fact, during memory consolidation, tubulin capping proteins increase their binding to other proteins [29], which is accompanied by MAP2 expression alterations [29, 30].

MAP-tau, another MT stabilizing protein found mainly in axons [22, 23], is also associated with learning and memory. Mice with increased levels of tau showed correlating improved memory before tau aggregation, and memory impairment after aggregation [31], and tau excess produced measurable impairment in memory in fruit fly and mice models [32, 33]. This suggests that an overabundance of tau causes excessive stabilization of the MT matrix inhibiting the dynamic reorganization

required in learning and memory. Indeed, a well-known hallmark of Alzheimer's disease, a disease of memory deterioration, is the accumulation of hyper-phosphorylated tau, unbound from MTs, into neurofibrillary tangles which results in neuronal degeneration and malformed neurites [34], suggesting that memory depends on proper functioning of the MT cytoskeleton.

Research on the molecular mechanisms of memory identifies Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) as crucial to long-term potentiation (LTP) contributing to learning and memory [35, 36]. Phosphorylation of MAP2 by CaMKII is fundamental to the potentiated synaptic response [37], and experiments indicate increased concentrations of dendritic mRNA for MAP2 and CaMKII during the intermediate phase of LTP [38]. CaMKII also directly phosphorylates the MT subunit protein tubulin on both its α and β monomer in the C-terminal region [39]. Additionally, learning via passive avoidance training induces changes in coexpressed MAP2 and protein kinase C (PKC) in rat models [40], and transgenic mice expressing altered MAP2 show decreased MAP2 phosphorylation by cAMP-dependent kinase (PKA) along with impaired contextual learning [41]. Such enzymatic events may be a triggering point for the MT matrix reorganization required for learning and memory formation.

While consciousness itself is hard to define, it is generally agreed upon that general anesthetics result in unconsciousness, making them a natural probe for functional sites of consciousness. Hallmarks of general anesthesia include hypnosis (unconsciousness) and amnesia (the prevention of memory formation), and it has been argued that hypnosis and amnesia are one and the same [42, 43]. The involvement of the cytoskeleton in memory has already been discussed above.

In recent years, evidence has accumulated for the interaction of anesthetics with neuronal MTs. Photo-labeling and gel electrophoresis have shown that the volatile anesthetic halothane binds directly to both α- and β-tubulin [44]. Differential in-gel electrophoresis investigations of protein expression determined that of 500 detectable proteins in rat cortical and hippocampal neurons, tubulin was altered prominently and was among the 2% of proteins affected by halothane, and among the 1% altered by isoflurane (being one of three proteins altered by both anesthetics) [45]. Additionally, tubulin has been found to be altered by desflurane [46], sevoflurane [47], as well as the neurosteroid anesthetics [48, 49].

The notion that the cytoskeleton plays a role in general anesthesia reaches back almost 40 years when Allison and Nunn first proposed the idea based on the depolymerization and structural alteration of MTs by volatile anesthetics [50]. This hypothesis was largely invalidated when it was found that the concentrations of anesthetics required to depolymerize MTs was far above the clinical dosage [100]. However, in more recent years this idea has been revived by quantum mobility theory [51, 52], which does not necessitate the depolymerization of MTs, but rather relies on hindrance of normal MT function by anesthetics. While the validity of quantum effects in MTs has been highly debated [53–55] this theory has resulted in much work being done in the area of cytoskeletal signaling and information processing in neurons.

J. Integr. Neurosci. 2010.09:103-122. Downloaded from www.worldscientific.com
by AUSTRALIAN NATIONAL UNIVERSITY on 03/13/15. For personal use only.

Along the line of this argument, without the need to invoke quantum theory, hindrance of intracellular signaling, through the interaction of anesthetics with MT, could be a contributing factor to the mechanism of general anesthesia, and memory formation.

3. Ionic Signaling via Cytoskeletal Microtubules

The electric properties of biomolecules (and biomolecular structures composed of them), such as tubulin, the constituent protein of MTs, and actin, are of crucial importance to a biophysical understanding of cellular processes. This is all the more important to the understanding of the electrically active neuron which possesses an extremely complex cytoskeletal architecture not seen in the cells of other tissues [8].

MTs have been shown to be affected by external electric fields. It has been demonstrated that pulsed electric fields can align MTs assembled *in vitro* [56], and that AC electric fields can have a pronounced effect on the mitotic spindles in several cancerous cell lines [57], thus indicating the importance of the electrical properties of MTs. These electric properties may involve both intrinsic effects of the protein and ionic contributions from counterions attracted to and concentrated near the MT by its electric field. Unfortunately, conductance measurements on biopolymers are fraught with difficulties due to the structural heterogeneity and instability of these polymers, the liquid state of samples and the dependence of biological systems on environmental factors such as pH, temperature, and ionic concentrations. Nanotechnology advances have improved techniques allowing more precise investigations to take place. Fortunately, despite the inherent difficulties, a number of experimenters have investigated either the intrinsic [58–60] or ionic [61, 62] conductivities of MTs.

MTs are hollow cylindrical structures comprised of the globular protein tubulin. The tubulin molecule is a heterodimer composed of α- and β-tubulin monomers. The α-β complex that assembles into MTs has dimensions of approximately $8\,\text{nm} \times 5\,\text{nm} \times 4\,\text{nm}$ [63] (see Fig. 1(a)). The inner and outer dimensions of an average MT cylinder are 15 nm and 25 nm, respectively, while their length typically varies from less than 200 nm to several micrometers, or more (see Fig. 1(b)). Each dimer possesses a highly flexible C-terminal tail region that can extend up to 4 nm from the dimer surface. Dimers bind together end-to-end (i.e., β to α) in string-like structures known as protofilaments. MTs in human cells typically have 13 protofilaments arranged side by side, generally in parallel arrangement [63], which wrap to form a cylinder, with the dimer C-terminal tails extending outwards from the MT surface. A slight shift between monomers in adjacent protofilaments results in a spiraling three-start left-handed helix of monomers. Two types of lattice structures have been observed [64]: the A-lattice structure possessing rotational symmetry and continuous wrapping, and the B-lattice which possesses a physical discontinuity called a seam running down the length of the MT (see Fig. 1). It is commonly accepted that, *in vivo*, MTs exhibit the B-lattice arrangement [65], however it has been suggested that dendritic MTs may prefer the A-lattice arrangement [52]. Due to the shape and spacing of

the tubulin dimers the MT possesses small, nanometer size openings between the outer environment and the inner MT lumen (see Fig. 1). Two distinct types of these nanopores exist for each lattice geometry.

Ionic conductance along MTs relies both on their electrostatic and structural properties. In particular, the surface of the tubulin dimer is largely negative, with a specifically large negative charge located on the C-terminal tail, with the remainder concentrated along the protofilament ridges [66] (see Fig. 2). This results in an overall negatively charged surface for a MT with an average linear charge density of 52.2 electronic charges (e) per dimer, or approximately 85 e/nm [62]. In solution, positive ions are attracted to the MT surface, while negative ions are repelled, creating a condensed ion cloud to counter the MT negative surface charge (see Fig. 3(b)).

In the presence of an applied voltage, the loosely held counterion cloud is free to migrate, creating an ion flow and an associated electrical current, giving rise to ionic conduction (see Fig. 3(c)). Based upon Ohm's law, conductivity is proportional

to ionic concentration, and so the condensed ionic environments surrounding AFs and MTs are expected to be good conductors in the presence of a voltage source. Consequently, these biofilaments can be thought of as conductive elements in the cells' cytoskeletal circuitry.

In regards to the ionic conductivity, direct measurement attempts of conductivity along MTs in solution were made in filled microchannels and determined to have an upper bound of 90 S/m [61]. Results well within this bound were found by Minoura *et al.* using an electro-orientation method which yielded an MT conductivity of 150 mS/m for intact MTs and 90 mS/m for subtilisin-treated MTs [62]. The enzyme called subtilisin cleaves the C-terminal tail region from MTs. The difference in conductivity due to subtilisin treatment was shown to be roughly proportional to the change in charges per dimer associated with the absence of C-termini. This suggests that counterions on the surface, including those on the negatively charged C-termini, are responsible for the 150 mS/m observed conductivity via the flow of

these condensed ions around the surface of the MT, a value roughly 15 times larger than the conductivity of the surrounding solution (9.5 mS/m).

Priel *et al.* applied a patch-clamp technique to measure electrical currents flowing along MTs following electrical stimulation [7]. They showed that the electrical current generated in solution by a pulse of applied voltage across a 20–50 μm distance is approximately twice the value when MTs are present. Additionally, the group found a maximum MT conductance of 9 nS. These results taken together strongly suggest that, for MTs in solution, the flow of condensed ions around the MT surface provides the observed MT conductivity.

Ionic conductance around seamless, A-lattice MTs was modeled using a theory of resistor networks, where a single MT was represented as a two-dimensional periodic helical lattice of monomer pairs, represented as resistors creating a series of conducting pathways connected in parallel [67]. Furthermore, this model was tested against random walk simulations of ionic conduction along the monomer lattice by considering the relationship between the stochastic random walk process and the theory of electrical networks. Theoretical modeling and computer simulation yielded comparable results.

Another circuit-based investigation used a nonlinear cable-like model of a MT [68], involving resistive, capacitive, and inductive elements in series and in parallel. The model developed considered the MT lumen separated from the rest of the ions in the bulk solution by the counterion condensation cloud, which acts as a dielectric medium providing resistive and capacitive components to the circuit. Additionally, the helical structure of the MT provided an inductive component in analogy to the helical ion flow induced by a solenoid. Solitary wave solutions, of a potentially unstable nature, were predicted qualitatively supporting ionic signal propagation and amplification by MTs.

It must be noted that in the above models, the effect of MAPs was not considered, and neither were the effects of the tubulin C-terminal tails. The charge on the C-terminal tails accounts for approximately 40% of the total MT negative surface charge, with the exact charge being determined by the particular tubulin isotype (or a mixture thereof) comprising the MT. As such, it is expected that positive counterions will condense in larger concentrations around these tails to compensate for their large electrostatic negativity. Fluctuations in the highly flexible C-terminal tail domain must be associated with corresponding movements of the surrounding ion cloud to preserve charge compensation. Thus, the effects of C-terminal tail dynamics are expected to have a significant impact on MT ionic conduction.

Molecular dynamics modeling of the time-dependent conformational states of C-termini interacting with neighboring C-termini was carried out where the MT surface interacts with the C-termini via positively charged surface regions. The inclusion of interactions with adjacent MAPs indicated a potential for C-termini generated electrostatic perturbations of counterions to be transmitted between adjacent MTs via MAP2 [69, 70], forming the basis of a network of electrical elements created by

J. Integr. Neurosci. 2010.09:103-122. Downloaded from www.worldscientific.com
by AUSTRALIAN NATIONAL UNIVERSITY on 03/13/15. For personal use only.

the architecture of the cytoskeleton in the cell. More recently, the effects of the C-terminal tails on ion transport along the MT have been specifically investigated [71]. In this case, ionic conductance was modeled in terms of positive ions hopping along a seamless lattice of ionic traps representing the large negative charge of the C-terminal tails along the MT surface. The simulations predicted critical ion concentrations required for conductance to emerge as a percolation threshold. It was shown that this effect can lead to the formation of complex conduction pathways, both of which are highly dependent on the charge of the C-terminal tails, something which is determined by the particular tubulin isoform whose distribution in the body is strongly tissue dependent with, for example, βIII tubulin being largely concentrated in neurons.

J. Integr. Neurosci. 2010.09:103-122. Downloaded from www.worldscientific.com
by AUSTRALIAN NATIONAL UNIVERSITY on 03/13/15. For personal use only.

A nonlinear RLC transmission line model of MTs viewed as rings of 13 tubulin dimers coupled together forming an electric circuit has been recently proposed [72]. In this model, the MT, with condensed counterions, was viewed as spatially separated from the rest of the ions in the bulk solution by a dielectric medium composed of an ionic layer depleted of positive ions. This layer provided both a fixed resistive component and a capacitive component that changes with the increasing concentration of counterions due to the flexibility of the C-terminal tail. Inductive components were also considered due to the 13 parallel currents arising from ionic wave flows along each protofilament. Solutions to this model indicated stable and robust anti-kink wave propagation with a velocity value close to experimental findings. It was also shown that even weak electric fields, such as a cellular intrinsic field, could tune both the direction and velocity of this propagation.

The latest research in this area generated an electric circuit model of the MT which incorporates not only the C-terminal tails, but also the nanopores within the MT wall, thus including not only ionic conductance along the outer surface of the MT, but conductance through the MT wall, and in the lumen as well [73]. This latest model effectively includes a 3D representation of the MT with ions flowing both along its surface and across it, in and out of the luminal space. Experimental evidence suggests importance for these nanopores in drug diffusion and MT–protein interactions. For example, the MT-stabilizing MAP tau, with its crucial function in axons, is believed to bind at a location in the MT lumen, suggesting that it passes through the nanopore to reach its binding site. It has been demonstrated that certain drugs (e.g., paclitaxel and epothilone) traverse the nanopores to find their binding sites in the MT lumen [74], or bind in the nanopore itself. Thus, it is assumed that based on their size, the nanopores are quite permeable to ions. Brownian dynamics simulations of ion conductance through B-lattice nanopores indicated a larger conductance traveling into the lumen for positive ions than for ions moving outside the MT, while negligible conductance was found for negative ions in either direction [73]. These results suggest that MTs give rise to complex electric conduction phenomena involving ions, solute molecules and potentially protons.

Finally, several authors have suggested that the flexible C-terminal tails can interact with positively charged residues on the body of tubulin [75, 76]. The formation and disruption of these interactions was proposed to act as a stochastic alternating voltage source on the cations close to outer surface of MT. Simulations including the effects of the asymmetrical conductance and this internal voltage source indicated that an ionic current can travel through the MT wall and propagate down the MT lumen [73]. This current adds directly to the longitudinal current along the outer MT surface arising from an external voltage source, indicating that MT can amplify low-intensity endogenous currents within the cell. Because the voltage source arising from the dynamic behavior of C-terminal tails drives cations into the lumen of the MT all along its outer surface, this effect could be an important factor enabling the dissipation of a potential gradient to be focused towards one end of the MT, regardless of the orientation of the source relative to the MT.

Overall, these results suggest that counterions condensed around the surface of the MT cytoskeleton are allowed to flow in the presence of potential differences, effectively making it a network of biological electrical wires. This may have important implications in the coupling of intracellular signals in all cells. However, as stated earlier, electrically active cells, such as neurons, generate potential differences via the flux of charged ions, and in these instances the mechanism of conduction along MT may be of extreme significance.

4. Connections Between Microtubule and Actin Networks and the Neuronal Membrane

Both AFs and MTs form networks using various binding proteins. There are over 100 actin-binding proteins implicated in cell types and locations. Of particular relevance are α-actinin and spectrin that promote neural plasticity. The protein α-actinin is known to link AFs to membrane channels, thereby coupling channel activity to the intracellular network. MAPs in neurons are responsible for the structured parallel network observed in the axon, as well as the mixed-polarity arrangement in dendrites. Specifically, MAP-tau is abundant in the axon, creating polarized bundles of MTs to span its length, while in developed neurons MAP2 is present in dendrites where it stabilizes the network of MTs to form a mixed polarity structure. Since MAP2 is relatively heavy and long compared to MAP-tau, the average distance between the MTs in the network developed in the axon is about 20 nm whereas in dendrites it measures 50–90 nm.

The dynamic interactions between both AF and MT cytoskeletons are central to neuronal cell morphology and function. Only recently have clear functional interactions between those cytoskeletal structures become apparent. Association of MT with AF in filopodia appears to guide MT growth along the most efficient path and play a key role in neurite initiation [77]. AF-MT interactions are also important for growth cone turning underlying axonal path-finding mechanisms [78].

Like MTs, AFs are also highly charged polymers, with a negative charge density of about 4 e/nm [79]. They are thinner than MTs with diameters of about 7 nm, they are less rigid by a factor of about 300, are typically shorter, often cross-linked by other proteins into bundles, and are closely associated with neuronal cell membranes [80]. Application of a patch-clamp technique to measure electrical currents flowing along AFs following electrical stimulation found that the charge transferred was consistent with the dynamic behavior of ion flow along the AF longitudinal filament axis and that this flow was doubled by including AFs in the solution [81]. Additionally, osmotic stress applied to a polymerized actin solution revealed a reduction in actin surface charge density with increasing stress and a nonlinear electric response upon application of electric fields, indicating that F-actin in solution may display non-ideal electro-osmotic properties consistent with ionic "cable" behavior [82]. Also, measured electrical signals from the end of an AF after an input voltage was applied indicate that AFs support ionic waves in the form of axial nonlinear currents [79]. Thus, like MTs, AFs are capable of ionic signal conduction and amplification.

In neurons, there is an increased presence of binding proteins capable of interacting with both MTs and F-actin, mediating signaling between both cytoskeletons. For example, MAP2 binds to F-actin efficiently, and induces actin bundle formation. MAP2 has also been found to localize in regions devoid of MTs in neurons [83], in particular in dendritic spines. Since actin bundles enter the spine neck and bind to the postsynaptic density (PSD), and on the other end are connected to the MT network filling the dendritic shaft, it has been hypothesized that a direct regulation of ion channels and thus synaptic strength by AFs and associated cytoskeletal structures controls and helps modify the electrical response of the neuron. In this picture, MTs arranged in networks of mixed polarity, receive signals in the form of electrical perturbations, from synapses via AFs connected to MTs by MAP2 [84], or via direct MT connections to PSD proteins by molecules such as CRIPT [85]. The MT network operates on the propagating waves and modulates the information it carries to control the output measured by remote membrane areas. This intracellular information processing mechanism effectively regulates the cell's electrical response [5].

Since voltage-gated Na^+ and Ca^{2+} channels play an important role in amplifying the excitatory postsynaptic potential (EPSP) responses towards the soma, channel regulation will be important also for dendritic interactions in the vicinity of the synaptic input. Voltage-gated channels may dynamically modify the local input properties — resistance and time constant, which in turn would influence the spatio-temporal integration of EPSPs and inhibitory postsynaptic potentials (IPSPs), thus, promoting highly nonlinear interactions. Hence, the nonlinear properties of dendrites may act as amplification/modulation devices. This control of membrane potential would modify synaptic integration and therefore modulate the whole neural response.

5. Enzymatic Control of Signal Propagation via Modification of Tubulin C-Termini

Reviews of the specialized role of tubulin isoforms suggest that the evolution of new cell types corresponds to the origin of specific tubulin isoforms [86]. It is interesting to note that of all tissues the brain possesses the largest variety of tubulin isotypes [87]. In particular, this suggests high probability for a very significant role of tubulin isoforms in neural network complexity and its origin [88].

The C-terminal is the most variable region among the many different tissue specific isotypes of tubulin, and, as such, has been suggested to mediate the specific cellular functions of MTs [87, 89]. The importance of the C-termini to the structure and function of MTs has been reviewed extensively [90–92], and includes effects on MT polymerization, and interaction with MAPs and a host of other proteins.

In this regard, it has been suggested that this C-terminal region acts as a chaperone to interactions with other proteins such as MAPs [93]. In fact, it has been shown that MAP tau triggers structural changes in elements on the MT surface [94], and simulations indicate these elements may be the C-termini [90]. The C-termini are also the sites of many of the post-translational modifications of tubulin, including polyglutamylation, polyglycylation, detyrosination/tyrosination, removal of glutamatic acid and phosphorylation of serine and tyrosine residues [95, 96]. These modifications are the result of enzymatic processes [97], and considering the involvement of the C-termini in MT polymerization and interaction with MAPs, are expected to have dramatic dynamic effects on the MT network. For example, modifications that change the electrostatic nature of the C-termini, by adding or removing charged residues, would effect the capacitance of the condensed ionic atmosphere surrounding a MT, as well as the magnitude of the voltage source arising from tail–body interactions. Thus, should the C-termini play a significant role in ionic conduction along MTs, as proposed by the simulations mentioned above, then these enzyme-triggered events would have great effects on ion flow, providing a mechanism for the regulation of intracellular signaling.

6. Discussion and Conclusions

MTs composed of tubulin and some associated proteins are ubiquitous cellular structures of eukaryotic cells important for organizing cytoplasmic properties and cellular movement. Their α- and β-tubulin subunits constitute heterodimers that associate into protofilaments with a strict α/β alternation. Protofilaments are able to form rings and spirals or associate laterally building up both different kinds of sheets and MTs or even macrotubules, depending on the prevailing environmental conditions during the assembly process. The various geometrical possibilities that MTs, AFs and other proteins present in the cytoskeleton give rise to the design of very complex architectures of these filamentous structural elements of neurons. However, their intrinsic electrical conduction and dielectric polarization properties open

an additional, entirely new spectrum of functional applications within the cellular machinery.

Due to the presence of a large electric dipole in each of the tubulin units (including the layer of bound structured water surrounding the solvent exposed area) and the negatively charged tubulin C-termini, electric fields are expected both to transport suspended MTs into a desired direction and to steer MTs actively driven by motor proteins. Correspondingly, in experiments performed at nearly physiological conditions, (pH 6.8 and about 120 mM ionic strength) individual suspended MTs were found to move steadily towards the positive electrode with an electrophoretic mobility: $2.6 \times 10^{-4}\,\mathrm{cm}^2/\mathrm{Vs}$ [98]. The electrophoretic mobility decreases with ionic strength and pH. The MT movement changed direction to the anode at pH 4.1, indicating a positive net charge has been created on MTs when they were kept at this low value of pH. Interpolation of the isoelectric point gives a value of about pH 4.2 for MTs, which is remarkably lower than that of α- and β-tubulin monomers found to be near pH 5.5. At pH 6.8, external electric fields forced MTs to glide across a kinesin-coated surface into a preferred direction to the anode, in accordance with the negative net charge of the MTs at this pH.

Interestingly for potential nanotechnology applications, the surface of tubulin molecules exposes a defined pattern of amino acid residues (histidines) that provides active sites for nucleation, organization, and binding of metal nano-particles. The doping or decorating of the MT with these nano-particles can be performed by using various processes such as precipitation, solvent evaporation, and vapor phase reactions. The formation of nanometre-size (diameter: 1.5–3.5 nm) immobilized noble metal particles on the MT surface has been experimentally demonstrated [99]. The particles formed have shown definite patterns reflecting the regular arrangement of the α- and β-tubulin subunits within the MT. By further particle growth, a quasi-continuous MT coating can be obtained resulting in Pd nanowires and, furthermore these wires can be assembled into circuits [99] (see Fig. 4). Such an isomolecular organization of nano-particles into functional 2D and 3D structures is a potential method for developing electronic devices with novel biophysical properties. These nano-particles may be deposited randomly or pseudo-randomly within the underlying MT geometry. This results in the formation of a MT with mechanical, electrical and magnetic properties that are different from the original MT. Electrically modified MTs can become useful in applications such as artificial nerves, neural networks and logic circuits, biosensors, neuron-to-neuron couplers, bioisolators and bioswitches. It is feasible to apply the intrinsic properties of MTs, as well as electrically and magnetically modified MTs, to enable the construction of electronic devices and electronic circuits. For example, a four-terminal device can be fabricated from MTs by depositing two parallel gold pads on a substrate, and adding a layer of MAPs between the gold pads to aid in the contact between the gold pads and the MTs. The application of an electric field across the two gold pads will align the MTs in a parallel plane, and allow for a low resistance state. Conversely, the removal or lack of an electric field between the gold pads provides for random

orientation of the MTs with respect to each other and to the gold pads. Variations on the configuration of the gold pads provide for inter-changeability between high- and low-resistance states when an electric field is applied. The above four-terminal logic device may also be used to provide electrical isolation of unwanted signals in the presence of an electric field. Noble metals that were used to decorate or coat the MTs for electric field response include gold and palladium. The use of ferromagnetic materials such as iron to decorate MTs may lead to creation of bioengineered structures that are highly responsive to an applied magnetic field.

The conventional thinking ascribes consciousness to the central nervous system only and hence, it is crucial to investigate what makes the MTs there suitable for information processing or at least for aiding the cognitive process. This would be in contrast to the MTs formed in almost every other cell of the body. On the other hand, cell shape determines whether or not external electric fields, such as that of the nerve impulse, may penetrate the cell. This implies a feedback mechanism between MTs and the cell shape. The goal of the studies reviewed in this article is to learn more about the function of tubulin and MTs and to discover novel properties which make them particularly useful within the nervous system. We hope to have shed light on the reason why MTs are important for neuron function and consciousness. We have also concluded that modifying biophysical properties of MTs using nanotechnology

may open a new range of possibilities such as bioelectronic artificial intelligence devices.

Microtubule as Nanobioelectronic Nonlinear Circuit*

Dalibor L. Sekulić[1], Miljko V. Satarić[1]

Abstract: In recent years, the use of biological molecules has offered exciting alternatives to conventional synthetic methods. Specific methods use various biological templates to direct the deposition and patterning of inorganic materials. Here we have established a new electrical model of microtubules as a biological nanoscale circuit based on polyelectrolyte features of cylindrical biopolymers. Our working hypothesis is that microtubules play an active role in sub-cellular computation and signaling via electronic and protonic conductivity and can thus be made useful in hybrid materials that offer novel electronic characteristics. We verify these hypotheses both computationally and analytically through a quantitative model based on the atomic resolution structures of the key functional proteins.

Keywords: Nanobioelectronics, Microtubule, Protein, Nano pore, Nonlinear circuit.

1 Introduction

Nanobioelectronics is a thriving new area of research at the interface between the life sciences and nanotechnology, which deals with structures of dimensions ranging from 1 nm to 100 nm, below the range of lithographic fabrication techniques [1]. Nanobiotechnology aims to exploit biomolecules and the processes carried out by them for the development of novel functional materials and devices [2] and, more speculatively, nanomachines, perhaps nanorobots. These developments open up an exciting possibility of building integrated systems in which electronic and biomolecular components function side–by–side. Biopolymer structures are attractive as templates to form nanoscale architectures for electronics because of their size, geometry and ability to interact with inorganic materials.

Proteins represent fertile territory for nanobioelectronics because they have properties ideal for engineering purposes. They possess sophisticated architectures at nanoscale dimensions, rich chemistry and versatile enzymatic

*Award for the best paper presented in Section *Microelectronics and Optoelectronics*, at Conference ETRAN 2011, June 6 – 9, Banja Vrućica – Teslić, Bosnia and Herzegovina.

activities. Proteins are capable of carrying out complex tasks in cells. We need think only of examples such as the linear motors of the cytoskeleton, voltage–gated ion channels, DNA replication complexes, or the photosynthetic reaction centres [2]. By genetic engineering and/or chemical modification or by using proteins in ways not found in nature, nanobiotechnology can harness the power of proteins to create new components for materials and devices.

Most studies in this area have been performed on DNA molecules [3, 4]. It has been shown that DNA may be used as a template to form silver nanowires connecting gold electrodes [5]. Microtubules (MTs) comprise another interesting type of protein structure that may be a good candidate for designing and manufacturing electronic nanodevices. MTs are cytoskeletal biopolymers shaped as nanotubes. *In vivo* MT cylinders have 13 protofilaments (PFs), as shown in Fig. 1a. The external and internal diameters of MTs are 25 and 15 nm, and the length can reach up to 10–15 μm in a cell. The dimensions of a constituent tubulin dimer (TD) are (4×4×8) nm^3, and there are 13 dimers from 13 PFs considered as an elementary ring of MT. An important point is that every tubulin has a long thin flexible tail (TT) protruding out from the MT cylinder (every dimer has two TT). These TTs have an important role in electric capacitance in our model, as shown Fig. 1b.

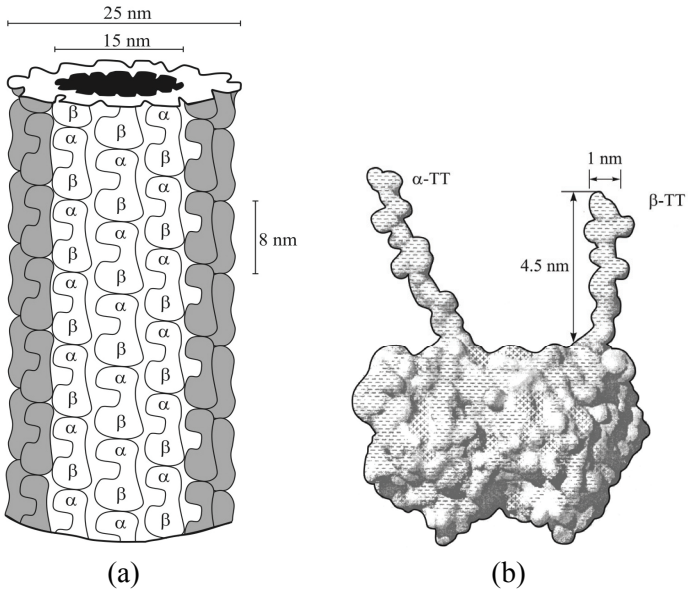

Fig. 1 – (a) *A MT hollow cylinder of* 13 *parallel PFs with denoted characteristic dimensions: outer and inner diameters of* 25 nm *and* 15 nm*, respectively, and TD length of* 8 nm; (b) *The topology of a* TD *with* TT*s whose dimensions are: the length of* 4.5 nm *and diameter of* 1 nm.

manning condensation = counterion condensation

In this paper, we explained the polyelectrolyte character of MT and described the basic components of the MT as a biomolecular nanoscale nonlinear electronic circuit. Then we set up an electrical model of the MT using capacitive and resistive components. Also, we analytically and numerically analyzed the voltage equation.

2 Characterization of the Electric Components of MT

In as much MTs are mostly negatively charged on their outer surface they are true polyelectrolyte polymers. This is the consequence of the fact that numerous amino acids forming tubulin have many negatively charged residues under physiological conditions. As a result, every MT attracts positive counter ions close to its surface creating so called ionic cloud (IC), while negative ions of cytosol are repelled such that a cylindrical depletion area is created around the MT. The width of this depleted layer is called the Bjerrum length, l_B, defined by equating the Coulomb attraction energy of the ions with the thermal energy:

$$e^2 / \left(4\pi\varepsilon_0 \varepsilon l_B\right) = \mathrm{k_B} T. \tag{1}$$

Taking $e = 1.6\times10^{-19}$ C, $\varepsilon_0 = 8.85\times10^{-12}$ F/m, $\varepsilon = 80$ (for cytosol) and $k_B = 1.38\times10^{-23}$ J/K, for the physiological temperature $T = 310$ K we obtain $l_B = 0.67$ nm. The occurrence of Manning condensation around the polymer of radius r also depends on the fact that the salt concentration n in the cytosol should be low enough to satisfy the inequality $l_{Db} >> r$, where the Debye length, $l_{Db,}$ is defined by

$$l_{Db}^{-1} = \left(8\pi n l_B\right)^{1/2}. \tag{2}$$

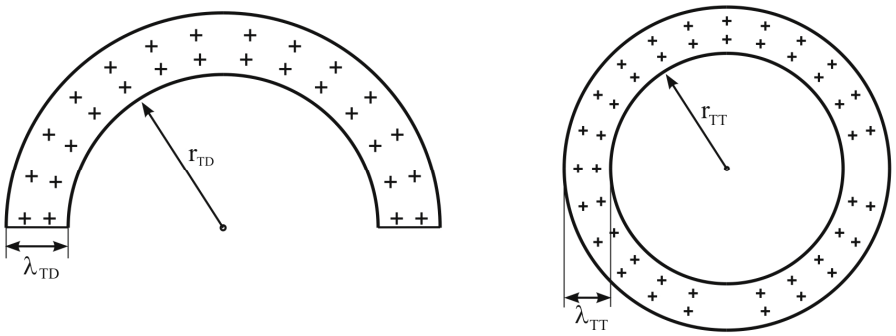

Fig. 2 – *Schematic representation of the counter–ion charge distributions surrounding a* TD (*left panel*) *and a* TT (*right panel*).

EUP = Elementary Unit of Protofilament

Since the radius of a TT is of the order of 0.5 nm and the radius of a TD is of the order of 2.5 nm, while the Debye length for the cytosol is of the order of 10 nm [6], we see that the condition in (2) holds for both radii. Thus, we are now able to reliably estimate the respective condensate thickness λ:

$$\lambda = A\left(rl_{Db}\right)^{1/2}, \quad A<1, \tag{3}$$

where A depends only weakly on the Manning parameter q_0. Taking $A = 1/2$ one finds the corresponding values for the TD (λ_{TD}) and TT (λ_{TT}) as follows: $\lambda_{TD} = 2.5$ nm; $\lambda_{TT} = 1.1$ nm. These values will be used in our calculations of the corresponding capacity and resistivity, see Fig. 2.

2.1 The capacitance of an elementary unit of MT

In an earlier paper [7], a detailed Poisson-Boltzmann approach was used to evaluate the capacitance of an elementary ring of an MT which consists of 13 dimers. Here, we adopt the same expression which reads:

$$C_0 = \frac{2\pi\varepsilon_0\varepsilon l}{\ln\left(1+\dfrac{l_B}{R_{IC}}\right)}, \tag{4}$$

where l stands for the length of a polymer unit and $R_{IC} = r_{TD} + \lambda_{TT}$ for the outer radius of an IC. The other parameters have already been introduced. We first estimate the elementary unit of each MT protofilament (EUP) capacitance contributed by a TD, see Fig. 3. With $l_{TD} = 8$ nm and $R_{IC} = r_{TD} + \lambda_{TT} = 5$ nm, we find for TD (including only the outer surface) $C_{TD} = 1.4\times10^{-16}$ F. Analogously, we can consider an extended TT as a smaller cylinder with the radius $r_{TT} = 0.5$ nm and the thickness of its IC equal to $\lambda_{TT} = 1$ nm. Its extended effective length should be $l_{TT}^{eff} = 4.5\text{ nm} - 2.5\text{ nm} = 2\text{ nm}$ meaning that its part close to the tubulin surface is already embedded. Thus, we now estimate the corresponding capacitance, $C_{TT} = 0.26\times10^{-16}$ F. Accounting for the fact that two TTs are present in each tubulin dimer, we finally obtain $2\times C_{TT} = 0.52\times10^{-16}$ F. The two capacitance values above are considered to correspond to a parallel arrangement with respect to each other, so that the total maximal capacitance of an EUP is readily estimated as:

$$C_0 = C_{TD} + 2\times C_{TT} = 1.92\times10^{-16}\,\text{F}. \tag{5}$$

We have emphasized that TTs capacitance must change with an increasing concentration of condensed cations due to the shrinking of flexible TTs. These changes are slightly different due to the different structures of α and β type TTs. To include this case we introduce the reduced factor of nonlinearity as follows

$$b_0 = \frac{b_\alpha b_\beta}{b_\alpha + b_\beta}, \tag{6}$$

where b_α and b_β stand for the respective TTs. This implies that the charge of an EUP capacitor diminishes with an increased voltage in a nonlinear way $\Delta C_0 = C_0 b_0 v$, $b_0 v << 1$.

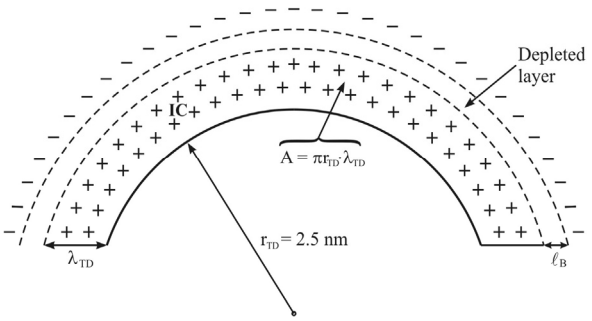

Fig. 3 – *Schematic illustration of the calculation of the MT capacitance.*

Additionally, we account for the tilting movements of TTs under the combined action of thermal fluctuations [8] and a changing voltage due to an incoming ionic wave. Thus, the part of EUP capacitance contributed by TTs should also change by TTs tilt as shown in Fig. 4. The change of the effective length of a TT is an additional factor affecting the capacitance, ΔC_{TT}. We assume that this change can be adequately described by the oscillating function

$$\Delta l_{TT}^{eff} = l_{TT}^{eff} \sin\left[\Omega\left(t - t_0\right)\right] \cong l_{TT}^{eff} \Omega\left(t - t_0\right). \tag{7}$$

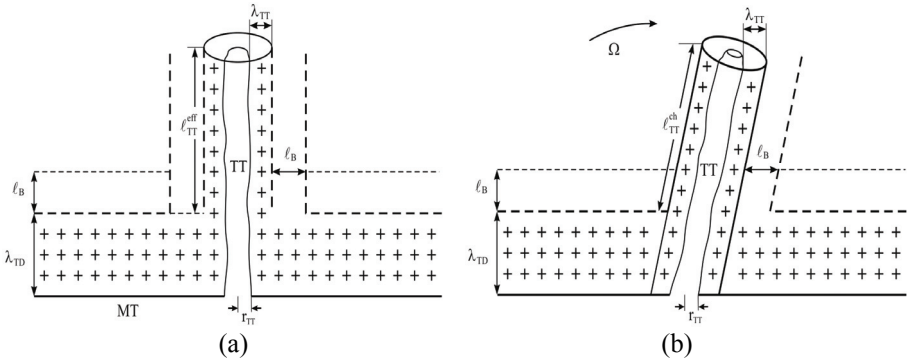

Fig. 4 – *A comparison between*: (a) *an extended* TT;
(b) *a tilting* TT *due to oscillations.*

So that the capacitance changes linearly with a change in the effective TTs length

$$\Delta C_{TT} = C_0 \Gamma_0 \Omega(t - t_0), \tag{8}$$

where the frequency Ω is much lower than the inverse charging time of the EUP capacitor due to the strong viscous damping of the TT tilt, thus justifying the

linearization of the above sine function in (7). In some sense, this effect is similar in character to the thermal ratchet mechanism combined with an asymmetric ionic potential. Including the two aspects of TTs dynamics described above, the charge of EUP can be expressed as follows

$$Q = C_0\left[1-\Gamma_0\Omega(t-t_0)-b_0 v\right]v, \tag{9}$$

where Γ_0 is a dimensionless parameter.

2.2 The conductance of Nano–pores

Between neighboring PFs there are two distinct types of (NPs). NP–1, see Fig. 5 left, is located where an inter–dimer β/α interface of one TD lies next to the inter–dimer β/α interface of the adjacent TD molecule. The so–called NP–2 arises where an intra–dimer interface of one dimer lies next to the intra–dimer interface of an adjacent TD of a neighboring PF, see Fig. 5 right. Freedman et al [8] used HOLE and AMBER programs to estimate the effective radius of the narrowest points within these NPs and found them to be 0.4 nm and 0.47 nm for type–1 and type–2 NPs, respectively.

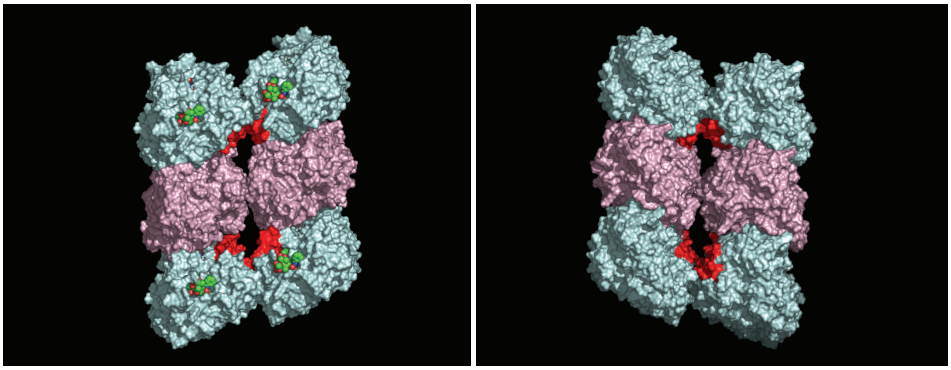

Fig. 5 – *An illustration of the NPs in the A and B MT lattices, respectively.*

Based on the modified version of the Poisson–Boltzmann equation, the conductances of NPs are determined in terms of Brownian dynamics of ions. For the type–1 NP, inner and outer cationic conductances were calculated to be 2.93 nS and 1.22 nS, respectively, while for type–2 NP the respective values of 7.80 nS and 4.98 nS were found.

Finally, we could include the conductance of both NPs to account for the leakage of IC cations into the lumen area. Thus we have

$$G_0 = \sigma_1 + \sigma_2 = (2.93 + 7.8)\text{nS} = 10.7\,\text{nS}. \tag{10}$$

It is expected that NPs exert greater resistance than the volume of IC around EUP.

2.3 The resistance of an elementary unit of MT

Regarding the ohmic resistance, if we ignore ionic current leaks through the depleted layer, the dominant current flows in parallel with the MT axis charging EUP capacitors and partly leaking through NPs. The resistance attributed to this kind of ionic flow can be estimated on the basis of experimental evidence provided by the electro–orientation method performed on MTs *in vitro* [6]. Taking the reported measured value of MT ionic conductivity as $\sigma = (0.15 \pm 0.01)\ \mathrm{Sm}^{-1}$, and adopting a simplifying assumption that the resistivity within an IC patch beyond an EUP is homogeneous, the resistance of an EUP with the length l = 8 nm and the cross–sectional area $A = \pi r_{TD}\lambda_{TD}$, $A = 19.625\ \mathrm{nm}^2$, see Fig. 3, is estimated as:

$$R_0 = \frac{1}{\sigma}\frac{l}{A} = 2.7\times10^9\,\Omega\ . \tag{11}$$

This is obviously an extremely high value of resistance which is most likely an over–estimate. We therefore prefer the computed resistance shown in Table 3 of reference [8], referred to as the outer sheath–outer sheath resistance for complete 13 PFs, namely $R_{13} = 4.75\times10^6\ \Omega$. The resistance for our EUP will be 13 times greater, i.e.,

$$R_0 = 13R_{13} = 6.2\times10^7\,\Omega\ . \tag{12}$$

This value appears to be more consistent with the resistance of two NPs which follows from (10).

2.4 The inductance of an elementary unit of MT

The straightforward calculation performed in [9] revealed that the order of magnitude of the inductance of an elementary ring in MT is of the order of L~10−15 H. This is very small value regarding pertaining reactive resistance. For example, if the frequency is of the order of MHz we have ωL~10−9 Ω for inductive impedance, while capacitive impedance amounts (ωC)–1~109 Ω. Similar discrepancy holds for the energies of corresponding fields

$$\frac{1}{2}Li^2 \ll \frac{1}{2}C_0v^2, \tag{13}$$

since i is of the order of nA and v of the order of several mV. Thus, the role of inductance in this model could be safely ignored.

3 The Model of MT as Nonlinear Circuit

On the basis of above estimations for the resistive components of the MT we are now in the position to establish the corresponding model of MT as nonlinear nanoscale circuit. A typical section scheme is shown in Fig. 6. Applying Kirchhoff's low to ladder of ERs, we have:

$$i_n - i_{n+1} = \frac{\partial Q_n}{\partial t} + G_0 v_n, \qquad v_{n-1} - v_n = R_0 i_n \ . \tag{14}$$

Introducing the characteristic impedance of our system $Z = 1/(C_0\omega)$ and establishing new function $u(x, t)$, $u_n = Z^{1/2} i_n = Z^{-1/2} v_n$, we can safely expand u_n in a continuum approximation using a Taylor series in terms of a small spatial parameter l (the length of a dimer). Then using the travelling–wave form of the function $u(x, t)$ with dimensionless space and time variables (ξ, τ), we get the following voltage equation

$$\begin{aligned} &\left(\frac{ZC_0 s}{T_0} - 2\right)\frac{\partial u}{\partial \tau} + \frac{1}{3}\frac{\partial^3 u}{\partial \xi^3} + ZC_0\Gamma_0\Omega\left(\xi - \xi_0\right)\frac{\partial u}{\partial \xi} + \\ &+ 2\frac{Z^{3/2} b_0 C_0 s}{T_0} u \frac{\partial u}{\partial \xi} + \left(ZG_0 + Z^{-1}R_0 - ZC_0\Gamma_0\Omega\right)u = 0. \end{aligned} \tag{15}$$

Here, $T_0 = R_0 C_0$ is the characteristic charging (discharging) time of an EUP capacitor C_0 through the resistance R_0 and $v_0 = l/T_0$ is the characteristic velocity of spreading the ionic wave. The dimensionless speed, space and time variables are chosen to be respectively:

$$s = \frac{v}{v_0} \le 1, \quad \xi = \frac{x}{l} - \tau, \quad \tau = s\frac{t}{T_0} \ . \tag{16}$$

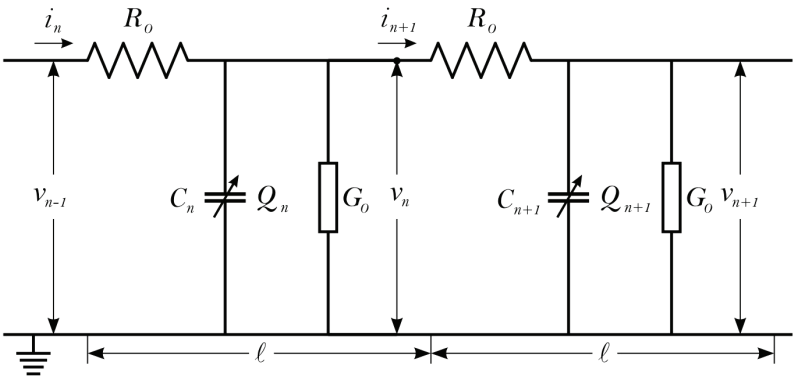

Fig. 6 – *An effective circuit diagram for the n-th* ER *with characteristic elements for Kirchhoff's laws.*

4 Analisis of the Voltage Equation

Imposing that the condition

$$\frac{ZC_0 s}{T_0} > 2 \tag{17}$$

holds, we then estimate the characteristic impedance of EUP as $Z = 1.24\times10^8\ \Omega$ for $s = 1$. For $s = 1$ one obtains the cutoff frequency $\omega_{max} = 4.3\times10^7\ s^{-1}$ or $f_{max} = 6.8\times10^6$ Hz. This indicates that the characteristic frequency matches the order of magnitude of frequency Ω which describes the TTs oscillations. We now establish the compact form of (15) as:

$$\frac{\partial u}{\partial \tau} + \beta\frac{\partial^3 u}{\partial \xi^3} + \alpha u\frac{\partial u}{\partial \xi} + \gamma(\xi)\frac{\partial u}{\partial \xi} + \delta u = 0, \tag{18}$$

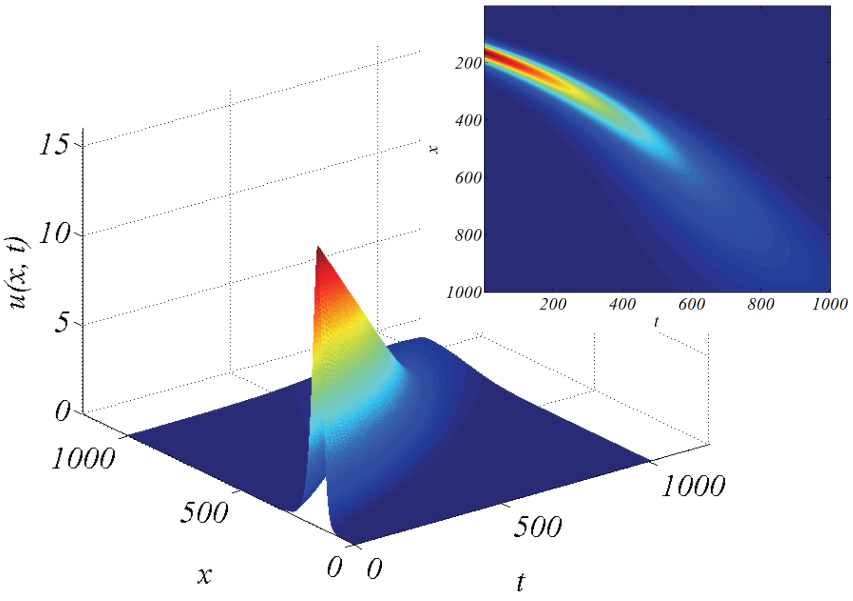
where the abbreviations were introduced as follows:

$$\alpha = \frac{2Z^{3/2}b_0C_0s}{T_0\left(\frac{ZC_0s}{T_0}-2\right)}, \quad \beta = \frac{1}{3\left(\frac{ZC_0s}{T_0}-2\right)},$$
$$\delta = \frac{ZG_0 + Z^{-1}R_0 - ZC_0\Gamma_0\Omega}{\left(\frac{ZC_0s}{T_0}-2\right)}, \quad \gamma(\xi) = \frac{ZC_0\Gamma_0\Omega(\xi-\xi_0)}{\left(\frac{ZC_0s}{T_0}-2\right)} = \gamma_0(\xi-\xi_0). \tag{19}$$

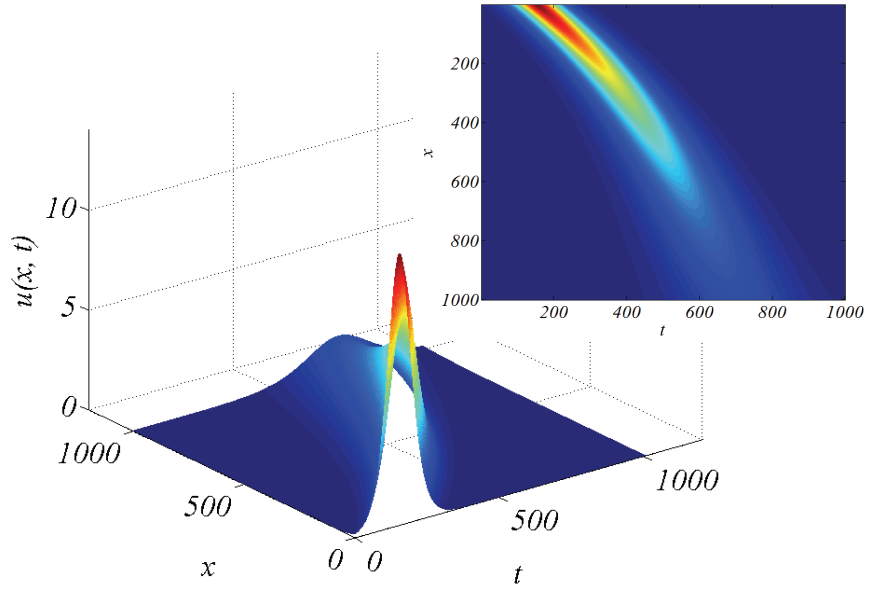
The detailed procedure of solving (18) is given in [10], so that the function $u(\xi, \tau)$ has the following form:

$$u(\xi,\tau) = u_0\exp(-2\gamma_0\tau)\cosh^{-2}\left\{\left[\frac{\alpha u_0}{4\beta}\exp(-2\gamma_0\tau)\right]^{1/2}\cdot\right.$$
$$\left.\cdot\left[\xi-\xi_0\left(1-\exp(\gamma_0\tau)\right)+\frac{\alpha u_0}{3\beta}\left(1-\exp(3\gamma_0\tau)\right)\exp(-2\gamma_0\tau)\right]\right\}. \tag{20}$$

If we use the set of estimated and chosen parameters, we readily see that all dimensionless parameters (19) lie between zero and one ($\beta = 0.33$, $\gamma_0 = 0.17$, $\delta = 0.34$) staying within the same order of magnitude. This suggests that we should inspect numerically the behaviour of the solution of (18) when the parameters α, β, γ_0 and ξ_0 take slightly different values which are done next. Analysing the set of plots in Fig. 7 we can see the competition between nonlinearity α and the dispersion β, as well as the role of inhomogeneity γ_0. In the case represented in Fig. 7b we have balanced all parameters. The soliton solution preserves its width but its amplitude decays rather rapidly so that over the length of about 500 l it becomes negligible. The above view shows the deceleration of the soliton solution along its path. Fig. 7c shows the case with increased nonlinearity ($\alpha = 0.5$). It is remarkable that it exhibits not only a higher localization but also a slower decay of its amplitude. The advantage of this case lies in the fact that the velocity of the soliton solution decreases very slightly.



(a)



(b)

Fig. 7 – *Numerical solutions of u(x, t) for:*
(a) $\alpha = 0.2$, $\beta = 0.33$, $\gamma_0 = 0.17$, $\xi_0 = 0.1$;
(b) $\alpha = 0.1$, $\beta = 0.1$, $\gamma_0 = 0.1$, $\xi_0 = 0.1$.

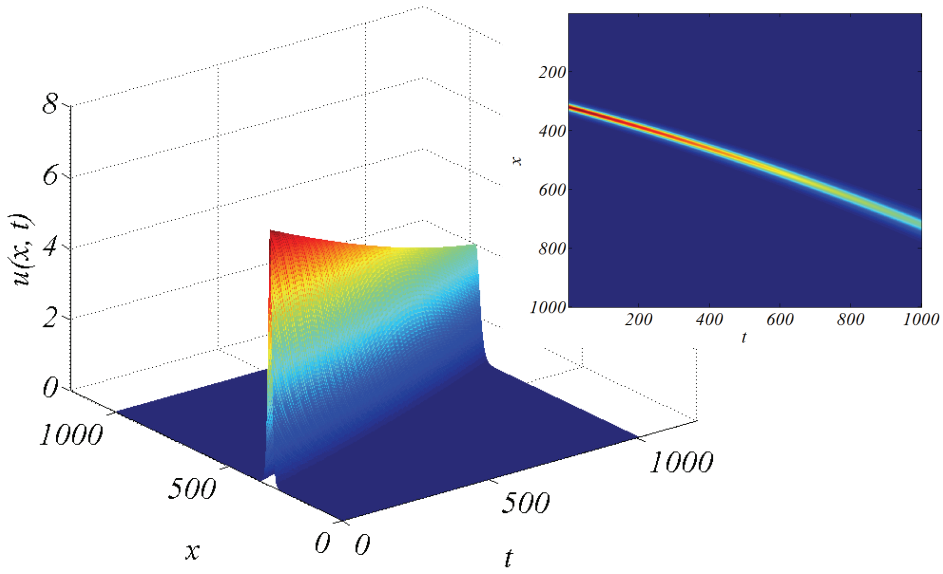


Fig. 7c – *Numerical solutions of u(x, t) for*: α = 0.5, β = 0.1, γ_0 = 0.1, ξ_0 = 0.1.

We estimate its average velocity as follows:

$$\left.\begin{aligned}\Delta x &\approx 400l = 400\times 8\text{nm} = 3.2\mu\text{m},\\ \Delta t &= 1000T_0 = 10^3\times 1.2\times 10^{-8}\,\text{s} = 1.2\times 10^{-5}\,\text{s}\end{aligned}\right\}\ v = \frac{\Delta x}{\Delta t} = 0.26\frac{\text{m}}{\text{s}}.$$

The range of this soliton is 3.2 μm which is of the order of the cell's diameter. Therefore, it appears that the ionic pulse with such parameter values could be efficiently transferred within the cell.

5 Conclusions

In this paper, we theoretically analysed the use of MTs as protein structure for building biomolecular nanoscale nonlinear circuit in the context of the polyelectrolyte character of these cytoskeletal filaments. We have taken into account the role of two aspects of this cylindrical biopolymer, its NPs and very sensitive TTs. Both of them are responsible for the nonlinear character of the overall electrical capacitance of MTs. Our solution, (20), was analyzed numerically for the set of parameters in Fig 7. It is apparent that the solitonic wave loses its energy due to ohmic resistance but it preserves the stable localized form. In the case presented in Fig. 7c with an increased nonlinearity parameter, the solitonic pulse exhibits greater robustness and it progresses with an almost constant velocity and only a slight decay of its initial amplitude. This

demonstrates the role of flexible TTs which could be of decisive importance for the stable localized character of ionic pulses along MTs. The order of magnitude of soliton–like localized pulses arising within the scope of our study ranges from mm/s to a several cm/s which are very reasonable values.

In this study, the particular attention was paid to the role of NPs existing between neighboring dimmers within a MT wall which exhibit properties like ionic channels. These NPs are candidates to explain some properties of MTs resembling to unipolar transistors enabling the rectification and amplification of ionic currents.

Finally, the experimental work of Priel et al [11] demonstrated that the electrical signal amplification resulting from the presence of MTs can be directly attributed to nonlinear ionic currents guided by MTs in close similarity to the framework developed by our present model. In fact, these measurements inspired the authors to consider the role MTs can play as biotransistors taking part in cognitive processes which is another interesting application of nonlinear ionic conductance of MTs.

It has been suggested that microtubules and other cytoskeletal filaments may act as electrical transmission lines. An electrical circuit model of the microtubule is constructed incorporating features of its cylindrical structure with nanopores in its walls. This model is used to study how ionic conductance along the lumen is affected by flux through the nanopores, both with and without an external potential applied across its two ends. Based on the results of Brownian dynamics simulations, the nanopores were found to have asymmetric inner and outer conductances, manifested as nonlinear *IV* curves. Our simulations indicate that a combination of this asymmetry and an internal voltage source arising from the motion of the *C*-terminal tails causes cations to be pumped across the microtubule wall and propagate in both directions down the microtubule through the lumen, returning to the bulk solution through its open ends. This effect is demonstrated to add directly to the longitudinal current through the lumen resulting from an external voltage source applied across the two ends of the microtubule. The predicted persistent currents directed through the microtubule wall and along the lumen could be significant in directing the dissipation of weak, endogenous potential gradients toward one end of the microtubule within the cellular environment.

I. INTRODUCTION

It has been proposed that cytoskeletal elements including actin and microtubules are involved in facilitating the propagation of electrical signals in the cell (see [1,2] for an in-depth discussion). Priel *et al.* [3] experimentally demonstrated that microtubules are excellent conductors of electrical signals and can amplify an electrical current stimulated by a pulse of applied voltage. The current collected 20–50 μm further down the microtubule (MT) was found to be double its value in the buffer solution with no MT present. Likewise, Minoura and Muto [4] found using electro-orientation experiments that the conductivity of the MT was 1.5×10^2 mS/m, which was 15 times higher than that of the surrounding buffer. Similar results have been obtained for electrical signal conduction along actin filaments [5]. Filamentous actin and MTs both share the characteristics of being protein biopolymers with highly negative linear charge densities and thus both structures are surrounded by condensed atmospheres of counterions lining their outer surfaces, which would lead to high conductances along these ionic atmospheres. However, the structure of the MT is somewhat more complex, being cylindrical in shape with a hollow interior and an additional negative linear charge density along its inner surface and having a latticelike wall interspersed with nanopores connecting the inner and outer surfaces. The question arises whether this cylindrical structure, and particularly its decorating nanopores, might be associated with novel bioelectronic properties that would contribute to the MT's proposed role in enhancing electrical signaling.

MTs self-assemble by polymerization of α/β-tubulin protein heterodimers (see supplementary material [6], Fig. S1a). These building blocks are arranged linearly into protofilaments and a ring of 13 protofilaments composes the wall of the cylindrical MT, which is typically several micrometers in length (and up to millimeters under special circumstances) and is 11.4 nm in radius at the midpoint of its wall. Each dimer in the MT has a length of 8.1 nm, a width of about 6.5 nm, and a radial dimension of about 4.6 nm [7]. A wide space, approximately 15 nm in diameter, known as the lumen, makes up the inner core of the cylinder.

The wall of a MT is generally characterized by what is known as a *B*-lattice structure, displaying two distinct types of nanopores (although it should be noted that there are two additional types of nanopores seen in the *A*-lattice structure). One nanopore in the *B*-lattice (nanopore 1) is located in the region where the interdimer β/α interface of one tubulin molecule lies next to the interdimer β/α interface of the adjacent tubulin molecule. A second nanopore (called nanopore 2) arises where the α/β intradimer interface of one tubulin molecule lies next to the α/β intradimer interface of the adjacent tubulin molecule (see supplementary material [6], Figs. S1a and S1b). The effective radius at the narrowest point of the pore is approximately 4.0 Å for the type 1 pore and 4.7 Å for the type 2 pore when calculated by the HOLE program [8] with AMBER radii [9].

Little is known about the biological relevance of the nanopores or of the lumen, which are difficult to probe experimentally. Interestingly, chemotherapy drugs of the taxane family are believed to diffuse through the MT wall via the nanopores to a binding site known to be located in the lumen [10,11]. There is also evidence for binding of ligands within the nanopore; for example, the MT-disrupting agent cyclostreptin has been shown to bind at a site within the MT nanopore [12]. Additionally, the microtubule-associated protein (MAP) tau has been observed binding to a site in the lumen

 ©2010 The American Physical Society

[13,14]. Based on their size, the nanopores are expected to be quite permeable to the atmosphere of counterions covering both sides of the MT. The flexible carboxy-terminal tail domains of tubulin, consisting of approximately the last ten residues on α-tubulin and 18 residues on β-tubulin, depending on the tubulin isotype, extend from the outer surface of the MT over the nanopores (see supplementary material [6], Fig. S1a). These tail domains have a high proportion of negatively charged residues; for example, the tail domain of βI tubulin has nine Glu residues and two Asp residues and that of αIV tubulin includes five Glu residues and two Asp residues, although the exact numbers vary slightly with isotype. This requires large numbers of counterions for charge compensation and the fluctuations of the tail domains must be associated with accompanying movements of these counterions.

No other study has yet focused on the motion of the surrounding counterions through the nanopores and around the MT, although this effect is a distinct possibility even just due to its geometrical similarity with ion flows across ion channels in membranes. Here, we intend to examine the flux of these cations under both equilibrium conditions and under a constant perturbative electrostatic potential difference between the two ends of the MT. That is, we have constructed a physical model to calculate electric current through the sides of the MT, in addition to that flowing in the longitudinal direction along a MT. To parameterize this model, we have performed detailed atomic-scale calculations of the conductances of ions through a MT's nanopores using three-dimensional (3D) Brownian dynamics. The results of our simulations will be presented in this paper and will hopefully guide future experimental validation of the predicted effect.

There is evidence in many cellular systems of an important and complex role for MTs in regulating ion-channel gating in the plasma membrane, although the mechanism of this influence has not been explained. For example, an intact MT structure has been shown to be essential for the activity of gamma-aminobutyric acid receptors in hippocampal neurons [15], for the functioning of polycystin-2 calcium channels in the kidney [16,17], and has been associated with a decreased activation threshold of Na^+ currents [18] and increased currents of Na^+ [19] and of Ca^{2+} [20,21] in neurons. On the other hand, in other studies, MT depolymerization has been associated with increased calcium currents in cardiac myocytes and in neurons [22–25]. Studies also show that ion channels can be anchored to MTs through other proteins [15,26]. Thus electrically excitable cells may possess ion channels which, by a somewhat different mechanism, have a similarly important dependence on MTs to that of mechanosensitive channels, which are tethered by other proteins to MT bundles thought to regulate their opening and closing [27,28].

The observations that MTs can regulate ion-channel activity, together with their remarkable conductive properties, and also the fact that both dendrites and axons in neurons are dense in MTs and moreover display distinctly developed cytoskeletal architectures [29] suggest that MTs may play a role in electrical signal conduction in neurons. Various instances suggest that local amplification of ion concentration could be important during the extremely complex process of action potential generation. These include the generation of an axonal action potential by distributed processing of the synaptic activity at distinct dendritic sites [30], the observation of noninactivating behavior in a small percentage of dendritic sodium channels [31], and the reduced voltage firing threshold for channels located in the axonal hillock [32].

While there is as yet no experimental confirmation that this includes electrical signal conduction, an abundance of experimental evidence supports some role of MTs during neuronal signaling. In most tissues, MTs are dynamic, growing and shrinking, but are less so in the neurons, where however rearrangement of MTs occurs during learning. Impaired learning has been found to correlate with decreased MAP2 levels [33–35], an excess of MAP tau [36,37], and can be brought on by colchicine-induced changes in MT dynamics [38–40]. Additionally, memory consolidation is accompanied by increased binding of tubulin to other neuronal proteins [41], by alterations in MAP2 expression [41–46], and by MAP 1B phosphorylation [47].

The remainder of this paper is divided into three sections. In the first, the various elements of the model we develop for ion propagation along MTs are described. Methods used to estimate the necessary parameters are described, including calculations of the electrical conductances of the two major types of pores in the MT wall by Brownian dynamics, and voltage differences arising from the fluctuating *C*-terminal domains. In the next section, we present the parameter set derived for the circuit model and give results. Finally, there is a conclusion section, in which results of our modeling are used to suggest future experimental and computational studies.

II. MODEL DEVELOPMENT

We have developed an electrical circuit model for the conduction of cations along a MT, with various electrical elements, which we describe below. Since anions are scarce in the intracellular environment and in the medium surrounding the negatively charged MT in particular, we make the approximation that potassium cations are the only charge carriers present.

The approximation is also made that the MT has cylindrical symmetry, which allows it to be represented in two dimensions, with the y axis representing the radial direction and the x axis oriented along the axis of the MT. The volume surrounding the MT is divided into four concentric cylindrical shells. Because counterion clouds result in reduced resistivities, two cylindrical shells are chosen to represent the condensed ionic atmospheres adjacent to the inner and outer surfaces, respectively, while two additional shells correspond to outer bulk solution and the luminal volume. In Fig. 1, linear wires are used to depict each of these cylindrical volumes, since in our model, averaging is performed of currents and voltages over units of cylindrical shells extending the length of one tubulin monomer along the MT. The row of tubulin monomers, which has been sketched in Fig. 1, represents the wall of the MT. A set of resistances regulates the numbers of cations allowed to cross between adjacent cylindrical shells in response to a voltage difference across the

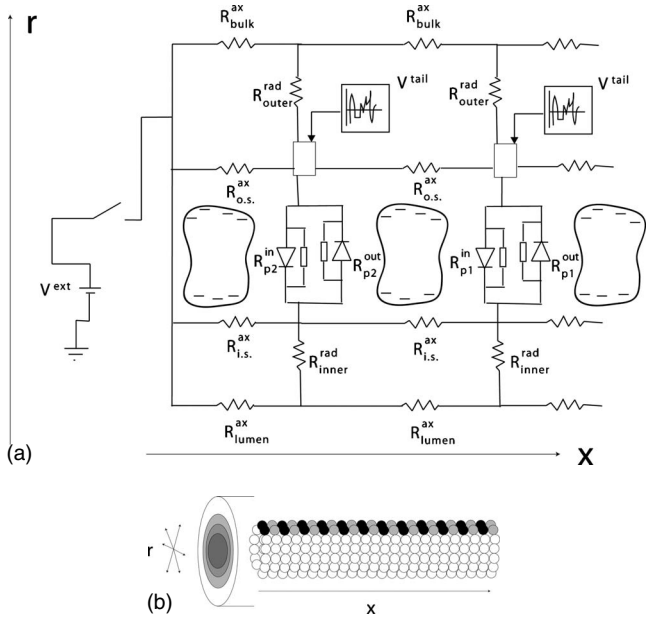

FIG. 1. (a) Two-dimensional electrical circuit model of the microtubule. The vertical direction is radial and the horizontal direction is along the axis of the microtubule. The various electrical resistances, in addition to the voltage sources, are labeled to show the physical placements of these components relative to the microtubule in the model. Abbreviations "o.s." and "i.s." are used to denote the ionic atmospheres close to the outer surface and inner surface, respectively; "ax" stands for axial and "rad" for radial. (b) Schematic representation of a microtubule, depicting the relationship between the molecular structure and the electrical circuit image shown in part (a).

boundary between the two volumes. In the case of motion of cations across the wall of the microtubule, these resistances depend on the permeabilities of the two types of nanopores.

The specific currents that we have chosen to calculate and analyze in the present work are the local currents flowing out of each of the four regions at the right-hand end of the MT. Note that this does not represent the current between the two ends of the MT, as there is also a current flowing at the other end.

Considering that the Bjerrum length, defined as the separation at which the electrostatic interaction energy equals thermal energy, is 7.13 Å at a temperature of 293 K [2], we chose to consider a 10-Å-wide layer near the inner surface and a layer near the outer surface 40-Å wide, which is approximately 10 Å extending beyond the positions of the *C*-termini.

A. Conductances

To determine conductances, we made use of the well-known relation, based on the equivalent of Ohm's law for ionic flows

$$G = \frac{\sigma(c)A}{l} = \frac{\Lambda_0^{K^+} cA}{l}, \tag{1}$$

where c is the cationic concentration, l is the distance in the direction of ionic flow, $\sigma(c)$ is the conductivity at a concentration c of cations, A is the cross-sectional area, and Λ_0 is the proportionality coefficient determining conductivity as a function of ionic concentration, which is approximately equal to 7.5 $(\Omega m)^{-1}\,M^{-1}$ for K^+ [48,49]. Further details of the evaluation of conductances are given in the supplementary material [6].

B. Brownian dynamics

The conductances of the nanopores occurring in the MT lattice limit the flow of ions between the inside and the outside of the MT. We made use of a grand canonical Monte Carlo program (GCMC-BD) created by the Roux group for computing channel conductances by Brownian dynamics simulations [50–53]. This method has been shown to be successful at determining accurate current-voltage (*I-V*) curves for ion channels, especially those with sufficiently wide cross-sectional areas ($>\sim 20$ Å^2) to allow ion motion to be suitably described by Langevin dynamics [53,54]. The nanopores in the MT wall are comparable in area to ion channels to which the program has been successfully applied.

The program uses the Ermak-McCammon equation [55] to generate the dynamics of ions undergoing random solvent collisions. All interactions in the system are being described via a multi-ion potential of mean force (PMF) and thus the equations of motion can be expressed as

$$\dot{\mathbf{r}}_i(t) = -\frac{D_i}{k_B T}\nabla_i W(\mathbf{r}_1, \mathbf{r}_2, \ldots) + \zeta_i(t), \tag{2}$$

where $\boldsymbol{r}_i$ is the position, D_i is the diffusion constant of ion i, and $\zeta_i(t)$ is the Gaussian random noise. The multi-ion PMF, W, is given by [51,52]

$$W(\mathbf{r}_1, \mathbf{r}_2, \ldots) = \sum_{i,j} u_{ij}(|\mathbf{r}_i - \mathbf{r}_j|) + \sum_i U_{core}(\mathbf{r}_i) + \Delta W_{sf}(\mathbf{r}_1, \mathbf{r}_2, \ldots), \tag{3}$$

where u_{ij} is the direct ion-ion interaction, U_{core} is the repulsive potential arising from the excluded volume of the protein, and ΔW_{sf} is the electrostatic potential from the static charge distribution of the protein together with the electric field term V [56,57]. ΔW_{sf} is determined as

$$\Delta W_{sf}(\mathbf{r}_1, \mathbf{r}_2, \ldots) = \sum_i q_i \phi_{sf}(\mathbf{r}_i), \tag{4}$$

where the electrostatic potential ϕ_{sf} is calculated using a modified version of the Poisson-Boltzmann equation, known as the PB-V equation,

$$\nabla[\varepsilon(r)\,\nabla\,\phi(r)] - \bar{\kappa}^2(r)[\phi(r) - V\Theta(r)] = -4\pi\lambda\rho^{prot}(r). \tag{5}$$

Here, Θ is the Heavyside step function equal to 0 for negative values of the z coordinate of the position vector $\mathbf{r} = (x, y, z)$ and 1 for nonnegative z, where the z axis is oriented through the pore and perpendicular to the axis of the MT; ε is the space-dependent dielectric constant, set equal to 1 in the inner and buffer regions; $\bar{\kappa}^2$ is the space-dependent ionic screening factor, set equal to 0 in the inner and buffer

regions; and ρ^{prot} is the charge density of the protein [56,57]. Details of Brownian dynamics calculations are given in the supplemental section.

Some explanation is in order concerning the source of the electric field term V. In situations in which GCMC-BD has been applied in the literature [50–54], the voltage V represents a membrane potential arising from a difference in local ionic composition on either side of the membrane in which the channel is embedded and is accounted for by Eq. (5). Here, V is accounted for by the same formalism, but represents, rather, a potential gradient across the nanopore in the MT wall arising from the fluctuating positions of the *C*-terminal tail domains and the fact that the number of ions screening the charges on these tubulin domains can be either in excess or insufficient. In what follows, this issue will be addressed in greater detail.

C. *C*-terminal tails

The charge of the *C*-terminal β-tubulin tail is generally -12 or -11 elementary charges, depending on the β-tubulin isotype, and that of the α-tubulin (isotype *IV*) tail is -7 charges. Although the remainder of the tubulin dimer is also negatively charged (with a total of ~ 50 negative charges), each tubulin monomer has a positively charged cluster of residues, which may interact with the *C*-terminus of the neighboring monomer [58].

We have performed an investigation of potential tail-body interactions of the *C*-terminal tails with positively charged residues on the surface of the tubulin dimer by molecular-dynamics simulation. Briefly, we first employed a molecular-dynamics simulated annealing approach to determine tail conformations. 15 high-temperature implicitly solvated MT dimers were generated at a temperature of 5000 K and were then slowly cooled to a target temperature of 300 K. Our annealing schedule used steps of 1000 K over periods of 400 ps until the temperature was below 2000 K and then used a 0.8 power-law cooling schedule. The tubulin dimers were then placed into a MT lattice and following equilibration, molecular-dynamics simulations were performed over periods of 10 ns, with periodic boundary conditions at a temperature of 300 K. The details of these simulations will be published separately. However, it was found that *C*-terminal tails can exist in multiple states involving different numbers of salt bridges and that the tails dynamically oscillate between these states as tail-body interactions form and then give way to interactions of tail residues with water and ions, with several such switches occurring within a single nanosecond.

When the negatively charged residues of the tails interact with positively charged residues on the tubulin dimer, fewer cations in the surrounding solvent are required to stabilize the negative charges on the protein, in comparison to when the tail residues are more extended away from the MT surface. There is also expected to be a corresponding decrease in the equilibrium number of surrounding anions, which however are not considered in our model. Since the exact equilibrium number of counterions within the condensed ionic atmosphere surrounding the outer surface of the MT varies as the positions of the *C*-terminal tails undergo thermal fluctuations, the chemical potential oscillates stochastically between being attractive or repulsive for the influx of additional cations. Thus, the motion of the *C*-terminal tails as they alternately attach and detach from the MT surface may be viewed as a stochastic voltage source acting on the surrounding cations.

To estimate the voltage difference corresponding to the variation in the *C*-terminal tail position, we performed calculations of the capacitance of the volume corresponding to the outer counterion sheath. This capacitance was defined as the coefficient of proportionality between the number of K^+ ions in this outer ionic atmosphere and a potential placed between this layer and the outer bulk solution. Ion counts for a range of potential differences were calculated by solving the PB-V Eq. (5) as implemented in the PB-PNP program [51,52]. Further computational details are given in the supplemental section [6]. The resulting curves for each pore type shown in the supplementary material [6], Figs. S2a and S2b, are highly linear and the two have a nearly identical slope corresponding to a capacitance of 1.15×10^{-8} nF.

With a variation of the tail-body interactions, corresponding to different positions of the *C*-terminal tails, the linear plot of equilibrium ion count versus potential is expected to shift up or down. If a single additional cation beyond the equilibrium number is present within the outer counterion sheath after a *C*-terminal tail has switched position to interact with the tubulin body, the line is shifted down by $1e$. This corresponds to a repulsive voltage equal to $1e$ divided by the capacitance, or ~ 14 mV. Likewise, when the *C*-terminal tail switches to a more extended conformation, there is an attractive potential of the same magnitude. In reality, a continuum of many different states is taken on by the *C*-terminal tails. Thus, the thermal fluctuations of the *C*-terminal tails on a ring of 13 monomers in the MT can be modeled as a stochastically alternating battery with a maximum voltage magnitude of $\Delta n^{*}7$ mV, where Δn is the variation in the equilibrium number of counterions in the condensed ionic atmosphere surrounding the ring. The frequency of oscillation was chosen to be 10/ns.

Note that the assertion that a current is driven by the stochastic motion of the *C*-terminal tails in no way represents a violation of energy conservation, as molecular-dynamics simulations clearly demonstrate that thermal energy is sufficient to drive large-scale fluctuations in the positions of these domains.

D. Electrical circuit

A circuit model was created to represent a MT with 20 monomers along its length using the Simulink and Simpowersystems modules of MATLAB R2009A [59]. Resistances, as well as both the external voltage and the stochastic alternating voltage and its frequency, were read as inputs. The program solved for voltages and currents at each segment of the circuit and propagated these in time using a time step of 1 ns. A switch, or circuit breaker, seen in Fig. 1, was implemented to connect the circuit to the external voltage source and opens at time zero to allow current to cross. The sources of time dependence in the model consisted of a stochastic bat-

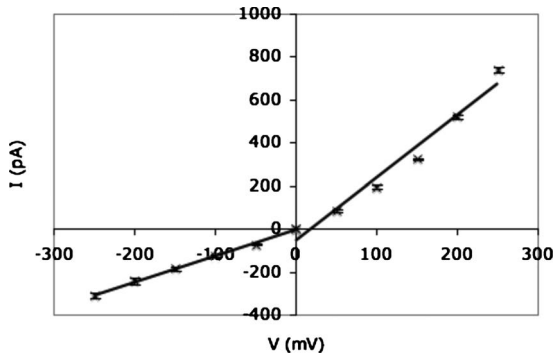

FIG. 2. Current-voltage relation from GCMC-BD simulation for conductance of cations through the type 1 pore. Error bars represent standard deviations over five independent data subsets.

tery representing the motion of the *C*-terminal tails as described above, as well as the integrators used to determine net charge transfer. The random battery generates uniformly distributed numbers over an interval between the positive and negative values of its specified voltage, with a specifiable starting seed. Because the time-dependent current showed large stochastic oscillations, its time integration was carried out to determine the amount of net charge transferred as a function of time at the end of the MT held at lower potential in each of the four cylindrical regions.

III. RESULTS

A. Pore conductances determined by Brownian dynamics

Calculated currents as a function of voltage difference for the conduction of cations across the nanopore of type 1 are plotted in Fig. 2. The *IV* curve showing the conduction of anions through this pore, as well as curves depicting the conduction of positive and negative ions through the nanopore of type 2, is shown in supplementary material [6], Fig. S3. Error bars representing standard deviations, also shown in the figure, were at most 12, 9.0, 32, and 3.7 pA for Fig. 2 and parts (a), (b), and (c), respectively, in Fig. S3 of [6]. Conductances through nanopores were determined from the slopes of linear fits of the *IV* curves shown in the figures. Both types of pores show asymmetric inner and outer conductances of cations. For the type 1 pore, inner and outer cationic conductances were found to be 2.93 and 1.22 nS, respectively. The conductance of cations was found to be somewhat greater for the type 2 pore, with calculated values of 7.80 and 4.98 nS, respectively, for inner and outer conductances. The cylindrical shell-like wall of the MT has a sandwichlike electrostatic potential being negative on the inside, even more negative on the outside, and positive in the center (see supplementary material [6], Fig. S1b). The very negative potential on the outer surface attracts cations into the pore at a positive potential and also makes it difficult for anions to enter the pore at a negative potential.

Both nanopores were found to be almost completely impermeable to anions at negative potentials (43.7 and 11.8 pS for types 1 and 2 pores, respectively). The positive parts of the anion conductance curves in supplementary material [6], Figs. S3a and S3c, are fit well by exponential curves, as shown. Conductances of anions into the pores increase substantially as the voltage is raised above 150 mV, from about 11.8 to 198 pS for the type 2 pore and from 240 pS to 1.10 nS for the type 2 pore, as determined from linear fits of the positive voltage data in the intervals between 0 and 150 mV and between 150 and 250 mV, respectively. The difficulty for anions to enter the pore is most likely partially due to the composition of the constriction zone. As determined by the HOLE program [8], the constriction zone of pore 1 is bounded by α-tubulin residue Thr 130, by Phe 212 of the adjacent β tubulin, and Asp 327 of the other α tubulin. In pore 2, the constriction zone is bounded by residues Thr 94 of α tubulin, Asp 128 of the adjacent β tubulin, and Asp 218 of the other α tubulin. Thus, the negatively charged Asp residues may make it difficult for anions to breach this area and especially so in the type pore 2 where there are two such charged residues.

Asymmetric conductances have been measured in ion channels by GCMC-BD in the past, giving good agreement with experiment [50]. For example, for the OmpF pore, conductances were calculated to be 1.36 and 1.15 nS with positive and negative voltages across the channel, respectively, compared to values of 1.25 and 1.13 nS determined experimentally [53].

To assess the role of the protein charge distribution in contributing to nanopore conductances, calculations were repeated for the type 2 pore, but this time with all protein charges turned off. We found that this led to the cation conductance being reduced by a factor of about 15. The conductance of anions was much larger than for the charged model, being increased by a factor of about 24 at a negative potential and by a factor of about 4 at high positive potentials. These results show that electrostatics has a very significant effect on the conductive properties of the nanopores. We also investigated the effect of a different *C*-terminal tail conformation; with a different position with respect to the MT, the conductance of cations was changed by only 11% and there was very little effect on the conductance of anions. Within our circuit model, a pair of forward-biased diodes was used to model the asymmetric conductance of each MT pore, with one controlling the flow of cations into the MT and the other regulating the outward flux, as is illustrated in Fig. 1.

B. Parameterization of electrical circuit

The repeating unit of two monomers is illustrated in Fig. 1. Values of resistances, which were calculated as described above for use in our model, are given in Table I. The bulk resistance shown in the table was calculated using an outer radius of 50 nm for the entire system. This value was chosen based on the typical distance of 100 nm separating parallel MTs in the cell such as a neuron. Resistance is smallest in the bulk region, followed by the outer condensed ionic atmosphere and the inner condensed ionic atmosphere, with the inner lumen having the smallest conductance.

C. Application of circuit model to dynamics of ionic flow

The time-integrated currents running parallel to the MT axis through each of the four cylindrical regions, which is

TABLE I. Computed resistances in Ohms. Diagonal elements describe the flow of K^+ ions along cylindrical shells running parallel to the microtubule axis in each of four regions. Values corresponding to flow between adjacent volumes are shown as off-diagonal elements, with the region of positive potential given in the first column; upper and lower values represent flow through pore 1 and pore 2, respectively.

	Inner lumen	Inner sheath	Outer sheath	Outer bulk
Inner lumen	1.77×10^{7}	1.07×10^{6}		
Inner sheath	1.07×10^{6}	1.25×10^{7}	6.41×10^{7}	
			1.54×10^{7}	
Outer sheath		2.65×10^{7}	4.75×10^{6}	4.06×10^{6}
		9.86×10^{6}		
Outer bulk			4.06×10^{6}	5.31×10^{5}

along each of the four electrical transmission lines shown in Fig. 1, were measured at the right-hand end of the MT; these are plotted in Fig. 3. A value of 28 mV was used for the stochastic voltage source and 1 mV for the external voltage source applied across the two ends of the MT.

Asymmetric conduction of microtubule pores enhances ionic flow through the lumen. The elements of the circuit model that confer nonlinearity are the asymmetric conductances of the nanopores and the stochastic tail battery. To determine what effect these have on the longitudinal currents, we compared results for the case where there is no internal voltage from the tail movement (see supplementary material [6], Fig. S4), when there is no asymmetry in the conductance in supplementary material [6], Fig. S5, and when there is neither asymmetry nor an internal voltage. The same values corresponding to inward resistances were assigned to the outer resistances to model symmetric conduction.

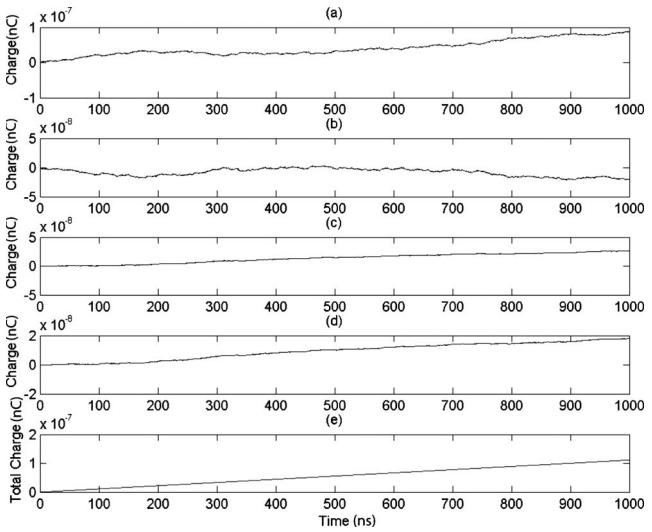

FIG. 3. Time-integrated current (nC) for asymmetric pore conductance plotted against time (ns), with an external voltage of 1 mV and a stochastic voltage of 28 mV. The five panels are, from top to bottom, time-integrated current through (a) the bulk solution outside the microtubule, (b) the outer ionic atmosphere of the microtubule, (c) the inner ionic atmosphere of the microtubule, (d) the rest of the lumen and (e) summed for (a-d).

Without the voltage created by the stochastic motion of the *C*-terminal tails, plots of charge transferred versus time are linear, indicating a constant current. In this case, it makes no difference whether the conductance of the nanopores is symmetric (not shown) or asymmetric, as there is no driving force on the ions in the lateral direction. The net charge transferred in the bulk region after the end of 1000 ns is 1.0×10^{-7} nC, while a net charge of about 1.1×10^{-8} nC flows along the outer ionic atmosphere, which has a smaller area although its conductivity is greater. Only 4×10^{-9} nC is transferred along the inner ionic atmosphere of the MT and even less (3×10^{-9} nC) through the central lumen.

When the *C*-terminal tail fluctuation is accounted for in the model but with symmetric pore conduction, the summed charge transferred along the inner ionic atmosphere and the lumen is 3.1×10^{-10} nC at the end of the 1000 ns time period. Small fluctuations on the time scale of the tail motions are exhibited in the plots, as well as larger time-scale fluctuations, representing an oscillatory exchange of ions between the bulk solution and the condensed atmosphere of counterions near the MT's surface.

When the conductance asymmetry of the pores is included in the model, the total charge transfer in the lumen increases to about 4.4×10^{-8} nC, with 2.6×10^{-8} nC moving along the inner ionic atmosphere and 1.8×10^{-8} nC moving through the inner lumen. It may be noted by comparing values at 500 ns to those at 1000 ns that the average currents in the two luminal regions are well converged by 1000 ns. Thus, the overall charge transferred divided by the total time may be thought of as the average current and the total average current through the lumen predicted by our circuit model is 4.4×10^{-2} nA for Fig. 3. These results demonstrate that the conductance asymmetry of the MT wall allows the random internal battery to pump cations transversely through the nanopores into the lumen, from which they are directed out of one of the open ends of the MT.

Total longitudinal charge transferred along MT is independent of nanopores. In each of Fig. 3 and Figs. S4 and S5 of supplementary material [6], the value of total charge transferred after 1000 ns is identical. Therefore, the summed current along the outer ionic atmosphere and in the bulk, which without the asymmetric conductance or the internal random battery had been 1.1×10^{-1} nA, is reduced by the additional 3.7×10^{-2} nA current which is now shunted through the lumen; that is, the additional luminal current is drawn from the outer ionic atmosphere and the outer bulk solution.

Two-dimensional (2D) spatial-temporal plots reveal that net ionic current flows inward through some pores and outward through others. Net charge transfer was determined as a function of time and position along the MT by measuring time-integrated current outputs loaded from the four electrical wires at positions immediately to the right of each of the 20 tubulin monomers to yield 2D spatial-temporal plots. A random battery voltage of 28 mV was used and external voltages of 0 and 1 mV, as shown in Fig. 4 and Fig. S6 of supplementary material [6], respectively. The average currents at the end of the 1000 steps, given by the overall charge transferred divided by total time, are directed to the right

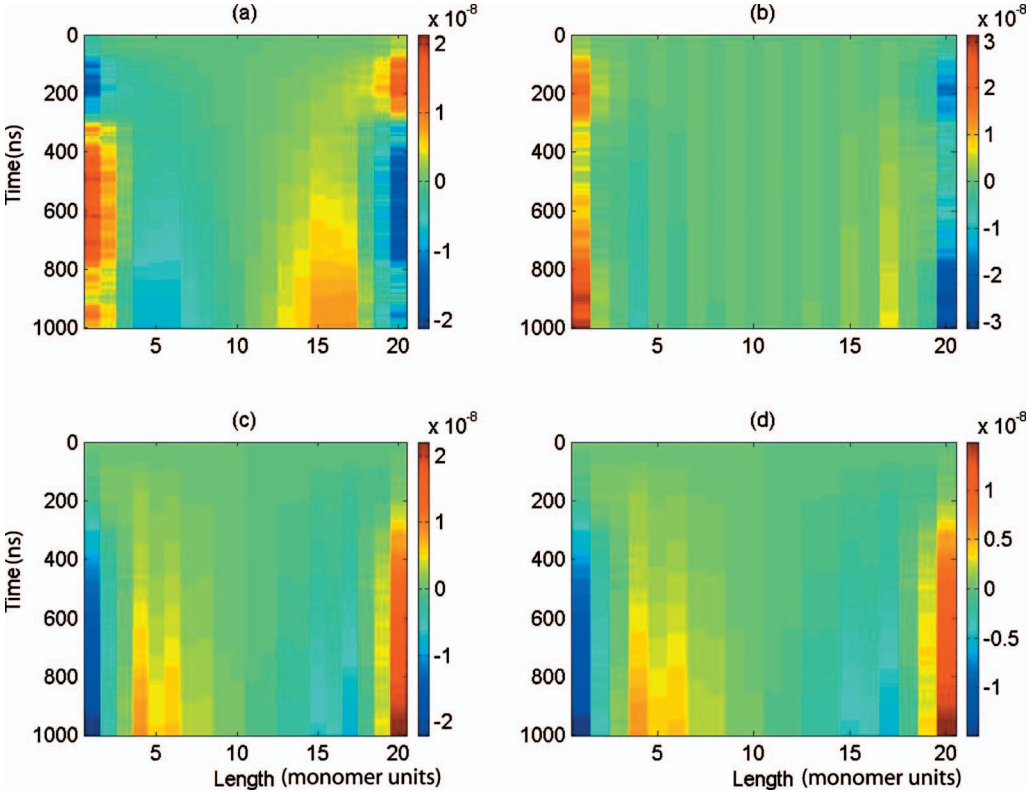

FIG. 4. (Color) Color plot showing integrated current (nC) as a function of time (ns) and tubulin unit through (a) the bulk solution outside the microtubule, (b) the outer ionic atmosphere of the microtubule, (c) the inner ionic atmosphere of the microtubule, and (d) the rest of the lumen. A stochastic voltage of 28 mV was used and an external voltage of 0 mV.

where the area adjacent to the x axis is colored red or yellow and to the left if the coloring is blue. An interesting pattern of currents arises surrounding the MT's wall in the 0 mV case. Close to the ends of the MT, the current flows into the MT and out through the open ends (since, for example, at the left-hand end, the direction of the current is to the right just outside of the microtubule's wall [Fig. 4(b)] and to the left along the wall's inner side [Fig. 4(c)]). On either side of the center, the current follows a loop, so that there are currents flowing away from the center on the outside of the MT and toward the center on the inside. The pattern of currents is symmetric about the center of the MT. The current driven through the wall of the MT leaves either one or the other end of the MT with equal probability. This is to be expected, since no potential gradient between the two ends of a MT means no net current between the two ends. With the 1 mV applied voltage, within the lumen, there is a multidirectional spatial gradient of charge transfer, whereas in the bulk solution at any given time, the direction of charge flow is much more uniform along the length of the MT.

Net current driven through pores adds directly to that induced by the external potential, independent of value of external potential or MT length. In Fig. 5, the current-voltage (IV) curves are shown for total luminal current versus external voltage for values of the random battery equal to 14 and 28 mV, respectively. Simulations were run for values of the external voltage ranging from −100 to 100 mV. Plots were determined to be linear over the entire range of voltages. In the case of symmetric conductance, the IV curve passes through the origin. Asymmetric conductance of the pores shifts the curve toward positive currents. However, the slope is unchanged, showing that the current being driven through the nanopores adds directly to the current induced by the external potential. The effect of varying the length of the MT was also examined using MTs composed of 10 or 30 monomers (see Fig. S7 of supplementary material [6]). The y intercepts of the resulting plots both coincide with that obtained for a length of 20 monomers, although the slope changes as a result of the altered voltage per unit distance. That is, additional tail batteries associated with a longer MT cannot increase the transverse current across the MT wall

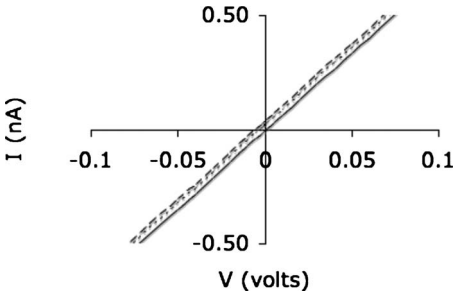

FIG. 5. Current-voltage relations calculated using the circuit model for conductance of cations through the microtubule lumen. A microtubule length of 20 monomers was used. Dotted line corresponds to a stochastic voltage of 14 mV and dashed line to a stochastic voltage of 28 mV. Solid line corresponds to symmetric pore conductance.

and the same net current is pumped across independent of length.

It is important to note that, within our model, the main function served by the thermally driven tails is the pumping of cations from the bulk solution to the lumen. While this continually adds to the population of cations within the lumen, at the same time (in the absence of an external voltage), the added cations leave the lumen mainly from both ends of the microtubule, returning back to the bulk to maintain an equilibrium state. As a result, there is neither a net current into the lumen nor through it in the longitudinal direction, i.e., no charge accumulates within the lumen.

Net current through pores is roughly linear in the value of the tail battery. The positive shifts of the *IV* curves given by the *y* intercepts of the plots in Fig. 5 were 0.021 and 0.037 nA for random battery voltages of 14 and 28 mV, respectively. If the random battery is increased to 140 mV, then the shift is 0.19 mV. Thus the value of the current scales almost linearly with the unknown random voltage.

Luminal current at the end of the microtubule driven by fluctuations of C-terminal tails exceeds that driven by the external battery at small values of the external voltage. At zero or even small negative values of the voltage, a positive current persists at the end of the MT, just as there was a backward flow of charges at the opposite end for small positive values of the voltage. The *x* intercept on each plot in Fig. 5 or Fig. S7 of supplementary material [6] corresponds to not only the external voltage at which forward current vanishes, but also the magnitude of external voltage required to halt the backward flow of ionic current. Most importantly, for positive external voltages smaller than the absolute value of the *x* intercept on the plot, the potential associated with the stochastic fluctuation of *C*-terminal tails is the dominant driving force acting on the cations, whereas as the external potential is increased beyond this point, the stochastic tail voltage, while still adding to the total longitudinal current, contributes less than the external battery to this total. In summary, the addition to the longitudinal current by the current through the MT wall is most important at small values of the external voltage.

D. Theoretical justification

Our computational model demonstrates that the influx of cations through the nanopores results in an addition to the transfer of cations to the more negative end of the MT through the lumen. We now attempt to provide some basic understanding of this effect by using a simple theoretical model.

Consider the *n*th unit of a MT, shown in Fig. 6. Here I_n^b, I_n^{os}, I_n^{is}, and I_n^l are the current in the bulk (*b*), outer surface (os), inner surface (is), and the lumen (*l*), respectively. The random tail batteries $\varepsilon_n(t)$ and $\varepsilon_{n+1}(t)$ are time dependent and could be in different phases, and so in general $\varepsilon_n(t)$ will not equal $\varepsilon_{n+1}(t)$ in both magnitude and sign. The time-dependent resistor blocks $R_n(t)$ and $R_{n+1}(t)$ are determined by the two sets of resistances R_{p1}^{in} and R_{p1}^{out}, and R_{p2}^{in} and R_{p2}^{out}, respectively,

$$R_n(t) = (1/2)[R_{p2}^{\text{in}}(1 + \varepsilon_n/|\varepsilon_n|) + R_{p2}^{\text{out}}(1 - \varepsilon_n/|\varepsilon_n|)], \quad (6)$$

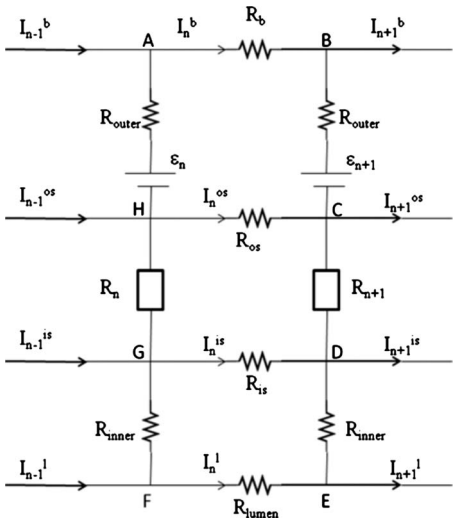

FIG. 6. *n*th unit of the same microtubule model shown in Fig. 1.

$$R_{n+1}(t) = (1/2)[R_{p1}^{\text{in}}(1 + \varepsilon_{n+1}/|\varepsilon_{n+1}|) + R_{p1}^{\text{out}}(1 - \varepsilon_{n+1}/|\varepsilon_{n+1}|)]. \quad (7)$$

The direction of the current in the branch labeled HG(CD) in Fig. 6 for HG (CD) branch depends on whether the tail battery ε_n (ε_{n+1}) is pushing the charge carriers through the nanopores or pulling out from them. As a result, the current flows in or out through different resistors. The term $\varepsilon_n/|\varepsilon_n|$ in the above equation represents the dependence of these resistances on the state of the tail battery. In the symmetric case $R_{p2}^{\text{out}} = R_{p2}^{\text{in}} = R_{p1}^{\text{out}} = R_{p1}^{\text{in}}$, and so $R_n(t) = R_{n+1}(t)$.

To extract some information on the current or the resulting accumulated charges in the lumen, Kirchhoff's rules are applied:

Loop ABCHA

$$\varepsilon_n(t) - \varepsilon_{n+1}(t) - (R_b + 2R_{\text{outer}})I_n^b + R_{\text{outer}}(I_{n-1}^b + I_{n+1}^b) + R_{\text{os}}I_n^{\text{os}} = 0. \quad (8a)$$

Loop HCDGH

$$R_{\text{is}}I_n^{\text{is}} - (R_{\text{os}} + R_n + R_{n+1})I_n^{\text{os}} + R_nI_{n-1}^{\text{os}} + R_{n+1}I_{n+1}^{\text{os}} = 0. \quad (8b)$$

Loop GDEFG

$$R_{\text{lumen}}I_n^l - (R_{\text{is}} + 2R_{\text{inner}})I_n^{\text{is}} + R_{\text{inner}}(I_{n-1}^{\text{is}} + I_{n+1}^{\text{is}}) = 0. \quad (8c)$$

The difference $\Delta I_n^l = I_{n+1}^l - I_n^l$ represents the change in the current through the lumen from the *n*th unit to $(n+1)$th unit, which can be shown by combining Eqs. (8a)–(8c) to satisfy

$$R_{\text{os}}R_{\text{lumen}}\Delta I_n^l = [R_{\text{os}} - \Delta^2 R_n(t)][\Delta^2\varepsilon_n(t) + R_b\Delta I_n^b], \quad (9)$$

where $\Delta F_n = F_{n+1} - F_n$ and $\Delta^2 F_n = F_{n+1} - 2F_n + F_{n-1}$ for any function F_n. For small values of the external battery, one expects that the bulk current does not change significantly and so $\Delta I_n^b \sim 0$. Therefore,

$$R_{\text{os}}R_{\text{lumen}}\Delta I_n^l \sim [R_{\text{os}} - \Delta^2 R_n(t)]\Delta^2\varepsilon_n(t). \quad (10)$$

In the symmetric case $R_{n+2}(t)=R_{n+1}(t)=R_n(t)$ and so $\Delta^2 R_n(t)=0$,

$$R_{\text{lumen}}\Delta I_n^l \sim \Delta^2 \varepsilon_n(t) \tag{11}$$

or

$$R_{\text{lumen}}(d/dt)\Delta Q_n^l \sim \Delta^2 \varepsilon_n(t), \tag{12}$$

where ΔQ_n^l is the change in the accumulated charges in the lumen between units n and $n+1$. Since the tail battery $\varepsilon_n(t)$ is random in nature, its average value over the course of time should be zero. Therefore, $\Delta Q_n^l \sim 0$ and so one would not expect to see a significant change in the average value of the current through the lumen or in the resulting accumulated electric charges. This is what is seen in Fig. S5 of supplementary material [6].

In the asymmetric case, however, $\Delta^2 R_n(t)$ is not zero and so one has

$$R_{\text{os}}R_{\text{lumen}}\Delta Q_n^l \sim -\int dt \Delta^2 R_n(t)\Delta^2 \varepsilon_n(t). \tag{13}$$

It is clear that the above integrand has zeroth- and second-order terms in $\varepsilon_n(t)$,

$$\begin{aligned}\Delta^2 R_n(t)\Delta^2 \varepsilon_n(t) = [R_{p2}^{\text{in}} + R_{p2}^{\text{out}} - R_{p1}^{\text{in}} - R_{p1}^{\text{out}}] + (1/2)(R_{p2}^{\text{in}} - R_{p2}^{\text{out}}) \\ \times(\varepsilon_{n+1}/|\varepsilon_{n+1}| + \varepsilon_{n-1}/|\varepsilon_{n-1}|) \\ -(R_{p1}^{\text{in}} - R_{p1}^{\text{out}})\varepsilon_n/|\varepsilon_n|](\varepsilon_{n+1} - 2\varepsilon_n + \varepsilon_{n-1}).\end{aligned} \tag{14}$$

As a result, one expects the average accumulated charge to be nonzero over the course of time as we move along the MT units, as seen in Fig. 3.

IV. CONCLUSIONS

The key finding of the present work is the determination of the thermally driven currents involving the motion of cations circulating in and around the microtubule. Our model demonstrates how the MT's distinctive geometry, being a cylindrical biopolymer with channel-like nanopores and *C*-terminal tails extending outward from the surface, may enhance the conduction of cations through the lumen, as a result of asymmetry in ion conduction through the pores and fluctuating tail-body interactions. This was demonstrated by comparing the longitudinal current at the end of the microtubule obtained by our model with the results for symmetric pore conduction or where there is no stochastic voltage source from the tail movement.

However, our treatment of the difference in potential between the two ends of the MT as fixed entails that, within this model, the sum of longitudinal currents through all four cylindrical regions is necessarily constant, independent of the presence or absence of conduction through the sides of the MT. The type of situation that is more likely to arise in the cellular environment is a short-lived state of increased potential at one end of the MT, slowly dispersing as ions flow toward the other end. In that case, it may be expected that transferred charges would accumulate at the end with the more negative potential and that current passing through the lumen would not all back-propagate in the opposite direction along the bulk and outer surface, as in the results presented here. That is, the total longitudinal current may increase as a result of the current being focused through the pores into the lumen. In future work, a more realistic computational model allowing for dynamic equilibration, for example, by solution of the Smoluchowski equation, could be used to test this hypothesis. From a biological perspective, this could imply that when a weak potential difference occurs across its two ends, a MT may allow the resulting current to be amplified along its direction, preventing dissipation as random noise throughout the cell. It is possible that within the cellular environment, this may contribute to the opening of voltage-gated ion channels with which the MTs form a terminal connection.

It is also tantalizing to speculate about the role of the most structurally variable element of tubulin, its *C*-terminal tail region, that can be thought of as a tubulin isotype identifier. With major differences across the isotypes in both the length and charge of *C*-termini, their specialized role as an active dynamical element of the electrical circuitry formed by a MT may provide an explanation for tubulin isotype distribution differences among different cell types, e.g., the abundance of βIII tubulin in neurons [60].

Interestingly in this connection, Minoura and Muto [4] found that when the *C*-terminal tail region of the MT was cleaved by subtilisin digestion or when the pH was varied, the effect on conductance was proportional to the decrease in the net number of negative charges, indicating that the high conductivity was primarily due to the polarization response of the condensed atmosphere of counterions to the external voltage source. The volume for which conductance was calculated was 21.6 nm in radius and thus would have included a region of what we have referred to as the outer bulk solution. These observations agree with our results predicting that the stochastic motion of *C*-terminal tails has no effect on overall charge conduction. However, we expect that the "pipelike" conduction of cations through the lumen predicted here would increase the current focused at a narrow region at one end of the MT. Experimental testing of the results of the present model would require a narrowly focused current sensor capable of recording the isolated luminal current. Digestion of *C*-terminal tails by subtilisin or changes in pH or ionic concentrations could then be used to test our predictions of the involvement of *C*-terminal tails by ascertaining how MT conductivity through the lumen varies with the corresponding net negative charge of the dimer. The much-needed experimental validation of our predictions would undoubtedly lead to exciting new opportunities in the development of biological nanoscale electronic applications.

ABSTRACT

Tubulin, an α/β heterodimer, has had most of its 3D structure analyzed; however, the carboxy (C)-termini remain elusive. Importantly, the C-termini play critical roles in regulating microtubule structure and function. They are sites of most of the post-translational modifications of tubulin and interaction sites with molecular motors and microtubule-associated proteins. Simulated annealing was used in our molecular dynamics modeling to predict the interactions of the C-terminal tails with the tubulin dimer. We examined differences in their flexibility, interactions with the body of tubulin, and the existence of structural motifs. We found that the α-tubulin tail interacts with the H11 helix of β-tubulin, and the β-tubulin tail interacts with the H11 helix of α-tubulin. Tail domains and H10/B9 loops interact with each other and compete for interactions with positively-charged residues of the H11 helix on the neighboring monomer. In a simulation in which α-tubulin's H10/B9 loop switches on sub-nanosecond intervals between interactions with the C-terminal tail of α-tubulin and the H11 helix of β-tubulin, the intermediate domain of α-tubulin showed more fluctuations compared to those in the other simulations, indicating that tail domains may cause shifts in the position of this domain. This suggests that C-termini may affect the conformation of the tubulin dimer which may explain their essential function in microtubule formation and effects on ligand binding to microtubules. Our modeling also provides evidence for a disordered-helical/helical double-state system of the T3/H3 region of the microtubule, which could be linked to depolymerization following GTP hydrolysis.

INTRODUCTION

The tubulin protein polymerizes to form microtubules (MTs) which are cylindrical structures consisting typically of 13 protofilaments, each of which is comprised of repeats of α–β tubulin hetero-dimers. The carboxy (C)-terminal tail domains of all tubulin monomers are found on the outer surface of the MT. Both α- and β-tubulin consist of numerous isotypes, differing in amino acid sequence and cellular and tissue distribution.[1] The lengths and sequences of the C-terminal tails vary greatly depending on isotype; human isotypes typically consist of 10–13 residues on α-tubulin, and 18–24 residues on β-tubulin, and have a high proportion of negatively charged residues.[2,3] A great deal of evidence indicates that the C-terminal tails of both α- and β-tubulin play critical roles in regulating MT assembly and function, and in determining the conformation of the tubulin molecule,[4–8] roles whose details are very poorly known. C-terminal tail residues are necessary for the assembly of normal MTs; one recent cloning study has demonstrated that the first two tail residues of β-tubulin are indispensable for the formation of MTs in HeLa cells.[4] Tubulin polymers assembled *in vitro* from tubulin lacking both C-terminal tails (denoted as $\alpha_S\beta_S$ tubulin) display an altered morphology characterized by bundles of twisted filaments, sheets,[5] and hooks.[6,7] Moreover, the presence of alkali metal cations[8] or cleavage of tails[5] allows polymers to form at lower tubulin concentrations, and the reduction of negative charges on C-termini by covalent modification lowers the rate constant for MT disassembly.[9] Tubulin polymers lacking only the β-tubulin tail ($\alpha\beta_S$ tubulin) display a ring con-

formation, do not require GTP for polymerization, and are temperature insensitive.[10]

It is likely that the effects of the C-termini on MT assembly and tubulin conformation are critically dependent on the conformational interaction between the C-termini and other parts of the tubulin molecule. Nevertheless, the natures of these interactions are almost entirely unknown. Although a series of studies have determined the structure of the rest of the tubulin molecule, the structures of the C-termini have remained largely invisible to crystallographic methods. Thus, a molecular-level picture of the structures of tubulin protofilaments obtained by molecular dynamics (MD) simulations, including both tail dynamics and their interactions with the remainder of the protein, offers an opportunity to provide unique insights into a better comprehension of the biological functions of tail domains and their significance for MTs.

Depending on the isotype, the charge of the C-terminal tail of human β-tubulin is generally between −10 and −12 *e* and that of the α-tubulin tail is −7 or −8 *e*, not including post-translational modifications.[2,3] Although the remainder of the tubulin dimer is also negatively charged overall (the total charge of the dimer is approximately −50 *e*), there are also positively charged regions on the protein surface. By using reductive methylation, residue Lys 394, which together with Arg 390 and His 393 forms a positively-charged pocket on the surface of α-tubulin, has been shown to be essential to MT polymerization.[11,12] Because Lys 394 is less accessible to methylation in the MT polymer compared to when present in the dimer,[12,13] it has been suggested that this residue is involved in electrostatic interactions with the negatively-charged acidic residues in the tail regions.[14] The existence of such a "tail–body" electrostatic interaction was also supported by a study[15] in which the detached α-tubulin tail was computationally docked to the tubulin surface and found to bind at a site near Lys 394. Experimental findings that C-terminal tail cleavage can affect ligands that bind to tubulin, and that this influence seems to be due to electrostatic interactions, also indicate that tail–body interactions contribute to tubulin conformation. This evidence includes a study showing that cleaving the C-terminal tail on α-tubulin lowers the activation energy for colchicine binding to tubulin, and leads to pH independent binding.[16] Another such study showed that the influence of oligoanions on the stabilization of tubulin polymers by vinblastine is eliminated by the cleavage of the C-terminal tails of β-tubulin.[17]

lysine

The objective of this article is to use MD modeling in order to elucidate the issues surrounding the role of C-termini in structural and functional effects on the tubulin dimer and, consequently, in the biological behavior of MTs. The specific modeling tool that we apply to our analysis is simulated annealing in conjunction with MD simulation. Simulated annealing is an enhanced sampling technique in which heating followed by re-cooling of a molecular system can be used to determine its equilibrium structure. Heating allows the system to overcome energy barriers that would otherwise prevent the system from fully sampling configuration space, and slow cooling causes the system to freeze into a minimum energy structure. This method has frequently been applied within Monte Carlo simulations to determine conformational free energy minima[18,19]; more recently simulated annealing has been used within MD simulations,[20] as it is in the present work. Here, this technique is applied to obtain positions of C-terminal tails for the tubulin dimer. Subsequently, simulations are run of protofilaments formed from αβ tubulin, $\alpha\beta_s$ tubulin, and from $\alpha_s\beta_s$ tubulin. In this way, the effects of the tails on protofilament dynamics are investigated computationally.

We analyze MD trajectories to investigate the occurrence of tail–body interactions of the C-terminal tail regions with positively-charged residues on the tubulin surface. Structural motifs intrinsic to the C-terminal tail domains seen in the MD trajectories are also considered. Finally, we analyze the root mean square fluctuations of residues in trajectories with and without tail domains. We show that interactions of the tail domains with exposed residues on the surface of the remainder of the protein may play an important role in MT dynamics by influencing the large-scale conformation of tubulin's intermediate domain.

MATERIAL AND METHODS

Simulated annealing

After heating the tubulin dimer system to 5000 K, each of 12 models was slowly cooled to 300 K over 5.2 ns of simulation time. Out of these 12, three models were selected as starting positions in simulations of two explicitly-solvated tubulin protofilaments. The flowchart in Figure 1 summarizes the simulated annealing/MD simulation procedure adopted in our study to determine tubulin tail conformations, which we now describe in detail.

Our system consisted of a tubulin dimer, composed of human isotypes αIV and βI, modeled as described elsewhere[21]; these have C-terminal tails with lengths of 10 and 18 residues (residues α439–448 and β427–444), and charges of −8 and −12 *e*, respectively. Initial set-up was performed in the *leap* and *antechamber* modules of the AMBER9[22] program package using the AMBER03 force field to parameterize the tubulin protein.[23,24] MD was performed using the sander module of AMBER9.[22] Twelve high temperature implicitly-solvated MT dimers were generated by heating the dimer to 5000 K (chosen to make the tails mobile on a reasonable time scale), and then extracting structures from the simulation every

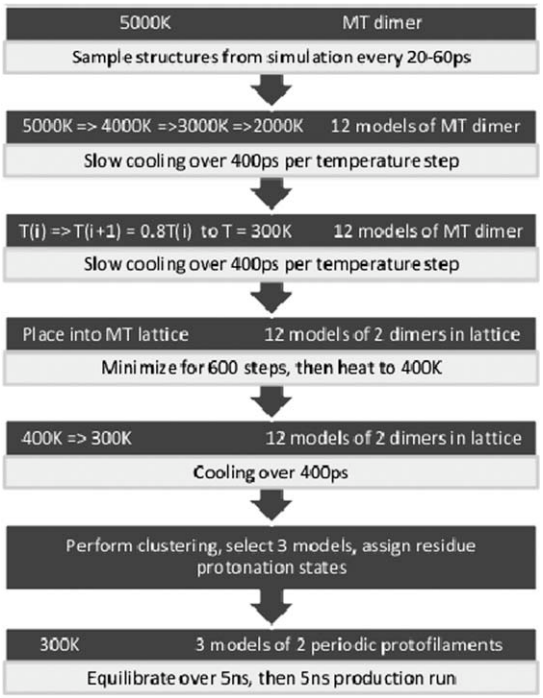

Figure 1

Flowchart illustrating the simulated annealing/MD simulation procedure used in this work to determine tubulin tail conformations.

20–60 ps. These were then slowly cooled to a target temperature of 300 K. Our annealing schedule used temperature reduction steps of 1000 K over 200 ps time periods, with equilibrations being performed at each of these temperatures for a period of another 200 ps, until the temperature was below 2000 K, and then used a 0.8-power law cooling-schedule again with 400 ps spent for each temperature stage. A time step of 1 fs was used throughout all simulations. The modified generalized Born method GB^{OBC} corresponding to model II in Ref. [25] (igb = 5) was employed to represent a 150 m*M* ionic solution and the temperature was maintained by a Langevin thermostat with a collision frequency of 2 ps^{-1}. All bonds involving hydrogens were constrained using the Shake[26] algorithm. A restraint weight of 15 kcal/mol was placed on residues 1–438 of α tubulin and 1–428 of β tubulin. Removal of center-of-mass translational and rotational motion was disabled. The non-bonded cut-off used was 50 Å.

Structures were fit to the original homology model by running simulations for 5000 steps with a restraint of 50 kcal/mol on the α-carbons of all residues not belonging to the C-terminal tail domains, forcing the α-carbons belonging to the main body of the dimer to assume a structure similar to the one determined by electron crystallography experiments. In some cases, the *autosculpt* feature of the Pymol program[27] was employed to slightly adjust the positions of β tubulin tail residues which overlapped with parts of the opposite β tubulin. Tubulin dimers were then placed into a configuration consistent with MT geometry by using the model of Li *et al.*[28] Two adjacent dimers were created as would exist in the MT lattice by using an in-house VMD[29] script, as described elsewhere.[30] These were then relaxed for 300 steps without solvent, and another 300 steps with implicit solvent. Afterwards the structures were heated to 400 K, and then cooled to 300 K over a period of 400 ps for further energy minimization, with the same restraint on the α-carbons belonging to the main body.

The 12 models of the tubulin dimer resulting from our simulated annealing procedure are shown in Figure 2. Structures were clustered in the *ptraj* module of AMBER using the means algorithm[31] to produce three clusters each for α- and β tubulin tails, by comparing positions of alpha-carbons based on root-mean-squared distance (RMSD) after fitting all tubulin dimers, excluding tail residues, to the position of one of the dimers. Clusters of α tubulin tail peptides contained five, four, and three elements, respectively, with mass weighted root-mean-square distances to the centroid of 0.6 Å for each of the three clusters. Clustering the β tubulin tail peptides resulted in one group of six elements, with a mass weighted root-mean-square distance to centroid of 1.4 Å, a second cluster with five elements and a mass weighted root-mean-square distance to centroid of 1.3 Å, and a third cluster with a single element only. Cluster

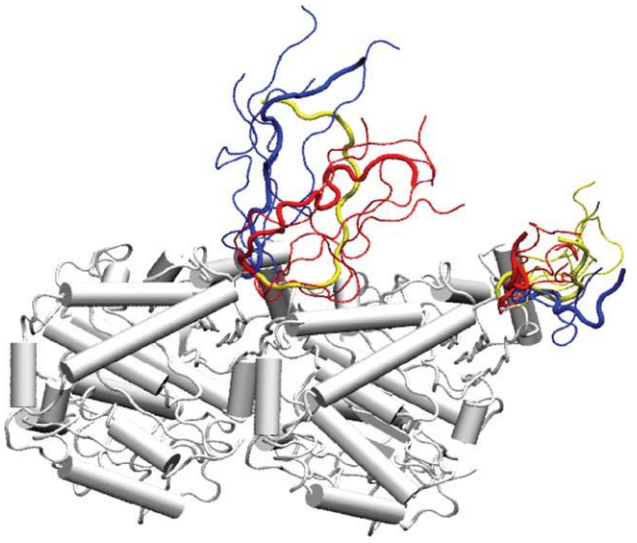

Figure 2

Tubulin dimer, showing three clusters obtained by simulated annealing MD for the C-terminal tail domains, colored in yellow, red, and blue, respectively. Cluster representatives *p1* (yellow), *p2* (red), and *p3* (blue) are depicted as thicker coils compared to other cluster elements. The dimer is viewed from above if positioned in a MT lattice with β-tubulin on the left and α-tubulin on the right.

representatives were chosen as the dimers having β tubulin tails closest to the cluster centroids. Because each of these three dimers fell into a different one of the three clusters corresponding to the α tubulin tails, we chose to retain the original pairing between α- and β tubulin monomers, rather than pairing cluster representatives for β tubulin tails with similarly chosen cluster representatives for α tubulin tails. As a further check on the appropriate number of representatives, hierarchical clustering of both β- and α-tubulin tails was performed using the MMTSB Toolset[32] command *jclust* with the *rmsd* mode, requesting a maximum of 50 structures, which gave two main clusters for the α-tubulin tail and three for the β-tubulin tail.

The three representative dimers, which were used to perform MD simulations, are shown in Figure 2. In the text that follows, we refer to these three models as *p1*, *p2*, and *p3*. In addition, we performed simulations with one or both tail domains removed. The α-tubulin tail position for the $\alpha\beta_S$ model was taken from model *p3*.

MD simulations

The *propka* program[33,34] was used to assign protonation states to Asp, Glu, His, and Lys residues on each of the three models; as a result His 309 was protonated on α-tubulin of model *p1*, His 307 on β-tubulin of models *p2* and *p3*, and α-tubulin residue Asp 46 was protonated on all three models.

The tubulin dimers were then placed into a MT lattice. The positions of GDP at the exchangeable site and GTP at the non-exchangeable site were taken from the PDB file 1TVK[35] and those of the Mg^{2+} ions from the PDB file 1JFF.[36] Parameterization of nucleotide co-factors was taken from reference.[37] The MD simulations included two adjacent protofilaments composed of two tubulin heterodimers; identical tail positions were used on both protofilaments. One hundred three Na ions were added to neutralize the system electrostatically, and following this 80 each of Na^+ and Cl^- were added to bring the ionic concentration to 100 m*M*. The system was placed into a periodic box with dimensions 81.2 Å by 107.5 Å by 152.5 Å, which was filled with pre-equilibrated explicit TIP3P water molecules[38] using the *leap* module of AMBER9. The protofilaments were aligned with the *x*-axis of the periodic box, and by setting the *x*-dimension of the box equal to 81.2 Å, or the length of one tubulin dimer, the periodic boundary conditions were taken advantage of to model the system as two periodic protofilaments. Structures were then converted from AMBER to Gromacs-style coordinate and topology formats using the *amb2gmx* perl script,[39] and simulations were performed with the Gromacs v3.4[40,41] program.

Structures were energy minimized, which also relieved any steric clashes with waters. The entire system was relaxed using 5000 steps of steepest descent (1000 steps), followed by conjugate gradient minimization. Following equilibration for 5 ns with a time step of 2 fs, MD simulation was performed over a period of another 5 ns with the same time step, with periodic boundary conditions at a temperature of 300 K and at constant atmospheric pressure. The Shake algorithm[26] was used to constrain bonds involving hydrogen in all simulations and we used a non-bonded cut-off of 12 Å. PME was employed to calculate long-range electrostatics.

Analysis

Analysis was then performed on the 5 ns production MD runs by using the suite of tools available in the Gromacs program package.[40,41] Only tail domains belonging to the protofilament positioned on the left when viewed from the minus to the plus end was used for analysis. The restriction of our analysis to these tail domains was made because of their physically central position relative to our models, in contrast to the peripheral position of the other set of tail domains, as seen in Figure 5.

For the examination of structural motifs, a matrix of scaled rho (rhosc) values was computed using the Gromacs[40,41] tool *g_rms*. This program compares each structure in trajectory *p1* to each structure in trajectory *p3*, after fitting the structures on top of one another by rotation and translation.[42] The structural similarity value rho is defined as a function of the two structures A and B by:

$$\rho(\mathrm{A},\ \mathrm{B}) = \frac{2\mathrm{RMSD}(\mathrm{A},\ \mathrm{B})}{\sqrt{R_{\mathrm{gyr}}^2(\mathrm{A})R_{\mathrm{gyr}}^2(\mathrm{B}) - \mathrm{RMSD}^2(\mathrm{A},\ \mathrm{B})}},$$

where R_{gyr} is the radius of gyration of a structure, and where RMSD gives the root mean scale deviation between two structures. Scaling the aligned principal moments of inertia of the two structures A and B to values that are all equal and satisfy $R_{\mathrm{gyr}} = 1$ prior to comparing structures, leads to a more universal, size-independent measure of similarity, rhosc, assuming values between 0 and 2. Values of rhosc less than 0.3 were used here as an indication of structural similarity, and the percentage of comparisons for which rhosc < 0.3 represents the percentage of total time for which the conformation of the motif is similar between the two models A and B.

The *g_min_dist* tool was employed to determine minimum distances between charged or aromatic residues belong to tubulin tail domains and other charged or aromatic residues. Residue pairs were included in this analysis if they came closer than 0.3 nm at any point during the simulations.

Average root-mean-square fluctuations (RMSF) were calculated using the *g_rmsf* program, as the averages over the simulation time, $\langle |\Delta R_i|^2 \rangle$, in the square fluctuation of

Table I

the position $\boldsymbol{R}_i$ of the α-carbon corresponding to each residue *i*.

Two programs *do_dssp* and *g_helix* were used in the analysis of helical content. The *do_dssp* program assigns secondary structure by identifying patterns of hydrogen bonding using the DSSP[43] algorithm. On the other hand, *g_helix* determines helicity based upon both hydrogen bonds and ϕ/ψ angles.

RESULTS AND DISCUSSION

Simulated annealing

Following annealing, α-tubulin tails were generally found to point in the longitudinal direction toward where the β-tubulin of the neighboring dimer would be in a MT lattice (see Fig. 2). There was a tendency of the β-tubulin tails to point laterally in the direction of where the right-hand adjacent protofilament would be if the dimer were part of a MT being viewed from the minus to the plus end (i.e., towards the intermediate, taxol-binding domain). However, the β-tubulin tails covered a large range of conformational space (Fig. 2).

By clustering the final endpoints of simulated annealing, and choosing representatives of different clusters (*p1*, *p2*, and *p3*) for subsequent simulation and analysis, we ensured that these three simulations were run from well-separated initial positions. Thus, while each of these simulations on its own does not demonstrate complete time-sampling of MD, a broader picture of the dynamic behavior of the protein system was obtained by considering all three simulations.

Structural motifs

A previous set of replica exchange MD simulations studied peptides composed of the residues forming the C-terminal tails of β-tubulin and identified three transient structural motifs as potential sites for casein kinase-2 (CK-2) phosphorylation and MAP2 binding.[3] We sought to determine, by analysis of our trajectories, whether these structural motifs found for the isolated tail structures, still characterize the tail domains within the context of a MT.

The proposed CK-2 motif, consisting of the residues DATA, occurs at the start of the β tubulin tail and is evolutionarily conserved between tubulin isotypes.[3] The structure of these four residues beginning with residue Asp 427 may be seen in Figure 3. The percentage of total comparisons for which rhosc values are less than 0.3 was found to be 93.6%, indicating a high degree of structural similarity for this sequence and is higher than that found in the original study.

Two motifs on the C-terminal tail, that were previously identified as making up the MAP2 binding site,[44] consist of sequences EEAE (residues 438–441) and EEEA (residues 441–444), respectively, contained in the last seven residues (EEAEEEA) of the β-tubulin tail domain.[3] The respective counts of rhosc values less than 0.3 for these two sequences are 14.7% and 2.8% of total comparisons. This is considerably less than in the previous study and our analysis suggests that these two regions take on little specific structure; however, the bound β-tubulin tail conformers identified below indicate that these residues remain solvent exposed and the possibility of a MAP2 induced structure cannot be ruled out.

Tail–body interactions

We performed analysis on our MD trajectories to investigate the occurrence of tail–body interactions of the C-terminal tail regions with positively-charged residues on the tubulin surface. Tables I and II show the charged residues that, at any point during our simulations, are involved in close contacts of oppositely-charged side-chains, with inter-residue distances of less than 0.3 nm, for each model. Because there were some very noticeable interactions between aromatic residues from the tails and charged residues from the tubulin body and vice versa, these were also included in our analysis. Figures 3 and 4 display models highlighting the tubulin residues involved in tail–body interactions of the β- and α-tubulin tails, respectively, for any one of the four models *p1*, *p2*, *p3*, and $\alpha\beta_S$.

		α Lys401- βTrp344	
$\alpha_S\beta_S$		α Lys401- βTrp344	

We observed that two kinds of tail–body interactions could take place. First, charged Glu and Asp residues of the C-terminal tails can interact with a cluster of positively-charged residues on H11 of the neighboring tubulin dimer. That is, the α-tubulin tail interacts with the H11 helix of β-tubulin, and the β-tubulin tail interacts with the H11 helix of α-tubulin. Figure 5 shows the positions of the H11 domain within the MT lattice, as well as the positions of the other domains that will be discussed below. At the inter-dimer longitudinal interface, negatively-charged residues of the α-tubulin tail interact with residues Lys 379, Arg 390, and Arg 391 on the H11 helix of β-tubulin. Likewise, at the intra-dimer interface, the β-tubulin tail interacts with the positively-charged cluster on α-tubulin containing the residue Lys 394, which has previously been identified as essential for MT polymerization, and His 393; Lys 401 on H11 can also be involved in this type of interaction. The charged tail residues involved are 441–443, 445, and 447–448 on α-tubulin and 431–432 on β-tubulin. We also noted that the ar-

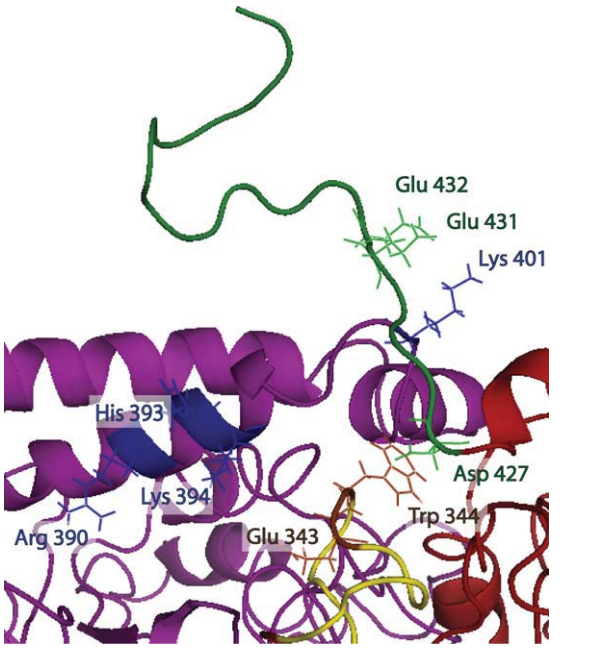

Figure 3

Charged and aromatic residues have been labeled and represented in stick mode that are involved in close contacts between the α-tubulin tail, shown in blue cartoon, and either the α-tubulin H10/B9 loop, shown in yellow cartoon, or the β-tubulin H11 helix, as well as those involved in interactions between the latter two regions. This figure was created using the Pymol molecular viewing program,[27] using model *p3*.

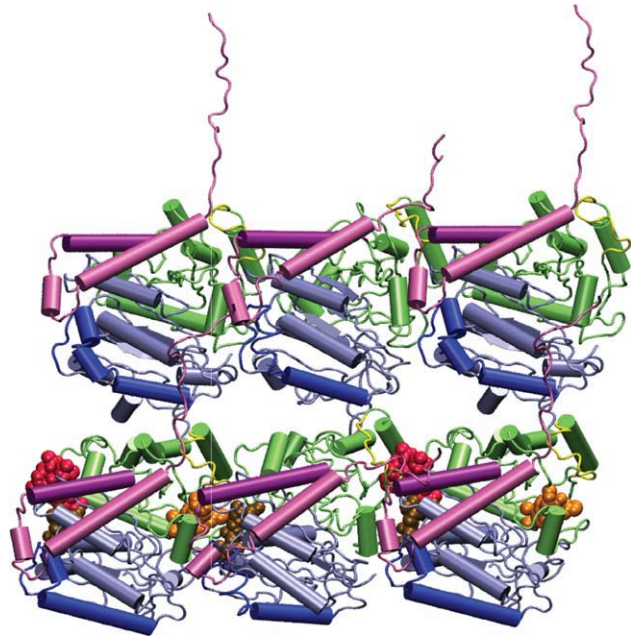

Figure 5

Representation of part of the MT lattice, showing β-α-β tubulin monomers comprising each of two protofilaments oriented with plus ends on the left-hand side. N-terminal domains are colored in blue, intermediate domains in green, and C-terminal domains in purple. The T3/H3 region is shaded in dark blue, the H10/B9 loop in yellow, and the H11 helix in dark purple. The positions of the binding sites of colchicine (orange), vinblastine (red), and nucleotides GDP and GTP (brown) are also illustrated for one of the protofilaments.

omatic residue Tyr 440 on the α-tubulin tail interacts with charged residues Arg 390 and Arg 391 on the H11 helix of β-tubulin by nonpolar side-chain stacking, as well as by interactions between charged Arg side-chains and the polar hydroxyl substituent on the Tyr ring.

The second kind of tail–body interaction observed was between tail residues and residues on the H10/B9 loop of the same tubulin monomer. These contacts are not between two charged residues but rather involve an aromatic residue and a charged residue. In the case of α-tubulin, the tail residue Tyr 440 interacts with Asp 345 of the H10/B9 loop; this contact involves both hydrophobic interactions between the two bulky side chains, and electrostatic attraction between the charged carboxylic acid group of the Asp side-chain and the polar hydroxyl substituent on the Tyr ring. In the case of β-tubulin, tail residues Asp 427 or Glu 431 engage in close nonpolar contacts with Trp 344 of the H10/B9 loop.

Interestingly, the H10/B9 loop can also interact with the positively-charged cluster on the H11 helix of the neighboring dimer, and these interactions are also shown in Tables I and II. In the case of the α H10/B9 loop and the β H11 helix, there can be a salt bridge established between αAsp 345 and residue Arg 390 of H11; also the bulky aromatic side chain of αTrp 346 engages in non-polar interactions with the long side chains of Arg 390 or Arg 391 from β H11. In the case of interaction between β-tubulin's H10/B9 loop and α-tubulin's H11 residues, Glu 343 of the β-tubulin loop can interact with Arg 390, His 393, and/or Lys 394 on α-tubulin's H11. Here also β Trp 344 interacts with residues His 393, Lys 394, and/or Lys 401 from the H11 helix of α-tubulin through both non-polar side-chain interactions and contacts between the aromatic rings of Trp and the positively-charged amine group on Lys. Note that it is likely that these (and possibly some of the other instances of interactions between positively-charged and aromatic residues discussed above) are cation–pi interactions, although our simulations did not employ a polarizable force-field capable of representing the electronic nature of these interactions.

For model *p1*, we plot in Figure 6 how minimum distances involving tail–body interactions of the α-tubulin tail vary throughout the simulation. During the first half of this simulation there is a strong interaction between β-tubulin's helix H11 and the H10/B9 loop of α-tubulin, at the longitudinal inter-dimer interface. During the second half of the simulation these interactions are reduced and instead increased interactions are observed between the α-tubulin tail and both β-tubulin's helix H11 and the H10/B9 loop of α-tubulin. This switch in interactions between the C-terminal tail, the H10/B9 loop, and the H11 helix of the neighboring dimer may be indicative of competing interactions between these three regions.

At the intra-dimer interface, as seen in Supporting Information Figure S3, for the *p1* model there are multiple close contacts between the β-tubulin tail, α-tubulin's helix H11, and the H10/B9 loop of α-tubulin. Although, as may be seen from Tables I and II, many residues or pairs of residues involved in tail–body interactions and in H11-H10/B9loop interactions are shared between models *p1*, *p2*, and *p3*, these models explore different regions in conformational space and thus their trajectories display qualitatively different behaviors. For example, in model *p2*, at the intra-dimer interface, the β-tubulin tail interacts with residue Lys 401 of the H11 helix on α-tubulin, but there is no interaction between αH11 and the H10/B9 loop of β-tubulin. On the other hand, in both the *p3* and $\alpha\beta_S$ simulations, αH11 interacts with β-tubulin's H10/B9 loop but not with the β-tubulin tail. In the $\alpha_S\beta_S$ simulation, without either tail domain present, almost continuous interaction was observed between the H10/B9 loop and the H11 helix of the adjacent monomer, at both monomer interfaces (see Supporting Information Fig. S2).

A physical model was previously created of ion dynamics in and around MTs, based on the application of a random alternating electric force on the surrounding cations by fluctuations in C-terminal tail positions.[45] The continuous breaking and formation of salt bridges give rise to an alternating voltage source on ions as the

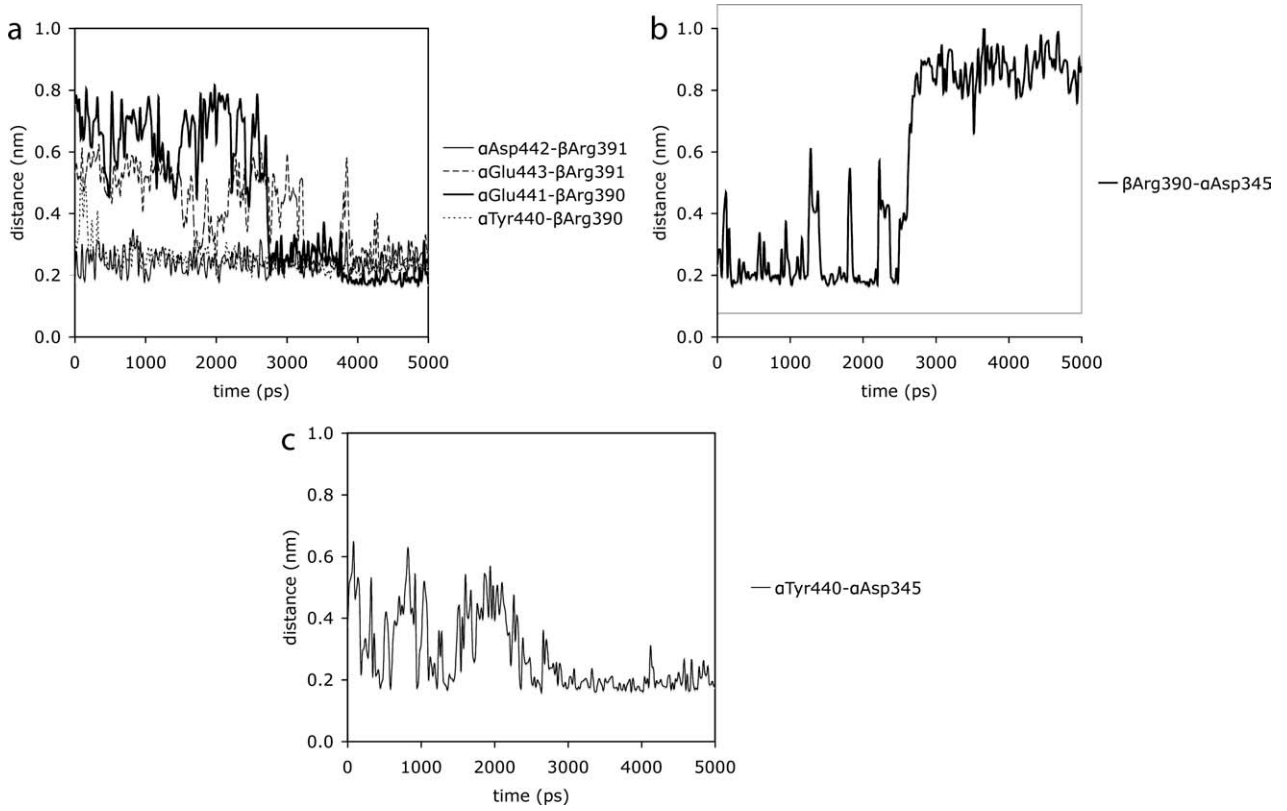

Figure 6

Minimum distances (nm), plotted for the *p1* model as a function of simulation time (ps), between charged or aromatic residues belonging to (**a**) α-tubulin's C-terminal tail domain and β-tubulin's H11 helix; (**b**) β-tubulin's H11 helix and α-tubulin's H10/B9 loop; and (**c**) α-tubulin's C-terminal tail domain and α-tubulin's H10/B9 loop.

tails dynamically oscillate between conformations where they either interact with the tubulin body or extend into more solvated conformations, as seen in Figure 6. This effect observed in our simulations appears to support the hypothesis that local charge reconfiguration due to the motion of C-termini tails can affect ionic flows and hence endow MTs with unique electro-conformational properties.

Structure and flexibility of tubulin body

The average RMSF of each residue of α-tubulin (excluding tail-residues) is plotted as a function of residue index *i* in Figure 7, and that of β-tubulin in Supporting Information Figure S6, corresponding to each of our simulations. The peaks in the RMSF plots show regions of high flexibility, and the highest peaks generally occur at solvent-accessible loops. Tubulin is known to have three main domains, which have been shown to be associated with major correlations in structural fluctuations.[46] These are the N-terminal nucleotide-binding domain, the intermediate taxol-binding domain, and the C-terminal domain, and consist of residues 1–205, 206–381, and 382–448, respectively, on α-tubulin and residues 1–203, 204–371, and 372–444, respectively, on β-tubulin. The last few residues of C-terminal domains show a high degree of flexibility in all models; the loop connecting helices H11 and H12, and H11 itself, may also be seen from the RMSF plots to be quite flexible for the *p3* and $\alpha_S\beta_S$ models. We will now briefly examine the main characteristics of RMSF plots for α- and β-tubulin that we observed first for the N-terminal domain, and then for the intermediate domain; we will also discuss some notable differences between models in RMS fluctuations and their significance.

N-terminal domain (residues α1-205, β1-203)

In the N-terminal domain, peaks are seen in the RMSF plots (Fig. 7 and Supporting Information Fig. S6) at residues α43–63, β45–47 in the region of the H1/B2 loop, which forms lateral contacts with neighboring monomers; at residues α69–74, β66–71 corresponding to the T2 loop; in the region of the H3 helix and T3 loop at residues α95–119, β91–120; and at residues α141–146 in the region of the glycine-rich signature loop, T4. In

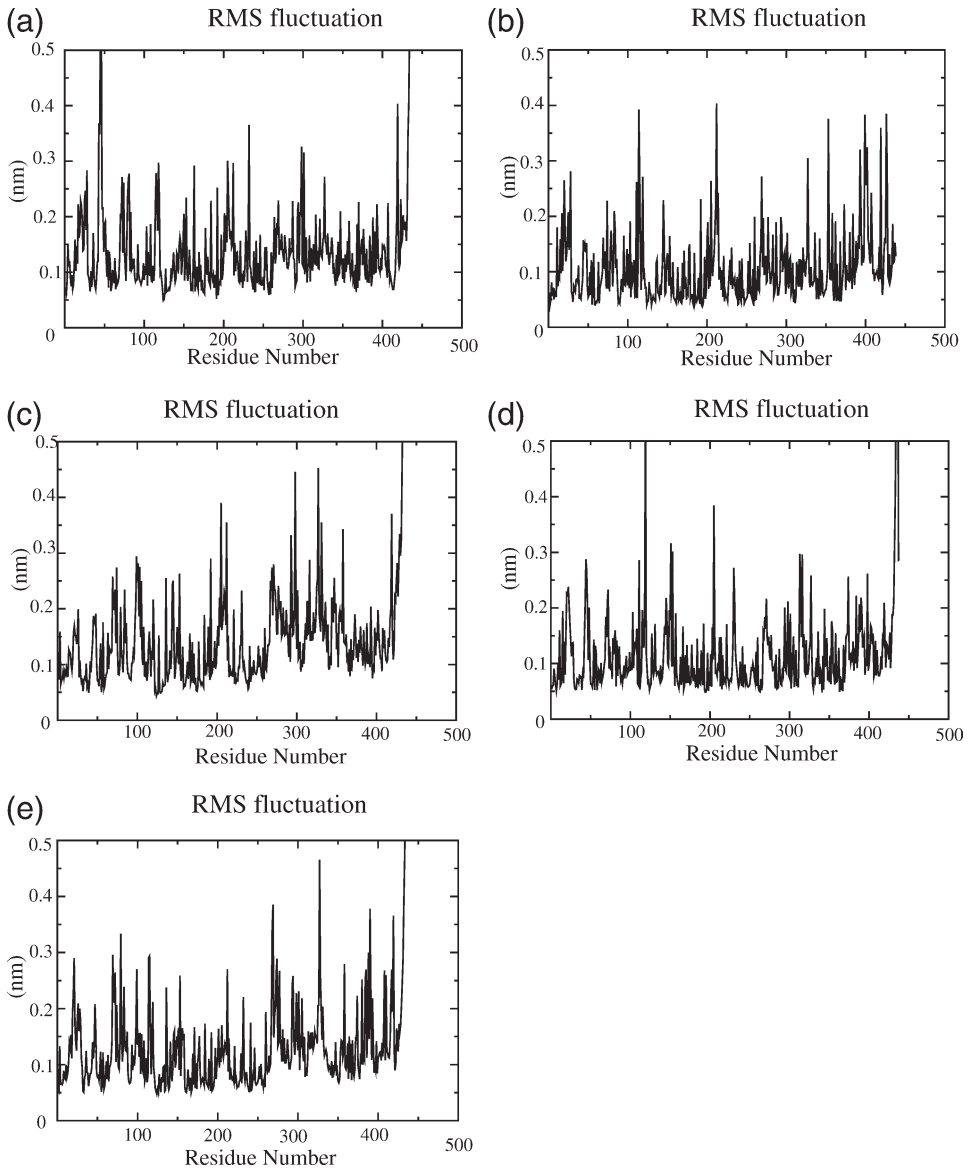

Figure 7

Time-averaged RMSF (nm) of each residue of α-tubulin plotted as a function of residue number for model (**a**) $\alpha\beta_S$, (**b**) $\alpha_S\beta_S$, (**c**) *p1*, (**d**) *p2*, and (**e**) *p3*.

Figure 7 and Supporting Information Figure S6, it may be noted that the peaks corresponding to the T3/H3 region on both α- and β-tubulin are much more pronounced in the RMSF plots for model *p2* than in the other plots. The T3/H3 region (residues α97–128 and β95–126) is located close to the nucleotide binding site, the exchangeable one in the case of β-tubulin, and the non-exchangeable one for α-tubulin. When secondary structure of the N-terminal domain is compared between the simulation trajectories (see Table III and Supporting Information Table S1), it is observed that there is a loss of α-helical structure for the *p2* trajectory compared to for the other trajectories. Upon examination, one noticeable instance of this is a less helical appearance of the H3 helix.

We, therefore, analyzed local secondary structure of the T3 loop and of the H3 helix for each of our models. In Figure 8 and Supporting Information Figure S7, we have plotted the percentage of the total simulation time during which each residue in this region is found in a helical form, calculated by the *g_helix* analysis tool. The plots in Figure 8 show that on average during the simulations the α-tubulin T3/H3 region has lost helicity for both the $\alpha\beta_S$ model and *p2* models, and that the β-tubulin T3/H3 region is much less helical for model *p2* compared to those in the other models.

Table III
Percentages of Residues in α-Tubulin's N-Terminal Domain Forming Various Types of Secondary Structure, Determined Using the do_dssp Gromacs[32,33] Analysis Tool

	$\alpha\beta_S$	$\alpha_S\beta_S$	*p1*	*p2*	*p3*

3-Helix	3.6	2.1	1.4	6.4	2.2

The category "Structure" represents all residues classified as α-helix, β-sheet, β-bridge, or turn.

Intermediate domain (residues α206–381, β204–371)

Major peaks seen in the RMSF plots (Fig. 7 and Supporting Information Fig. S6) in tubulin's intermediate domain are those corresponding to the region of longitudinal contacts at residues α200–232, β201–215; the flexible M-loop on β-tubulin at residues 276–284, and the N-loop on α-tubulin at residues 264–288; and the H10/B9 loop at residues α339–350 and β337–348. Greater RMS fluctuations of the intermediate domain of α-tubulin in the *p1* simulation compared to in the other simulations can be seen from the higher peaks on the RMSF plot corresponding to this simulation, and generally increased RMSF values for large parts of this domain. One instance of this is the greater fluctuation seen for model *p1* of residues corresponding to the H10/B9 loop. This is most likely related to the interchange of interactions between the H10/B9 loop, the H11 helix of β-tubulin, and the α-tubulin tail domain, as is observed in Figure 6 for this trajectory. That is, the formation and breaking of salt bridges causes the H10/B9 loop to assume two or more different positions. These interactions may indirectly lead to higher fluctuations of other parts of the intermediate domain of α-tubulin as well. In Figure 6, the sporadic interchange of interactions between the three domains is seen to occur primarily during the first half of the simulation. We thus examined the RMSF plot calculated for the first half of the simulation only [Supporting Information Fig. S8 (a)]. This plot also shows a high degree of fluctuation of residues in tubulin's intermediate domain. However, consistent with the more constant pattern of interactions during the second half of the simulation, the RMSF plot corresponding to this time interval shows much less fluctuation of the intermediate domain [Supporting Information Fig. S8 (b)]. Notice also that models *p2* and $\alpha_S\beta_S$ for which interactions between residues of

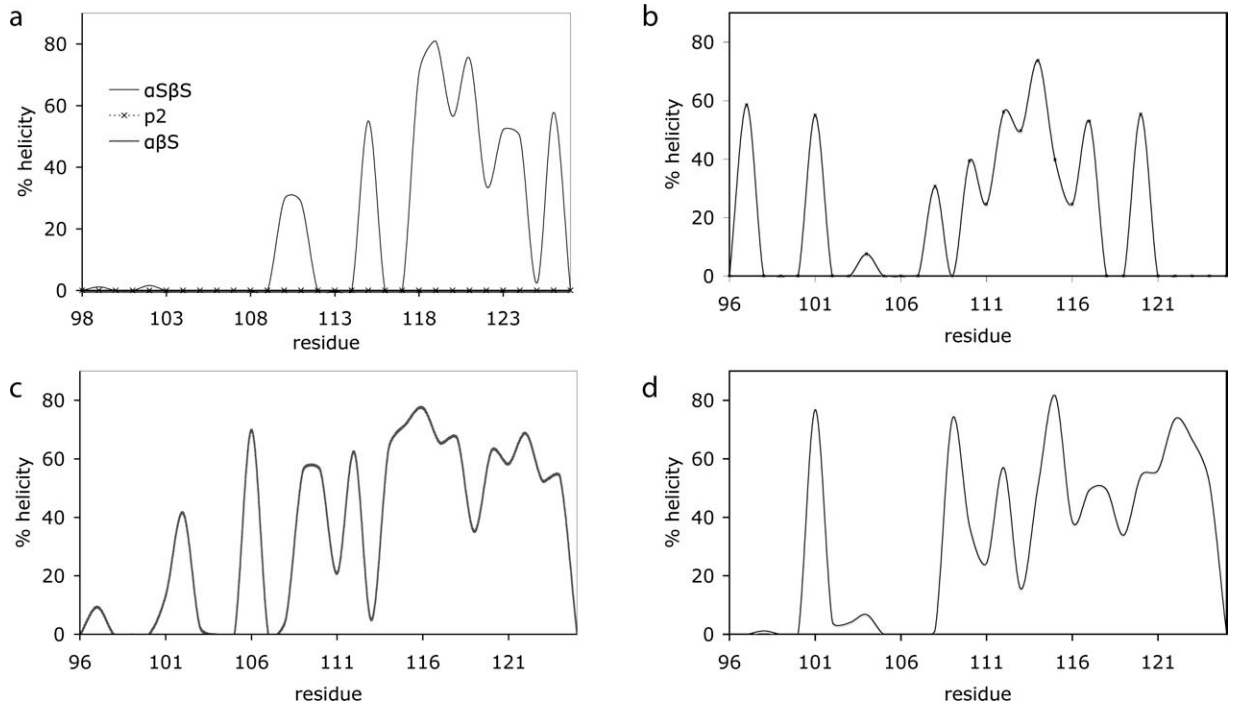

Figure 8
Percentage of total simulation time during which residues are found in a helical form plotted as a function of residue number for (**a**) the T3 loop/H3 helix domain of α-tubulin corresponding to models *p2*, $\alpha\beta_S$, and $\alpha_S\beta_S$; and for the same domain of β-tubulin corresponding to models (**b**) *p2*, (**c**) $\alpha\beta_S$, and (**d**) $\alpha_S\beta_S$.

tail domains and H10/B9 loops are entirely absent show much less fluctuation of residues in the intermediate domain than any of the other three simulations.

Experiments have shown that the polymers assembled from $\alpha_S\beta_S$ tubulin display an increased number of lateral interactions compared to normal MTs, causing junctions to form between polymer walls so that structures resemble hooked MTs with crescent-shaped cross-sections.[6,7] Structural changes in the intermediate domains of normal MTs caused by the disruption of H10/B9 loop-H11 helix interactions by tail domains may possibly lead to changes in positions of key structural elements involved in lateral contacts, which are located in the intermediate domain, such as the M or N loop.

Relevance to drug binding and efficacy

The observations made above, from our simulations, of interactions of the tubulin C-terminal tails with the rest of the protein and our suggestion that changes in the position of tubulin's intermediate domain arising from these interactions may offer an explanation for the role of tail domains in regulating MT assembly, will now be considered in the context of previous work performed by experimentalists.

As has been mentioned in the introduction, experiments have indicated that tail–body interactions within tubulin and tubulin polymers are capable of influencing the binding or efficacy of the tubulin-targeted cancer chemotherapy drugs, colchicine and vinblastine. Colchicine and vinblastine bind to opposite ends of β-tubulin, the former at the intra-dimer interface and the latter on the other end of β-tubulin close to where the N terminus of the α-tubulin tail from the neighboring dimer interfaces with β-tubulin in the context of a protofilament[47] (see Fig. 5). On the other hand, as we will now discuss, colchicine's binding is affected by cleaving the α-tubulin tail,[16] and vinblastine activity by cleaving the β-tubulin tail.[17] In this connection, it is noteworthy to mention that the effect of phomopsin A on the conformational stability of tubulin is also affected by the cleavage of tail domains. Phomopsin A, a non-competitive inhibitor of vinblastine binding[48] is an extremely good inhibitor[49,50] of the spontaneous denaturation[51,52] to which the tubulin dimer is prone. $\alpha_s\beta_s$ tubulin is more resistant to this decay than is undigested αβ tubulin, and the stabilizing effect of phomopsin A is even stronger with $\alpha_s\beta_s$ tubulin than with αβ tubulin.[53]

In experiments performed by Rai and Wolff[17] it was observed that the negative effect that oligo-anions such as sodium triphosphate have on vinblastine-induced polymerization of tubulin is prevented when the C-terminal tail on β-tubulin is removed by subtilisin digestion, although subsequently removing the α-tubulin C-terminal tail to form $\alpha_S\beta_S$ tubulin has no further effect. Note that these polymers are not MTs but are filamentous spirals.[54] Because this negative effect of oligo-anions on vinblastine-induced polymerization of tubulin could be induced in $\alpha\beta_S$ tubulin (recall that $\alpha\beta_S$ tubulin defines dimers lacking only the β-tubulin tail) by increasing the concentration of oligo-anions from 1 m*M* to 10 m*M*, a model was suggested in which there is an interaction favorable to polymer stabilization that is interfered with by both the β-tubulin tail domain and oligo-anions. More specifically, it was proposed that some residues on the tubulin body might interact with a positively-charged residue or region on the tubulin surface, and compete with β-tubulin tail residues for interactions with the same positive cluster.[17] An additive negative effect on stabilization from both this tail–body interaction and the blockage of the positive region by the added anions would then provide an explanation for both how the cleavage of tails allows vinblastine to stabilize tubulin polymers in the presence of a low concentration of anions, and how, when this concentration is increased, vinblastine cannot stabilize even $\alpha\beta_S$ polymers. The interaction between the H10/B9 loop on β tubulin and the positively-charged cluster on H11 of the neighboring α-tubulin, observed in our simulations, along with our observation of interactions between the β-tubulin tail and both of these domains competing with the former interaction, support such a model. From this perspective, the interaction between the H10/B9 loop on β tubulin and positively-charged residues on H11 of the neighboring α tubulin could be strengthened by vinblastine binding, contributing to vinblastine-induced polymer stabilization. On the other hand, the addition of anions would be expected to interfere with this longitudinal interaction. However, without the additive effect of the tail–body interactions, in $\alpha\beta_S$ polymers, vinblastine (albeit while bound to the end of β-tubulin distant from the H10/B9 loop) may be capable of stabilizing either the longitudinal loop–helix interaction and/or the accompanying large-scale effect on the position of the intermediate domain, in the presence of anions. The latter effect can be overridden by adding enough anions.

The effect of vinblastine on tubulin polymerization has been the object of investigations for many years. It turns out that vinblastine binds to MT ends with high affinity but also binds with a much lower affinity to tubulin sites located along the surface of the MT cylinder.[55–57] Approximately, 16–17 high-affinity binding sites located at MT ends have been determined to exist per MT. They are responsible for the well-known kinetic suppression effects of vinblastine, that is, its stabilization of MTs, at low concentrations (sub-micromolar).[58] The binding of vinblastine to the low affinity binding sites on the MT surface is believed to be responsible for the depolymerization of MTs at intermediate ($> 10\ \mu M$) drug concentrations. Finally at drug concentrations of $> 10\ \mu M$, the tubulin polymer stabilized by vinblastine, studied by Rai and Wolff,[17] is an alternate form of the polymer, not the

MT polymer. One possible explanation of the opposite effects of vinblastine on MT polymerization at submicromolar versus intermediate concentrations may be that in the vinblastine-bound polymer, the H11-H10/B9 loop interaction is stronger than normal, which can lead to increased MT stabilization when vinblastine binds to MT tips only; increasing the strengths of these interactions throughout other parts of the MT may lead to destabilization.

In a separate set of experiments, Chakraborty *et al.*[16] found that cleaving the α-tubulin tail domain lowers the activation energy and the on-rate for colchicine binding to the tubulin dimer. In contrast to the case of vinblastine effects on tubulin polymers, the effect is seen in $\alpha_S\beta_S$ tubulin but not $\alpha\beta_S$ tubulin, that is, cleavage of the β-tubulin tail alone has no effect on colchicine binding. Moreover, the binding affinity of colchicine for the tubulin dimer is normally dependent on pH, a factor known to affect tail conformation, but for the $\alpha_S\beta_S$ tubulin dimer, binding is independent of pH. To explain these findings, the authors suggested that although colchicine binds to β-tubulin at a site distant from the α-tubulin tail, tail–body interactions of the α-tubulin tail can cause large-scale conformational changes in the tubulin protein, which both promotes the binding of colchicine and leads to a higher activation energy for binding.[16] In support of this hypothesis it was noted that a 100 m*M* concentration of added NaCl, which would partially screen the electrostatic tail–body interactions, also lowers the activation energy and the on-rate for colchicine binding. It was speculated that the tail–body interaction might involve bending of the α-tubulin tail towards the positively-charged cluster on H11 of α-tubulin, affecting the colchicine binding site and leading to the altered kinetics.[15,16] This was not observed in any of our simulations. However, our MD modeling does support the proposed mechanism by which a tail–body interaction causes a conformational change in α-tubulin by a slightly different explanation, since our results indicate that the α-tubulin tail can interact with the H10/B9 loop, which may enable the intermediate domain to flex out laterally, leading to significant structural changes between normal and $\alpha_S\beta_S$ tubulin. By this line of reasoning, these changes would occur not only on the side of α-tubulin's intermediate domain close to the tail domain, but also extend to the distant side of this intermediate domain, near where colchicine binds to β-tubulin. It is also interesting to speculate whether, conversely, the drug activity of colchicine, which inhibits MT assembly, may involve altering the position of the intermediate domain of α-tubulin.

In summary, the combined results of the experiments from the literature,[16,17] which we have just described, and the simulations reported in the present article seem to indicate that both vinblastine effects on tubulin polymers and colchicine binding to tubulin are affected by shifts in the position of the entire intermediate domain of tubulin compared to that found in $\alpha_S\beta_S$ polymers or tubulin dimer, in the former case that of the β-tubulin monomer and in the latter that of α-tubulin. We propose that this shift is brought on by interactions between the tail domain, the H10/B9 loop, and in the case of vinblastine, the H11 helix of the neighboring monomer, all at the other longitudinal monomer interface from where drug-binding occurs. Experimental confirmation of large-scale conformational flexibility for tubulin's intermediate domain has already been supplied by photo-affinity labeling results demonstrating that cysteines 295, 305, 315, and 316 in the intermediate domain of α tubulin, but distant from the colchicine binding site, are affected by colchicine binding.[59]

CONCLUSIONS

Using computational techniques, we have determined two modes of interaction between the C-terminal tail domains with the main body of tubulin. Specifically, we have found an inter-monomer mode between charged residues on the α(β) tail and β(α)H11 and an intra-monomer mode, pairing aromatic (charged) residues on the α(β) tail with charged (aromatic) residues on the α(β) H10/B9 loop. As one would expect from the heretofore-elusive structures of the C-terminal tails, these interactions are non-specific and transient.

However, we also observe that the binding sites for the tails may bind laterally with each other, that is, the α(β) H10/B9 loop binds to β(α)H11. The result of this competitive interference is to increase flexibility in the intermediate domain with respect to $\alpha_S\beta_S$ tubulin. Such competitive behavior, in which another region of tubulin forms electrostatic interactions with the same positively charged region that the tubulin tail also binds to, has previously been hypothesized based on experimental results implicating tail–body interactions in vinblastine effects on tubulin polymers.[17] Based on the connection that we predict between flexibility of the intermediate domain and tail–body interactions, together with the experimental data showing that the binding or activity of colchicine[16] and vinblastine,[17] respectively, depend on electrostatic interactions of the tubulin tail domains far from the drug binding site, it seems likely that the binding or activity of these two drugs may be linked to the flexibility of tubulin's intermediate domain.

A natural test of the intermediate domain flexibility hypothesis and our proposed intra-monomer binding mode is to mutate residues Glu431 and Glu 432 belonging to the C-terminal tail domain of β-tubulin to alanines and then determine whether the negative effect of oligo-anions on vinblastine-induced polymerization of tubulin is eliminated, just as it is by cleavage of β-tubulin tail domains.[17] The analogous test for the inter-monomer mode is to mutate either of the two residues

Asp α345 on the H10/B9 loop or Tyr α440 on the C-terminal tail, predicted here to form extensive interactions with each other, to alanine, which should lead to pH independent binding of colchicine, in a similar manner that cleavage of the α-tubulin tail domain does.[16]

The C-terminal tails are also involved in the binding of several MAPs essential to the function of MTs. Following Luchko *et al.*,[3] we characterized three structural motifs possibly involved in the CK-2 phosphorylation and MAP2 binding. Falquet *et al.*[60] previously identified a conserved sequence for CK-2, which is found as DATA in the βI-tubulin tail. The DATA motif was found to have a very high similarity among our simulations; at least for the βI tail sequence, this indicates that the structure is persistent, and does not need to be induced for phosphorylation. As this structural motif has now been identified by two independent MD protocols, it should be considered a strong prediction. Contrary to the previous findings, the two proposed MAP2 binding motifs did not maintain similar structures between the models compared. However, since the sequence is experimentally known to be significant[44] and the residues are fully solvated, the possibility that these motifs are induced fit binding sites cannot be ruled out. Rather, further experimental and computational studies are needed to address this question. Some of this type of experimental study has been carried out on α-tubulin tails already, but we have not investigated proposed binding sites from this work.[61]

Beyond the scope of this study are the wide variety of post-translational modifications, particularly effecting the C-terminal tail domain, that tubulin is subject to. These include tyrosinolation/detyrosinolation of α, deglutamylation of α, polyglutamylation of both α and β, polyglycylation of both α and β, and phosphorylation of certain isotypes of β.[1] All of these could well affect the conformation of the tail domains and several also would alter the charges. These modifications may play critical roles in regulating the functions of MTs; for example, detyrosination of α promotes MT stability,[62] while polyglycylation of β is necessary for normal axoneme formation and polyglutamylation of α and/or β appears to mediate binding of MT-associated proteins (MAPs) and the motor protein kinesin to tubulin.[14,63–67] Some of these effects are likely to be indirect, that is, the presence of the modification in the C-terminal could conceivably act as a signal to some other protein or proteins which in turn could mediate the effect, that is, MT stability, axoneme formation, and so forth. Regardless, these modifications are of such scale that it is easy to hypothesize that they cause major conformational changes in the C-termini and that these changes in turn may mediate the ultimate effects of these modifications. It is likely that there exists a complex feedback loop between the probability of modification occurring and the conformational effect of modification. In addition, the binding of the C-termini to MAPs and motors is critical to the function of a variety of MT populations and is likely to also be regulated by conformational interactions involving the C-termini. These conformational effects and interactions and their likely functional outcomes are currently being examined.

Finally, we wish to comment on the lack of helicity of the T3/H3 region that was noted in two of the simulations. The issue of how MTs are destabilized by GTP hydrolysis is currently highly debated.[68–72] Along with MTs, actin filaments comprise one of three major components of the cytoskeleton and these two types of protein filaments have many remarkably similar properties including the utilization of a hydrolyzable nucleotide in polymer dynamics.[73] Experimental and computational studies indicate that in the case of actin polymerization, a loop-to-helix transition of the DNase-I binding (DB) loop is associated with hydrolysis of the nucleotide ATP to ADP and with the simultaneous structural change to a less stable actin polymer, as lateral contacts are lost in the less flexible helical structure.[74,75] Thus, the variability in the helicity of the T3/H3 region seen in our simulations together with the fact that the T3 loop of β-tubulin has been observed to be destabilized upon hydrolysis of the bound GTP to GDP,[68] raise the possibility that upon hydrolysis of the GTP bound to β-tubulin, the T3/H3 region might undergo a loop-to-helix transition similar to that in actin, causing a large-scale shift in the entire MT structure. Experimental testing of this hypothesis could be performed by applying techniques which have previously been used to analyze small changes in protein helical structure, such as Trp fluorescence,[76] FRET (Forster resonance energy transfer) emission spectra,[77,78] or EPR (electron paramagnetic resonance) data.[78] In this way, structural comparisons could be made of the T3/H3 region in MTs bound by different nucleotides or nucleotide-analogues.

ABSTRACT

Tubulin, an α/β heterodimer, has had most of its 3D structure analyzed; however, the carboxy (C)-termini remain elusive. Importantly, the C-termini play critical roles in regulating microtubule structure and function. They are sites of most of the post-translational modifications of tubulin and interaction sites with molecular motors and microtubule-associated proteins. Simulated annealing was used in our molecular dynamics modeling to predict the interactions of the C-terminal tails with the tubulin dimer. We examined differences in their flexibility, interactions with the body of tubulin, and the existence of structural motifs. We found that the α-tubulin tail interacts with the H11 helix of β-tubulin, and the β-tubulin tail interacts with the H11 helix of α-tubulin. Tail domains and H10/B9 loops interact with each other and compete for interactions with positively-charged residues of the H11 helix on the neighboring monomer. In a simulation in which α-tubulin's H10/B9 loop switches on sub-nanosecond intervals between interactions with the C-terminal tail of α-tubulin and the H11 helix of β-tubulin, the intermediate domain of α-tubulin showed more fluctuations compared to those in the other simulations, indicating that tail domains may cause shifts in the position of this domain. This suggests that C-termini may affect the conformation of the tubulin dimer which may explain their essential function in microtubule formation and effects on ligand binding to microtubules. Our modeling also provides evidence for a disordered-helical/helical double-state system of the T3/H3 region of the microtubule, which could be linked to depolymerization following GTP hydrolysis.

INTRODUCTION

The tubulin protein polymerizes to form microtubules (MTs) which are cylindrical structures consisting typically of 13 protofilaments, each of which is comprised of repeats of α–β tubulin hetero-dimers. The carboxy (C)-terminal tail domains of all tubulin monomers are found on the outer surface of the MT. Both α- and β-tubulin consist of numerous isotypes, differing in amino acid sequence and cellular and tissue distribution.[1] The lengths and sequences of the C-terminal tails vary greatly depending on isotype; human isotypes typically consist of 10–13 residues on α-tubulin, and 18–24 residues on β-tubulin, and have a high proportion of negatively charged residues.[2,3] A great deal of evidence indicates that the C-terminal tails of both α- and β-tubulin play critical roles in regulating MT assembly and function, and in determining the conformation of the tubulin molecule,[4–8] roles whose details are very poorly known. C-terminal tail residues are necessary for the assembly of normal MTs; one recent cloning study has demonstrated that the first two tail residues of β-tubulin are indispensable for the formation of MTs in HeLa cells.[4] Tubulin polymers assembled *in vitro* from tubulin lacking both C-terminal tails (denoted as $\alpha_S\beta_S$ tubulin) display an altered morphology characterized by bundles of twisted filaments, sheets,[5] and hooks.[6,7] Moreover, the presence of alkali metal cations[8] or cleavage of tails[5] allows polymers to form at lower tubulin concentrations, and the reduction of negative charges on C-termini by covalent modification lowers the rate constant for MT disassembly.[9] Tubulin polymers lacking only the β-tubulin tail ($\alpha\beta_S$ tubulin) display a ring con-

formation, do not require GTP for polymerization, and are temperature insensitive.[10]

It is likely that the effects of the C-termini on MT assembly and tubulin conformation are critically dependent on the conformational interaction between the C-termini and other parts of the tubulin molecule. Nevertheless, the natures of these interactions are almost entirely unknown. Although a series of studies have determined the structure of the rest of the tubulin molecule, the structures of the C-termini have remained largely invisible to crystallographic methods. Thus, a molecular-level picture of the structures of tubulin protofilaments obtained by molecular dynamics (MD) simulations, including both tail dynamics and their interactions with the remainder of the protein, offers an opportunity to provide unique insights into a better comprehension of the biological functions of tail domains and their significance for MTs.

Depending on the isotype, the charge of the C-terminal tail of human β-tubulin is generally between −10 and −12 *e* and that of the α-tubulin tail is −7 or −8 *e*, not including post-translational modifications.[2,3] Although the remainder of the tubulin dimer is also negatively charged overall (the total charge of the dimer is approximately −50 *e*), there are also positively charged regions on the protein surface. By using reductive methylation, residue Lys 394, which together with Arg 390 and His 393 forms a positively-charged pocket on the surface of α-tubulin, has been shown to be essential to MT polymerization.[11,12] Because Lys 394 is less accessible to methylation in the MT polymer compared to when present in the dimer,[12,13] it has been suggested that this residue is involved in electrostatic interactions with the negatively-charged acidic residues in the tail regions.[14] The existence of such a "tail–body" electrostatic interaction was also supported by a study[15] in which the detached α-tubulin tail was computationally docked to the tubulin surface and found to bind at a site near Lys 394. Experimental findings that C-terminal tail cleavage can affect ligands that bind to tubulin, and that this influence seems to be due to electrostatic interactions, also indicate that tail–body interactions contribute to tubulin conformation. This evidence includes a study showing that cleaving the C-terminal tail on α-tubulin lowers the activation energy for colchicine binding to tubulin, and leads to pH independent binding.[16] Another such study showed that the influence of oligoanions on the stabilization of tubulin polymers by vinblastine is eliminated by the cleavage of the C-terminal tails of β-tubulin.[17]

The objective of this article is to use MD modeling in order to elucidate the issues surrounding the role of C-termini in structural and functional effects on the tubulin dimer and, consequently, in the biological behavior of MTs. The specific modeling tool that we apply to our analysis is simulated annealing in conjunction with MD simulation. Simulated annealing is an enhanced sampling technique in which heating followed by re-cooling of a molecular system can be used to determine its equilibrium structure. Heating allows the system to overcome energy barriers that would otherwise prevent the system from fully sampling configuration space, and slow cooling causes the system to freeze into a minimum energy structure. This method has frequently been applied within Monte Carlo simulations to determine conformational free energy minima[18,19]; more recently simulated annealing has been used within MD simulations,[20] as it is in the present work. Here, this technique is applied to obtain positions of C-terminal tails for the tubulin dimer. Subsequently, simulations are run of protofilaments formed from αβ tubulin, $\alpha\beta_s$ tubulin, and from $\alpha_s\beta_s$ tubulin. In this way, the effects of the tails on protofilament dynamics are investigated computationally.

We analyze MD trajectories to investigate the occurrence of tail–body interactions of the C-terminal tail regions with positively-charged residues on the tubulin surface. Structural motifs intrinsic to the C-terminal tail domains seen in the MD trajectories are also considered. Finally, we analyze the root mean square fluctuations of residues in trajectories with and without tail domains. We show that interactions of the tail domains with exposed residues on the surface of the remainder of the protein may play an important role in MT dynamics by influencing the large-scale conformation of tubulin's intermediate domain.

MATERIAL AND METHODS

Simulated annealing

After heating the tubulin dimer system to 5000 K, each of 12 models was slowly cooled to 300 K over 5.2 ns of simulation time. Out of these 12, three models were selected as starting positions in simulations of two explicitly-solvated tubulin protofilaments. The flowchart in Figure 1 summarizes the simulated annealing/MD simulation procedure adopted in our study to determine tubulin tail conformations, which we now describe in detail.

Our system consisted of a tubulin dimer, composed of human isotypes αIV and βI, modeled as described elsewhere[21]; these have C-terminal tails with lengths of 10 and 18 residues (residues α439–448 and β427–444), and charges of −8 and −12 *e*, respectively. Initial set-up was performed in the *leap* and *antechamber* modules of the AMBER9[22] program package using the AMBER03 force field to parameterize the tubulin protein.[23,24] MD was performed using the sander module of AMBER9.[22] Twelve high temperature implicitly-solvated MT dimers were generated by heating the dimer to 5000 K (chosen to make the tails mobile on a reasonable time scale), and then extracting structures from the simulation every

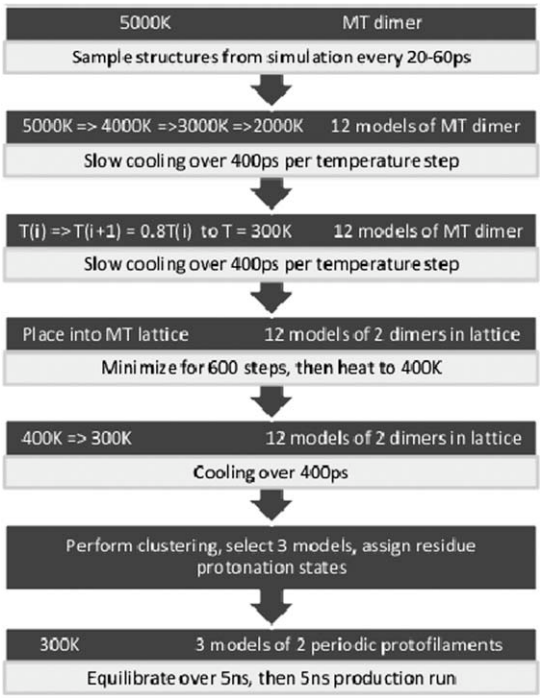

Figure 1

Flowchart illustrating the simulated annealing/MD simulation procedure used in this work to determine tubulin tail conformations.

20–60 ps. These were then slowly cooled to a target temperature of 300 K. Our annealing schedule used temperature reduction steps of 1000 K over 200 ps time periods, with equilibrations being performed at each of these temperatures for a period of another 200 ps, until the temperature was below 2000 K, and then used a 0.8-power law cooling-schedule again with 400 ps spent for each temperature stage. A time step of 1 fs was used throughout all simulations. The modified generalized Born method GB^{OBC} corresponding to model II in Ref. [25] (igb = 5) was employed to represent a 150 m*M* ionic solution and the temperature was maintained by a Langevin thermostat with a collision frequency of 2 ps^{-1}. All bonds involving hydrogens were constrained using the Shake[26] algorithm. A restraint weight of 15 kcal/mol was placed on residues 1–438 of α tubulin and 1–428 of β tubulin. Removal of center-of-mass translational and rotational motion was disabled. The non-bonded cut-off used was 50 Å.

Structures were fit to the original homology model by running simulations for 5000 steps with a restraint of 50 kcal/mol on the α-carbons of all residues not belonging to the C-terminal tail domains, forcing the α-carbons belonging to the main body of the dimer to assume a structure similar to the one determined by electron crystallography experiments. In some cases, the *autosculpt* feature of the Pymol program[27] was employed to slightly adjust the positions of β tubulin tail residues which overlapped with parts of the opposite β tubulin. Tubulin dimers were then placed into a configuration consistent with MT geometry by using the model of Li *et al.*[28] Two adjacent dimers were created as would exist in the MT lattice by using an in-house VMD[29] script, as described elsewhere.[30] These were then relaxed for 300 steps without solvent, and another 300 steps with implicit solvent. Afterwards the structures were heated to 400 K, and then cooled to 300 K over a period of 400 ps for further energy minimization, with the same restraint on the α-carbons belonging to the main body.

The 12 models of the tubulin dimer resulting from our simulated annealing procedure are shown in Figure 2. Structures were clustered in the *ptraj* module of AMBER using the means algorithm[31] to produce three clusters each for α- and β tubulin tails, by comparing positions of alpha-carbons based on root-mean-squared distance (RMSD) after fitting all tubulin dimers, excluding tail residues, to the position of one of the dimers. Clusters of α tubulin tail peptides contained five, four, and three elements, respectively, with mass weighted root-mean-square distances to the centroid of 0.6 Å for each of the three clusters. Clustering the β tubulin tail peptides resulted in one group of six elements, with a mass weighted root-mean-square distance to centroid of 1.4 Å, a second cluster with five elements and a mass weighted root-mean-square distance to centroid of 1.3 Å, and a third cluster with a single element only. Cluster

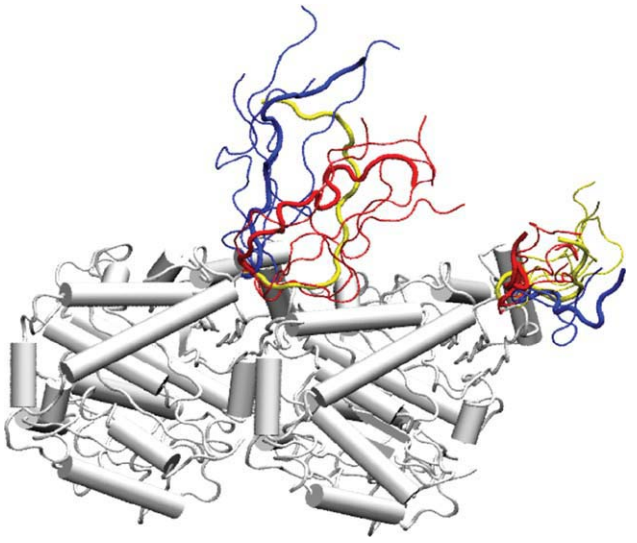

Figure 2

Tubulin dimer, showing three clusters obtained by simulated annealing MD for the C-terminal tail domains, colored in yellow, red, and blue, respectively. Cluster representatives *p1* (yellow), *p2* (red), and *p3* (blue) are depicted as thicker coils compared to other cluster elements. The dimer is viewed from above if positioned in a MT lattice with β-tubulin on the left and α-tubulin on the right.

representatives were chosen as the dimers having β tubulin tails closest to the cluster centroids. Because each of these three dimers fell into a different one of the three clusters corresponding to the α tubulin tails, we chose to retain the original pairing between α- and β tubulin monomers, rather than pairing cluster representatives for β tubulin tails with similarly chosen cluster representatives for α tubulin tails. As a further check on the appropriate number of representatives, hierarchical clustering of both β- and α-tubulin tails was performed using the MMTSB Toolset[32] command *jclust* with the *rmsd* mode, requesting a maximum of 50 structures, which gave two main clusters for the α-tubulin tail and three for the β-tubulin tail.

The three representative dimers, which were used to perform MD simulations, are shown in Figure 2. In the text that follows, we refer to these three models as *p1*, *p2*, and *p3*. In addition, we performed simulations with one or both tail domains removed. The α-tubulin tail position for the $\alpha\beta_S$ model was taken from model *p3*.

MD simulations

The *propka* program[33,34] was used to assign protonation states to Asp, Glu, His, and Lys residues on each of the three models; as a result His 309 was protonated on α-tubulin of model *p1*, His 307 on β-tubulin of models *p2* and *p3*, and α-tubulin residue Asp 46 was protonated on all three models.

The tubulin dimers were then placed into a MT lattice. The positions of GDP at the exchangeable site and GTP at the non-exchangeable site were taken from the PDB file 1TVK[35] and those of the Mg^{2+} ions from the PDB file 1JFF.[36] Parameterization of nucleotide co-factors was taken from reference.[37] The MD simulations included two adjacent protofilaments composed of two tubulin heterodimers; identical tail positions were used on both protofilaments. One hundred three Na ions were added to neutralize the system electrostatically, and following this 80 each of Na^+ and Cl^- were added to bring the ionic concentration to 100 m*M*. The system was placed into a periodic box with dimensions 81.2 Å by 107.5 Å by 152.5 Å, which was filled with pre-equilibrated explicit TIP3P water molecules[38] using the *leap* module of AMBER9. The protofilaments were aligned with the *x*-axis of the periodic box, and by setting the *x*-dimension of the box equal to 81.2 Å, or the length of one tubulin dimer, the periodic boundary conditions were taken advantage of to model the system as two periodic protofilaments. Structures were then converted from AMBER to Gromacs-style coordinate and topology formats using the *amb2gmx* perl script,[39] and simulations were performed with the Gromacs v3.4[40,41] program.

Structures were energy minimized, which also relieved any steric clashes with waters. The entire system was relaxed using 5000 steps of steepest descent (1000 steps), followed by conjugate gradient minimization. Following equilibration for 5 ns with a time step of 2 fs, MD simulation was performed over a period of another 5 ns with the same time step, with periodic boundary conditions at a temperature of 300 K and at constant atmospheric pressure. The Shake algorithm[26] was used to constrain bonds involving hydrogen in all simulations and we used a non-bonded cut-off of 12 Å. PME was employed to calculate long-range electrostatics.

Analysis

Analysis was then performed on the 5 ns production MD runs by using the suite of tools available in the Gromacs program package.[40,41] Only tail domains belonging to the protofilament positioned on the left when viewed from the minus to the plus end was used for analysis. The restriction of our analysis to these tail domains was made because of their physically central position relative to our models, in contrast to the peripheral position of the other set of tail domains, as seen in Figure 5.

For the examination of structural motifs, a matrix of scaled rho (rhosc) values was computed using the Gromacs[40,41] tool *g_rms*. This program compares each structure in trajectory *p1* to each structure in trajectory *p3*, after fitting the structures on top of one another by rotation and translation.[42] The structural similarity value rho is defined as a function of the two structures A and B by:

$$\rho(\mathrm{A},\ \mathrm{B}) = \frac{2\mathrm{RMSD}(\mathrm{A},\ \mathrm{B})}{\sqrt{R_{\mathrm{gyr}}^2(\mathrm{A})R_{\mathrm{gyr}}^2(\mathrm{B}) - \mathrm{RMSD}^2(\mathrm{A},\ \mathrm{B})}},$$

where R_{gyr} is the radius of gyration of a structure, and where RMSD gives the root mean scale deviation between two structures. Scaling the aligned principal moments of inertia of the two structures A and B to values that are all equal and satisfy $R_{\mathrm{gyr}} = 1$ prior to comparing structures, leads to a more universal, size-independent measure of similarity, rhosc, assuming values between 0 and 2. Values of rhosc less than 0.3 were used here as an indication of structural similarity, and the percentage of comparisons for which rhosc < 0.3 represents the percentage of total time for which the conformation of the motif is similar between the two models A and B.

The *g_min_dist* tool was employed to determine minimum distances between charged or aromatic residues belong to tubulin tail domains and other charged or aromatic residues. Residue pairs were included in this analysis if they came closer than 0.3 nm at any point during the simulations.

Average root-mean-square fluctuations (RMSF) were calculated using the *g_rmsf* program, as the averages over the simulation time, $\langle |\Delta R_i|^2 \rangle$, in the square fluctuation of

the position $\boldsymbol{R}_i$ of the α-carbon corresponding to each residue *i*.

Two programs *do_dssp* and *g_helix* were used in the analysis of helical content. The *do_dssp* program assigns secondary structure by identifying patterns of hydrogen bonding using the DSSP[43] algorithm. On the other hand, *g_helix* determines helicity based upon both hydrogen bonds and ϕ/ψ angles.

RESULTS AND DISCUSSION

Simulated annealing

Following annealing, α-tubulin tails were generally found to point in the longitudinal direction toward where the β-tubulin of the neighboring dimer would be in a MT lattice (see Fig. 2). There was a tendency of the β-tubulin tails to point laterally in the direction of where the right-hand adjacent protofilament would be if the dimer were part of a MT being viewed from the minus to the plus end (i.e., towards the intermediate, taxol-binding domain). However, the β-tubulin tails covered a large range of conformational space (Fig. 2).

By clustering the final endpoints of simulated annealing, and choosing representatives of different clusters (*p1*, *p2*, and *p3*) for subsequent simulation and analysis, we ensured that these three simulations were run from well-separated initial positions. Thus, while each of these simulations on its own does not demonstrate complete time-sampling of MD, a broader picture of the dynamic behavior of the protein system was obtained by considering all three simulations.

Structural motifs

A previous set of replica exchange MD simulations studied peptides composed of the residues forming the C-terminal tails of β-tubulin and identified three transient structural motifs as potential sites for casein kinase-2 (CK-2) phosphorylation and MAP2 binding.[3] We sought to determine, by analysis of our trajectories, whether these structural motifs found for the isolated tail structures, still characterize the tail domains within the context of a MT.

The proposed CK-2 motif, consisting of the residues DATA, occurs at the start of the β tubulin tail and is evolutionarily conserved between tubulin isotypes.[3] The structure of these four residues beginning with residue Asp 427 may be seen in Figure 3. The percentage of total comparisons for which rhosc values are less than 0.3 was found to be 93.6%, indicating a high degree of structural similarity for this sequence and is higher than that found in the original study.

Two motifs on the C-terminal tail, that were previously identified as making up the MAP2 binding site,[44] consist of sequences EEAE (residues 438–441) and EEEA (residues 441–444), respectively, contained in the last seven residues (EEAEEEA) of the β-tubulin tail domain.[3] The respective counts of rhosc values less than 0.3 for these two sequences are 14.7% and 2.8% of total comparisons. This is considerably less than in the previous study and our analysis suggests that these two regions take on little specific structure; however, the bound β-tubulin tail conformers identified below indicate that these residues remain solvent exposed and the possibility of a MAP2 induced structure cannot be ruled out.

Tail–body interactions

We performed analysis on our MD trajectories to investigate the occurrence of tail–body interactions of the C-terminal tail regions with positively-charged residues on the tubulin surface. Tables I and II show the charged residues that, at any point during our simulations, are involved in close contacts of oppositely-charged side-chains, with inter-residue distances of less than 0.3 nm, for each model. Because there were some very noticeable interactions between aromatic residues from the tails and charged residues from the tubulin body and vice versa, these were also included in our analysis. Figures 3 and 4 display models highlighting the tubulin residues involved in tail–body interactions of the β- and α-tubulin tails, respectively, for any one of the four models *p1*, *p2*, *p3*, and $\alpha\beta_S$.

$\alpha_S\beta_S$		α Lys401- βTrp344	

We observed that two kinds of tail–body interactions could take place. First, charged Glu and Asp residues of the C-terminal tails can interact with a cluster of positively-charged residues on H11 of the neighboring tubulin dimer. That is, the α-tubulin tail interacts with the H11 helix of β-tubulin, and the β-tubulin tail interacts with the H11 helix of α-tubulin. Figure 5 shows the positions of the H11 domain within the MT lattice, as well as the positions of the other domains that will be discussed below. At the inter-dimer longitudinal interface, negatively-charged residues of the α-tubulin tail interact with residues Lys 379, Arg 390, and Arg 391 on the H11 helix of β-tubulin. Likewise, at the intra-dimer interface, the β-tubulin tail interacts with the positively-charged cluster on α-tubulin containing the residue Lys 394, which has previously been identified as essential for MT polymerization, and His 393; Lys 401 on H11 can also be involved in this type of interaction. The charged tail residues involved are 441–443, 445, and 447–448 on α-tubulin and 431–432 on β-tubulin. We also noted that the ar-

Charged and aromatic residues have been labeled and represented in stick mode that are involved in close contacts between the α-tubulin tail, shown in blue cartoon, and either the α-tubulin H10/B9 loop, shown in yellow cartoon, or the β-tubulin H11 helix, as well as those involved in interactions between the latter two regions. This figure was created using the Pymol molecular viewing program,[27] using model *p3*.

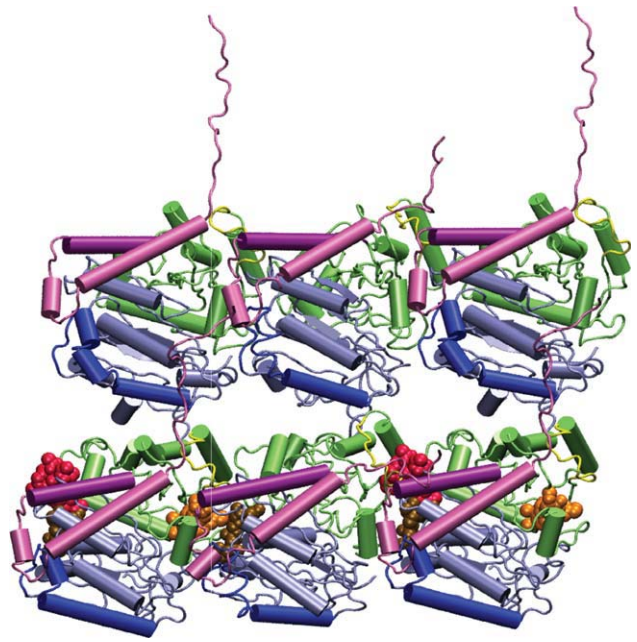

Figure 5

Representation of part of the MT lattice, showing β-α-β tubulin monomers comprising each of two protofilaments oriented with plus ends on the left-hand side. N-terminal domains are colored in blue, intermediate domains in green, and C-terminal domains in purple. The T3/H3 region is shaded in dark blue, the H10/B9 loop in yellow, and the H11 helix in dark purple. The positions of the binding sites of colchicine (orange), vinblastine (red), and nucleotides GDP and GTP (brown) are also illustrated for one of the protofilaments.

omatic residue Tyr 440 on the α-tubulin tail interacts with charged residues Arg 390 and Arg 391 on the H11 helix of β-tubulin by nonpolar side-chain stacking, as well as by interactions between charged Arg side-chains and the polar hydroxyl substituent on the Tyr ring.

The second kind of tail–body interaction observed was between tail residues and residues on the H10/B9 loop of the same tubulin monomer. These contacts are not between two charged residues but rather involve an aromatic residue and a charged residue. In the case of α-tubulin, the tail residue Tyr 440 interacts with Asp 345 of the H10/B9 loop; this contact involves both hydrophobic interactions between the two bulky side chains, and electrostatic attraction between the charged carboxylic acid group of the Asp side-chain and the polar hydroxyl substituent on the Tyr ring. In the case of β-tubulin, tail residues Asp 427 or Glu 431 engage in close nonpolar contacts with Trp 344 of the H10/B9 loop.

Interestingly, the H10/B9 loop can also interact with the positively-charged cluster on the H11 helix of the neighboring dimer, and these interactions are also shown in Tables I and II. In the case of the α H10/B9 loop and the β H11 helix, there can be a salt bridge established between αAsp 345 and residue Arg 390 of H11; also the bulky aromatic side chain of αTrp 346 engages in non-polar interactions with the long side chains of Arg 390 or Arg 391 from β H11. In the case of interaction between β-tubulin's H10/B9 loop and α-tubulin's H11 residues, Glu 343 of the β-tubulin loop can interact with Arg 390, His 393, and/or Lys 394 on α-tubulin's H11. Here also β Trp 344 interacts with residues His 393, Lys 394, and/or Lys 401 from the H11 helix of α-tubulin through both non-polar side-chain interactions and contacts between the aromatic rings of Trp and the positively-charged amine group on Lys. Note that it is likely that these (and possibly some of the other instances of interactions between positively-charged and aromatic residues discussed above) are cation–pi interactions, although our simulations did not employ a polarizable force-field capable of representing the electronic nature of these interactions.

For model *p1*, we plot in Figure 6 how minimum distances involving tail–body interactions of the α-tubulin tail vary throughout the simulation. During the first half of this simulation there is a strong interaction between β-tubulin's helix H11 and the H10/B9 loop of α-tubulin, at the longitudinal inter-dimer interface. During the second half of the simulation these interactions are reduced and instead increased interactions are observed between the α-tubulin tail and both β-tubulin's helix H11 and the H10/B9 loop of α-tubulin. This switch in interactions between the C-terminal tail, the H10/B9 loop, and the H11 helix of the neighboring dimer may be indicative of competing interactions between these three regions.

At the intra-dimer interface, as seen in Supporting Information Figure S3, for the *p1* model there are multiple close contacts between the β-tubulin tail, α-tubulin's helix H11, and the H10/B9 loop of α-tubulin. Although, as may be seen from Tables I and II, many residues or pairs of residues involved in tail–body interactions and in H11-H10/B9loop interactions are shared between models *p1*, *p2*, and *p3*, these models explore different regions in conformational space and thus their trajectories display qualitatively different behaviors. For example, in model *p2*, at the intra-dimer interface, the β-tubulin tail interacts with residue Lys 401 of the H11 helix on α-tubulin, but there is no interaction between αH11 and the H10/B9 loop of β-tubulin. On the other hand, in both the *p3* and $\alpha\beta_S$ simulations, αH11 interacts with β-tubulin's H10/B9 loop but not with the β-tubulin tail. In the $\alpha_S\beta_S$ simulation, without either tail domain present, almost continuous interaction was observed between the H10/B9 loop and the H11 helix of the adjacent monomer, at both monomer interfaces (see Supporting Information Fig. S2).

A physical model was previously created of ion dynamics in and around MTs, based on the application of a random alternating electric force on the surrounding cations by fluctuations in C-terminal tail positions.[45] The continuous breaking and formation of salt bridges give rise to an alternating voltage source on ions as the

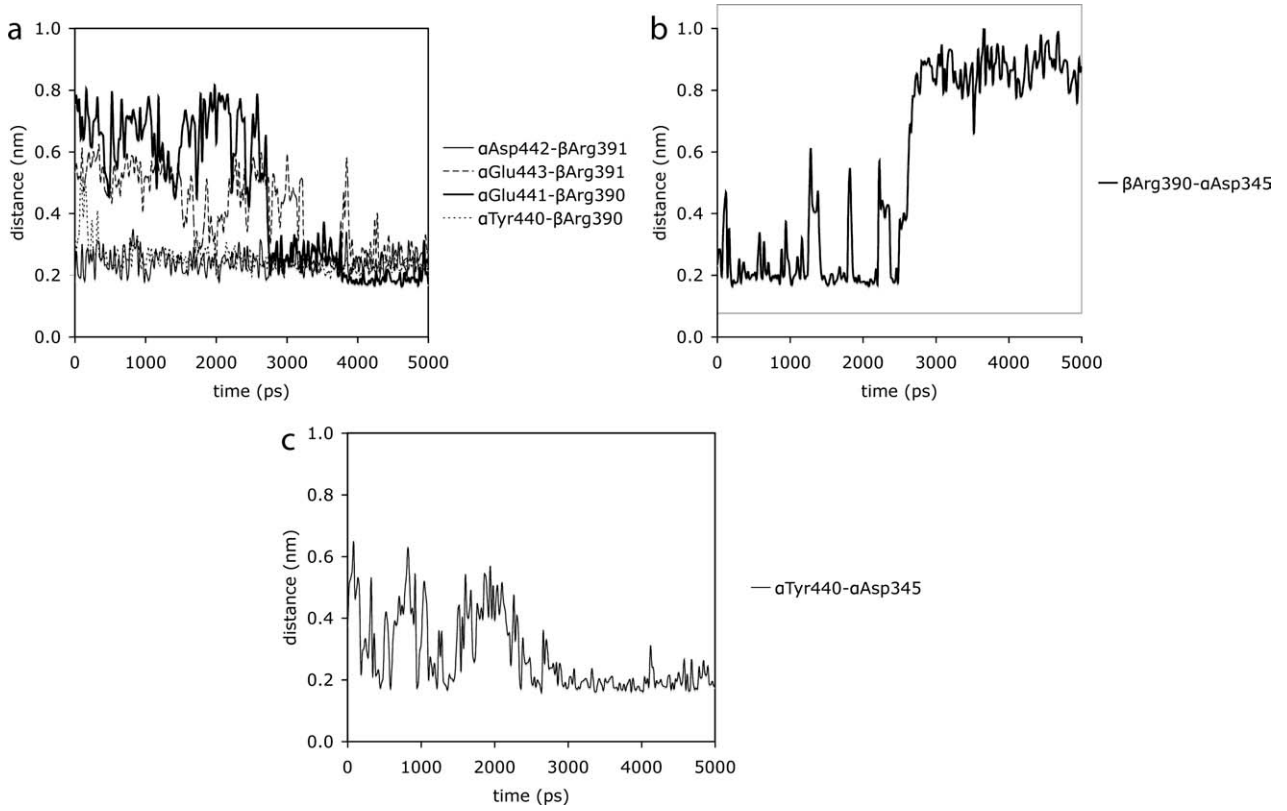

Figure 6

Minimum distances (nm), plotted for the *p1* model as a function of simulation time (ps), between charged or aromatic residues belonging to (**a**) α-tubulin's C-terminal tail domain and β-tubulin's H11 helix; (**b**) β-tubulin's H11 helix and α-tubulin's H10/B9 loop; and (**c**) α-tubulin's C-terminal tail domain and α-tubulin's H10/B9 loop.

tails dynamically oscillate between conformations where they either interact with the tubulin body or extend into more solvated conformations, as seen in Figure 6. This effect observed in our simulations appears to support the hypothesis that local charge reconfiguration due to the motion of C-termini tails can affect ionic flows and hence endow MTs with unique electro-conformational properties.

Structure and flexibility of tubulin body

The average RMSF of each residue of α-tubulin (excluding tail-residues) is plotted as a function of residue index *i* in Figure 7, and that of β-tubulin in Supporting Information Figure S6, corresponding to each of our simulations. The peaks in the RMSF plots show regions of high flexibility, and the highest peaks generally occur at solvent-accessible loops. Tubulin is known to have three main domains, which have been shown to be associated with major correlations in structural fluctuations.[46] These are the N-terminal nucleotide-binding domain, the intermediate taxol-binding domain, and the C-terminal domain, and consist of residues 1–205, 206–381, and 382–448, respectively, on α-tubulin and residues 1–203, 204–371, and 372–444, respectively, on β-tubulin. The last few residues of C-terminal domains show a high degree of flexibility in all models; the loop connecting helices H11 and H12, and H11 itself, may also be seen from the RMSF plots to be quite flexible for the *p3* and $\alpha_S\beta_S$ models. We will now briefly examine the main characteristics of RMSF plots for α- and β-tubulin that we observed first for the N-terminal domain, and then for the intermediate domain; we will also discuss some notable differences between models in RMS fluctuations and their significance.

N-terminal domain (residues α1-205, β1-203)

In the N-terminal domain, peaks are seen in the RMSF plots (Fig. 7 and Supporting Information Fig. S6) at residues α43–63, β45–47 in the region of the H1/B2 loop, which forms lateral contacts with neighboring monomers; at residues α69–74, β66–71 corresponding to the T2 loop; in the region of the H3 helix and T3 loop at residues α95–119, β91–120; and at residues α141–146 in the region of the glycine-rich signature loop, T4. In

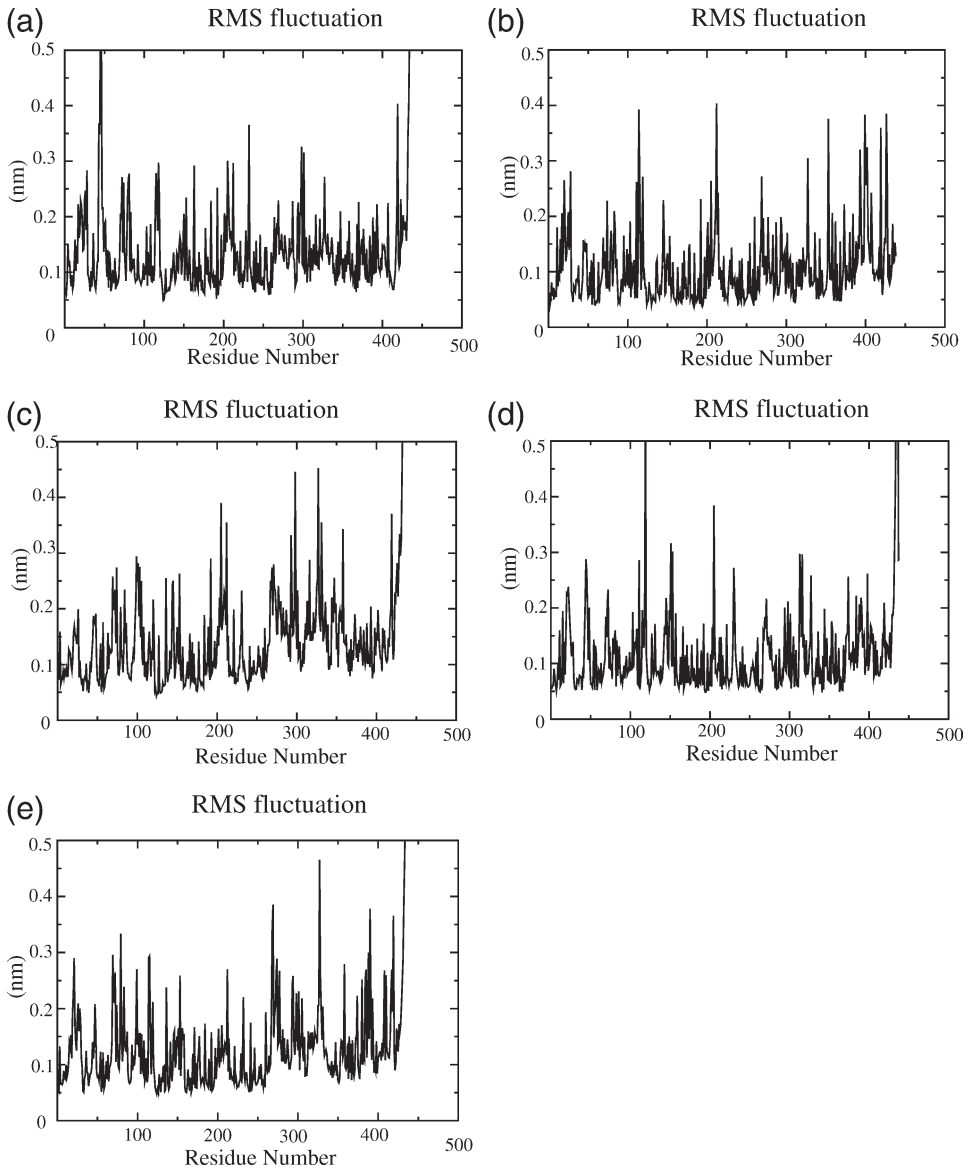

Figure 7

Time-averaged RMSF (nm) of each residue of α-tubulin plotted as a function of residue number for model (**a**) $\alpha\beta_S$, (**b**) $\alpha_S\beta_S$, (**c**) *p1*, (**d**) *p2*, and (**e**) *p3*.

Figure 7 and Supporting Information Figure S6, it may be noted that the peaks corresponding to the T3/H3 region on both α- and β-tubulin are much more pronounced in the RMSF plots for model *p2* than in the other plots. The T3/H3 region (residues α97–128 and β95–126) is located close to the nucleotide binding site, the exchangeable one in the case of β-tubulin, and the non-exchangeable one for α-tubulin. When secondary structure of the N-terminal domain is compared between the simulation trajectories (see Table III and Supporting Information Table S1), it is observed that there is a loss of α-helical structure for the *p2* trajectory compared to for the other trajectories. Upon examination, one noticeable instance of this is a less helical appearance of the H3 helix.

We, therefore, analyzed local secondary structure of the T3 loop and of the H3 helix for each of our models. In Figure 8 and Supporting Information Figure S7, we have plotted the percentage of the total simulation time during which each residue in this region is found in a helical form, calculated by the *g_helix* analysis tool. The plots in Figure 8 show that on average during the simulations the α-tubulin T3/H3 region has lost helicity for both the $\alpha\beta_S$ model and *p2* models, and that the β-tubulin T3/H3 region is much less helical for model *p2* compared to those in the other models.

Table III
Percentages of Residues in α-Tubulin's N-Terminal Domain Forming Various Types of Secondary Structure, Determined Using the do_dssp Gromacs[32,33] Analysis Tool

	$\alpha\beta_S$	$\alpha_S\beta_S$	*p1*	*p2*	*p3*
Structure	36	53	40	43	45
Coil	35	27	33	26	32
β-Sheet	2.2	7.4	1.9	11	6.2
β-Bridge	3.2	2.9	2.4	4.4	1.7
Bend	26	18	25	25	21
Turn	15	21	15	21	17
α-Helix	15	22	21	6.6	20
5-Helix	0.0	0.0	0.0	0.0	0.0
3-Helix	3.6	2.1	1.4	6.4	2.2

The category "Structure" represents all residues classified as α-helix, β-sheet, β-bridge, or turn.

Intermediate domain (residues α206–381, β204–371)

Major peaks seen in the RMSF plots (Fig. 7 and Supporting Information Fig. S6) in tubulin's intermediate domain are those corresponding to the region of longitudinal contacts at residues α200–232, β201–215; the flexible M-loop on β-tubulin at residues 276–284, and the N-loop on α-tubulin at residues 264–288; and the H10/B9 loop at residues α339–350 and β337–348. Greater RMS fluctuations of the intermediate domain of α-tubulin in the *p1* simulation compared to in the other simulations can be seen from the higher peaks on the RMSF plot corresponding to this simulation, and generally increased RMSF values for large parts of this domain. One instance of this is the greater fluctuation seen for model *p1* of residues corresponding to the H10/B9 loop. This is most likely related to the interchange of interactions between the H10/B9 loop, the H11 helix of β-tubulin, and the α-tubulin tail domain, as is observed in Figure 6 for this trajectory. That is, the formation and breaking of salt bridges causes the H10/B9 loop to assume two or more different positions. These interactions may indirectly lead to higher fluctuations of other parts of the intermediate domain of α-tubulin as well. In Figure 6, the sporadic interchange of interactions between the three domains is seen to occur primarily during the first half of the simulation. We thus examined the RMSF plot calculated for the first half of the simulation only [Supporting Information Fig. S8 (a)]. This plot also shows a high degree of fluctuation of residues in tubulin's intermediate domain. However, consistent with the more constant pattern of interactions during the second half of the simulation, the RMSF plot corresponding to this time interval shows much less fluctuation of the intermediate domain [Supporting Information Fig. S8 (b)]. Notice also that models *p2* and $\alpha_S\beta_S$ for which interactions between residues of

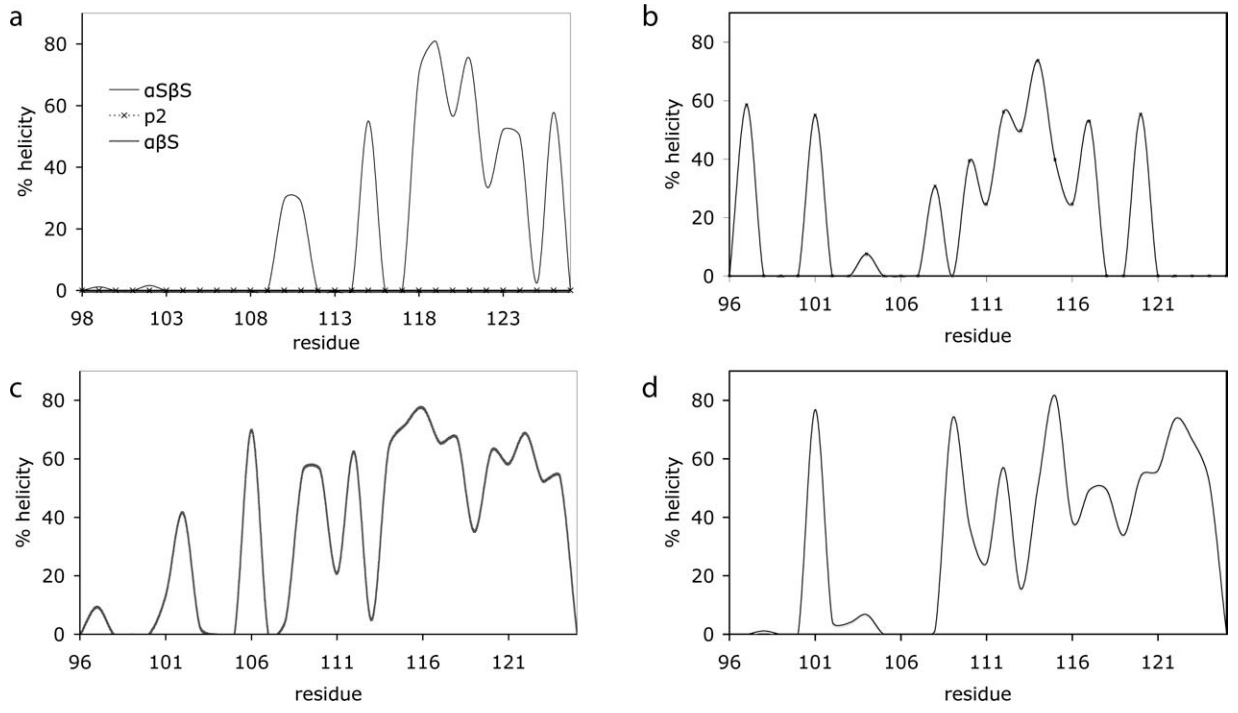

Figure 8
Percentage of total simulation time during which residues are found in a helical form plotted as a function of residue number for (**a**) the T3 loop/H3 helix domain of α-tubulin corresponding to models *p2*, $\alpha\beta_S$, and $\alpha_S\beta_S$; and for the same domain of β-tubulin corresponding to models (**b**) *p2*, (**c**) $\alpha\beta_S$, and (**d**) $\alpha_S\beta_S$.

tail domains and H10/B9 loops are entirely absent show much less fluctuation of residues in the intermediate domain than any of the other three simulations.

Experiments have shown that the polymers assembled from $\alpha_S\beta_S$ tubulin display an increased number of lateral interactions compared to normal MTs, causing junctions to form between polymer walls so that structures resemble hooked MTs with crescent-shaped cross-sections.[6,7] Structural changes in the intermediate domains of normal MTs caused by the disruption of H10/B9 loop-H11 helix interactions by tail domains may possibly lead to changes in positions of key structural elements involved in lateral contacts, which are located in the intermediate domain, such as the M or N loop.

Relevance to drug binding and efficacy

The observations made above, from our simulations, of interactions of the tubulin C-terminal tails with the rest of the protein and our suggestion that changes in the position of tubulin's intermediate domain arising from these interactions may offer an explanation for the role of tail domains in regulating MT assembly, will now be considered in the context of previous work performed by experimentalists.

As has been mentioned in the introduction, experiments have indicated that tail–body interactions within tubulin and tubulin polymers are capable of influencing the binding or efficacy of the tubulin-targeted cancer chemotherapy drugs, colchicine and vinblastine. Colchicine and vinblastine bind to opposite ends of β-tubulin, the former at the intra-dimer interface and the latter on the other end of β-tubulin close to where the N terminus of the α-tubulin tail from the neighboring dimer interfaces with β-tubulin in the context of a protofilament[47] (see Fig. 5). On the other hand, as we will now discuss, colchicine's binding is affected by cleaving the α-tubulin tail,[16] and vinblastine activity by cleaving the β-tubulin tail.[17] In this connection, it is noteworthy to mention that the effect of phomopsin A on the conformational stability of tubulin is also affected by the cleavage of tail domains. Phomopsin A, a non-competitive inhibitor of vinblastine binding[48] is an extremely good inhibitor[49,50] of the spontaneous denaturation[51,52] to which the tubulin dimer is prone. $\alpha_s\beta_s$ tubulin is more resistant to this decay than is undigested αβ tubulin, and the stabilizing effect of phomopsin A is even stronger with $\alpha_s\beta_s$ tubulin than with αβ tubulin.[53]

In experiments performed by Rai and Wolff[17] it was observed that the negative effect that oligo-anions such as sodium triphosphate have on vinblastine-induced polymerization of tubulin is prevented when the C-terminal tail on β-tubulin is removed by subtilisin digestion, although subsequently removing the α-tubulin C-terminal tail to form $\alpha_S\beta_S$ tubulin has no further effect. Note that these polymers are not MTs but are filamentous spirals.[54] Because this negative effect of oligo-anions on vinblastine-induced polymerization of tubulin could be induced in $\alpha\beta_S$ tubulin (recall that $\alpha\beta_S$ tubulin defines dimers lacking only the β-tubulin tail) by increasing the concentration of oligo-anions from 1 m*M* to 10 m*M*, a model was suggested in which there is an interaction favorable to polymer stabilization that is interfered with by both the β-tubulin tail domain and oligo-anions. More specifically, it was proposed that some residues on the tubulin body might interact with a positively-charged residue or region on the tubulin surface, and compete with β-tubulin tail residues for interactions with the same positive cluster.[17] An additive negative effect on stabilization from both this tail–body interaction and the blockage of the positive region by the added anions would then provide an explanation for both how the cleavage of tails allows vinblastine to stabilize tubulin polymers in the presence of a low concentration of anions, and how, when this concentration is increased, vinblastine cannot stabilize even $\alpha\beta_S$ polymers. The interaction between the H10/B9 loop on β tubulin and the positively-charged cluster on H11 of the neighboring α-tubulin, observed in our simulations, along with our observation of interactions between the β-tubulin tail and both of these domains competing with the former interaction, support such a model. From this perspective, the interaction between the H10/B9 loop on β tubulin and positively-charged residues on H11 of the neighboring α tubulin could be strengthened by vinblastine binding, contributing to vinblastine-induced polymer stabilization. On the other hand, the addition of anions would be expected to interfere with this longitudinal interaction. However, without the additive effect of the tail–body interactions, in $\alpha\beta_S$ polymers, vinblastine (albeit while bound to the end of β-tubulin distant from the H10/B9 loop) may be capable of stabilizing either the longitudinal loop–helix interaction and/or the accompanying large-scale effect on the position of the intermediate domain, in the presence of anions. The latter effect can be overridden by adding enough anions.

The effect of vinblastine on tubulin polymerization has been the object of investigations for many years. It turns out that vinblastine binds to MT ends with high affinity but also binds with a much lower affinity to tubulin sites located along the surface of the MT cylinder.[55–57] Approximately, 16–17 high-affinity binding sites located at MT ends have been determined to exist per MT. They are responsible for the well-known kinetic suppression effects of vinblastine, that is, its stabilization of MTs, at low concentrations (sub-micromolar).[58] The binding of vinblastine to the low affinity binding sites on the MT surface is believed to be responsible for the depolymerization of MTs at intermediate ($> 10\ \mu M$) drug concentrations. Finally at drug concentrations of $> 10\ \mu M$, the tubulin polymer stabilized by vinblastine, studied by Rai and Wolff,[17] is an alternate form of the polymer, not the

MT polymer. One possible explanation of the opposite effects of vinblastine on MT polymerization at submicromolar versus intermediate concentrations may be that in the vinblastine-bound polymer, the H11-H10/B9 loop interaction is stronger than normal, which can lead to increased MT stabilization when vinblastine binds to MT tips only; increasing the strengths of these interactions throughout other parts of the MT may lead to destabilization.

In a separate set of experiments, Chakraborty *et al.*[16] found that cleaving the α-tubulin tail domain lowers the activation energy and the on-rate for colchicine binding to the tubulin dimer. In contrast to the case of vinblastine effects on tubulin polymers, the effect is seen in $\alpha_S\beta_S$ tubulin but not $\alpha\beta_S$ tubulin, that is, cleavage of the β-tubulin tail alone has no effect on colchicine binding. Moreover, the binding affinity of colchicine for the tubulin dimer is normally dependent on pH, a factor known to affect tail conformation, but for the $\alpha_S\beta_S$ tubulin dimer, binding is independent of pH. To explain these findings, the authors suggested that although colchicine binds to β-tubulin at a site distant from the α-tubulin tail, tail–body interactions of the α-tubulin tail can cause large-scale conformational changes in the tubulin protein, which both promotes the binding of colchicine and leads to a higher activation energy for binding.[16] In support of this hypothesis it was noted that a 100 m*M* concentration of added NaCl, which would partially screen the electrostatic tail–body interactions, also lowers the activation energy and the on-rate for colchicine binding. It was speculated that the tail–body interaction might involve bending of the α-tubulin tail towards the positively-charged cluster on H11 of α-tubulin, affecting the colchicine binding site and leading to the altered kinetics.[15,16] This was not observed in any of our simulations. However, our MD modeling does support the proposed mechanism by which a tail–body interaction causes a conformational change in α-tubulin by a slightly different explanation, since our results indicate that the α-tubulin tail can interact with the H10/B9 loop, which may enable the intermediate domain to flex out laterally, leading to significant structural changes between normal and $\alpha_S\beta_S$ tubulin. By this line of reasoning, these changes would occur not only on the side of α-tubulin's intermediate domain close to the tail domain, but also extend to the distant side of this intermediate domain, near where colchicine binds to β-tubulin. It is also interesting to speculate whether, conversely, the drug activity of colchicine, which inhibits MT assembly, may involve altering the position of the intermediate domain of α-tubulin.

In summary, the combined results of the experiments from the literature,[16,17] which we have just described, and the simulations reported in the present article seem to indicate that both vinblastine effects on tubulin polymers and colchicine binding to tubulin are affected by shifts in the position of the entire intermediate domain of tubulin compared to that found in $\alpha_S\beta_S$ polymers or tubulin dimer, in the former case that of the β-tubulin monomer and in the latter that of α-tubulin. We propose that this shift is brought on by interactions between the tail domain, the H10/B9 loop, and in the case of vinblastine, the H11 helix of the neighboring monomer, all at the other longitudinal monomer interface from where drug-binding occurs. Experimental confirmation of large-scale conformational flexibility for tubulin's intermediate domain has already been supplied by photo-affinity labeling results demonstrating that cysteines 295, 305, 315, and 316 in the intermediate domain of α tubulin, but distant from the colchicine binding site, are affected by colchicine binding.[59]

CONCLUSIONS

Using computational techniques, we have determined two modes of interaction between the C-terminal tail domains with the main body of tubulin. Specifically, we have found an inter-monomer mode between charged residues on the α(β) tail and β(α)H11 and an intra-monomer mode, pairing aromatic (charged) residues on the α(β) tail with charged (aromatic) residues on the α(β) H10/B9 loop. As one would expect from the heretofore-elusive structures of the C-terminal tails, these interactions are non-specific and transient.

However, we also observe that the binding sites for the tails may bind laterally with each other, that is, the α(β) H10/B9 loop binds to β(α)H11. The result of this competitive interference is to increase flexibility in the intermediate domain with respect to $\alpha_S\beta_S$ tubulin. Such competitive behavior, in which another region of tubulin forms electrostatic interactions with the same positively charged region that the tubulin tail also binds to, has previously been hypothesized based on experimental results implicating tail–body interactions in vinblastine effects on tubulin polymers.[17] Based on the connection that we predict between flexibility of the intermediate domain and tail–body interactions, together with the experimental data showing that the binding or activity of colchicine[16] and vinblastine,[17] respectively, depend on electrostatic interactions of the tubulin tail domains far from the drug binding site, it seems likely that the binding or activity of these two drugs may be linked to the flexibility of tubulin's intermediate domain.

A natural test of the intermediate domain flexibility hypothesis and our proposed intra-monomer binding mode is to mutate residues Glu431 and Glu 432 belonging to the C-terminal tail domain of β-tubulin to alanines and then determine whether the negative effect of oligo-anions on vinblastine-induced polymerization of tubulin is eliminated, just as it is by cleavage of β-tubulin tail domains.[17] The analogous test for the inter-monomer mode is to mutate either of the two residues

Asp α345 on the H10/B9 loop or Tyr α440 on the C-terminal tail, predicted here to form extensive interactions with each other, to alanine, which should lead to pH independent binding of colchicine, in a similar manner that cleavage of the α-tubulin tail domain does.[16]

The C-terminal tails are also involved in the binding of several MAPs essential to the function of MTs. Following Luchko *et al.*,[3] we characterized three structural motifs possibly involved in the CK-2 phosphorylation and MAP2 binding. Falquet *et al.*[60] previously identified a conserved sequence for CK-2, which is found as DATA in the βI-tubulin tail. The DATA motif was found to have a very high similarity among our simulations; at least for the βI tail sequence, this indicates that the structure is persistent, and does not need to be induced for phosphorylation. As this structural motif has now been identified by two independent MD protocols, it should be considered a strong prediction. Contrary to the previous findings, the two proposed MAP2 binding motifs did not maintain similar structures between the models compared. However, since the sequence is experimentally known to be significant[44] and the residues are fully solvated, the possibility that these motifs are induced fit binding sites cannot be ruled out. Rather, further experimental and computational studies are needed to address this question. Some of this type of experimental study has been carried out on α-tubulin tails already, but we have not investigated proposed binding sites from this work.[61]

Beyond the scope of this study are the wide variety of post-translational modifications, particularly effecting the C-terminal tail domain, that tubulin is subject to. These include tyrosinolation/detyrosinolation of α, deglutamylation of α, polyglutamylation of both α and β, polyglycylation of both α and β, and phosphorylation of certain isotypes of β.[1] All of these could well affect the conformation of the tail domains and several also would alter the charges. These modifications may play critical roles in regulating the functions of MTs; for example, detyrosination of α promotes MT stability,[62] while polyglycylation of β is necessary for normal axoneme formation and polyglutamylation of α and/or β appears to mediate binding of MT-associated proteins (MAPs) and the motor protein kinesin to tubulin.[14,63–67] Some of these effects are likely to be indirect, that is, the presence of the modification in the C-terminal could conceivably act as a signal to some other protein or proteins which in turn could mediate the effect, that is, MT stability, axoneme formation, and so forth. Regardless, these modifications are of such scale that it is easy to hypothesize that they cause major conformational changes in the C-termini and that these changes in turn may mediate the ultimate effects of these modifications. It is likely that there exists a complex feedback loop between the probability of modification occurring and the conformational effect of modification. In addition, the binding of the C-termini to MAPs and motors is critical to the function of a variety of MT populations and is likely to also be regulated by conformational interactions involving the C-termini. These conformational effects and interactions and their likely functional outcomes are currently being examined.

Finally, we wish to comment on the lack of helicity of the T3/H3 region that was noted in two of the simulations. The issue of how MTs are destabilized by GTP hydrolysis is currently highly debated.[68–72] Along with MTs, actin filaments comprise one of three major components of the cytoskeleton and these two types of protein filaments have many remarkably similar properties including the utilization of a hydrolyzable nucleotide in polymer dynamics.[73] Experimental and computational studies indicate that in the case of actin polymerization, a loop-to-helix transition of the DNase-I binding (DB) loop is associated with hydrolysis of the nucleotide ATP to ADP and with the simultaneous structural change to a less stable actin polymer, as lateral contacts are lost in the less flexible helical structure.[74,75] Thus, the variability in the helicity of the T3/H3 region seen in our simulations together with the fact that the T3 loop of β-tubulin has been observed to be destabilized upon hydrolysis of the bound GTP to GDP,[68] raise the possibility that upon hydrolysis of the GTP bound to β-tubulin, the T3/H3 region might undergo a loop-to-helix transition similar to that in actin, causing a large-scale shift in the entire MT structure. Experimental testing of this hypothesis could be performed by applying techniques which have previously been used to analyze small changes in protein helical structure, such as Trp fluorescence,[76] FRET (Forster resonance energy transfer) emission spectra,[77,78] or EPR (electron paramagnetic resonance) data.[78] In this way, structural comparisons could be made of the T3/H3 region in MTs bound by different nucleotides or nucleotide-analogues.

Abstract— We present the results of molecular dynamics computations based on the atomic resolution structure of tubulin. Values of net charge, charge distribution and dipole moment components are obtained for the tubulin heterodimer. Physical consequences of these results are discussed for microtubules in terms of the effects on test charges, test dipoles, and neighboring microtubules. © 2005 Elsevier Ltd. All rights reserved.

1. INTRODUCTION

Microtubules (MTs) are protein filaments of the cytoskeleton [1] with their outer diameter roughly 23 nm, and a hollow interior with a diameter of roughly 15 nm (see Figure 1). Their lengths vary but commonly reach 5–10 μm dimensions. They are composed of 12 to 17 protofilaments when self-assembled in vitro and almost exclusively of 13 protofilaments in vivo. These protofilaments are strongly bound internally and are connected via weaker lateral bonds to form a sheet that is wrapped up into a tube in the nucleation process [2].

MTs are found in nearly all eukaryotic cells and they perform a variety of key cellular functions. In addition, to providing rigidity and structural integrity to a living cell, they serve as tracks for motor protein transport. They also form the core of cilia and flagella which beat in a coordinated manner to either move objects along the cell membrane or to propel the cell through its environment. Perhaps most importantly, microtubules form mitotic spindles that segregate chromosomes during cell division.

In general, there are three types of action modes of chemical antitumor compounds, namely:

(a) DNA targeting compounds that kill the cell by destroying or blocking the use of its genetic material,

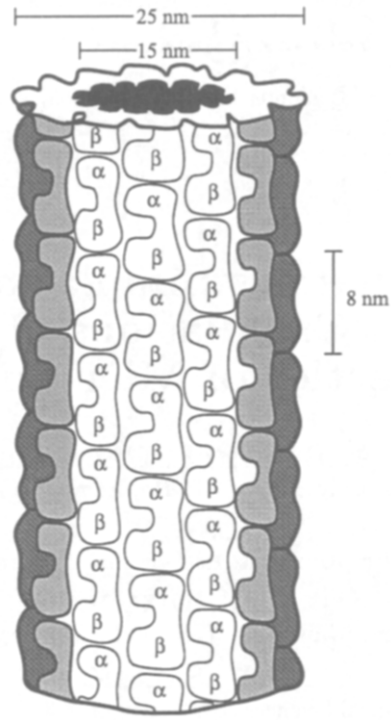

Figure 1. A section of a typical microtubule demonstrating the helical nature of its construction and the hollow interior which is filled with cytoplasm. Each vertical column is known as a protofilament and the typical MT has 13 protofilaments.

(b) compounds which inhibit normal cell functions, and
(c) the so-called spindle poisons which block the mitosis by interfering with the normal behavior of microtubules.

All the above-mentioned chemicals are very toxic. However, one interesting feature of the spindle poison compounds is that they more specifically target fast dividing cells, which is a particular property of cancerous cells. There are two ways by which the spindle poisons can block the mitosis. First, colchicine and vinblastine block the mitosis by preventing the formation of the mitotic spindle. In fact, they inhibit the polymerization of tubulin into microtubules. Second compounds such as taxol and rhazinilam stop the mitosis between the metaphase and the anaphase. They do so by stabilizing the microtubule polymer through binding to tubulin at specific locations as shown in Figure 3. Since the depolymerization is blocked making the microtubules static, the chromosomes cannot migrate toward the poles and cell division cannot be accomplished. It is our belief that analyzing some key physical properties of tubulin and microtubules such as their electrical charge and dipole distributions, we will gain important insights into the mechanism of cell division and possible means of controlling it via sophisticated physical and chemical agents.

The general structure of MTs has been well established experimentally [3,4]. A small difference between the α and β monomers of tubulin allows the existence of several lattice types (see Figure 2). Moving around the MT in a left-handed sense, protofilaments of the A lattice have a vertical shift of 4.92 nm upwards relative to their neighbors. In the B lattice this offset is only 0.92 nm because the α and β monomers have switched positions in alternating filaments. This change results in the development of a structural discontinuity in the B lattice known as a seam [4,5]. In addition, Chrétien *et al.* [6] observed that, the protofilament number need not be conserved along the length of a microtubule leading to the emergence of structural defects in the lattice. Furthermore, Sosa *et al.* [7] showed evidence of more than one seam in microtubules.

The idea that protofilaments have flexible connections, allowing for the presence of defects [8], could explain the anti-parallel alignment of protofilaments in the presence of Zn^{2+} ions. The zinc ion may favor one orientation for hydrophobic bonding. This is also consistent with the

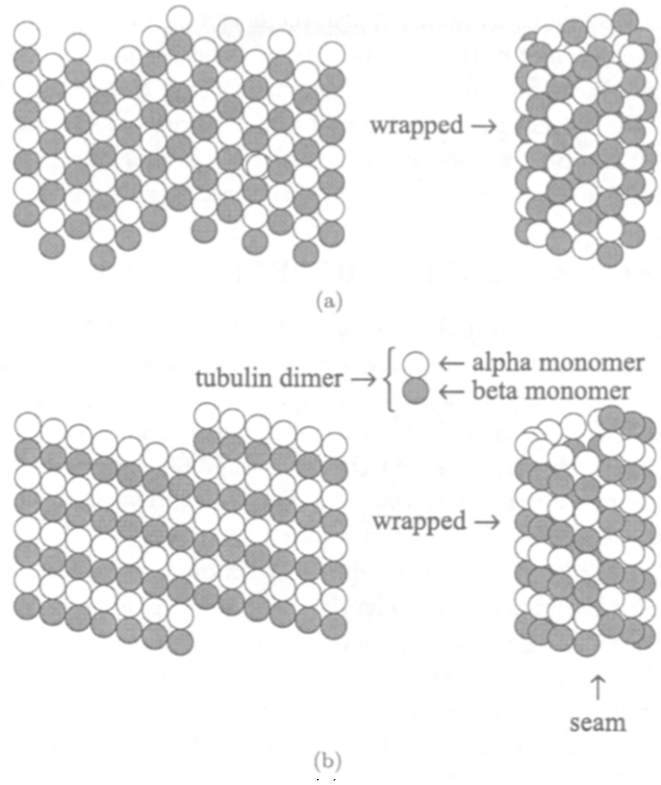

Figure 2. The 13A and 13B MT lattices: (a) in the A lattice, perfect helical spirals are formed. (b) in the B lattice, there is a structural discontinuity known as the seam.

observation of MT assembly in which a seam appears to "zip up" the cylinder behind the assembly edge [2].

In 1998 Nogales *et al.* [9] reported crystallization of tubulin in the presence of zinc ions. Their results were made available through the Protein Data Bank (PDB) [10] (PDB entry: 1TUB) which allowed us to view the three-dimensional atomic resolution structure of tubulin (see Figure 3) using RasMol [11]. Each tubulin monomer is composed of more than 400 amino acids and, in spite of their similarity, slight folding differences can be seen. It is worth stressing that several different versions of both tubulin α and β forms exist an are called isotypes [12] when found in

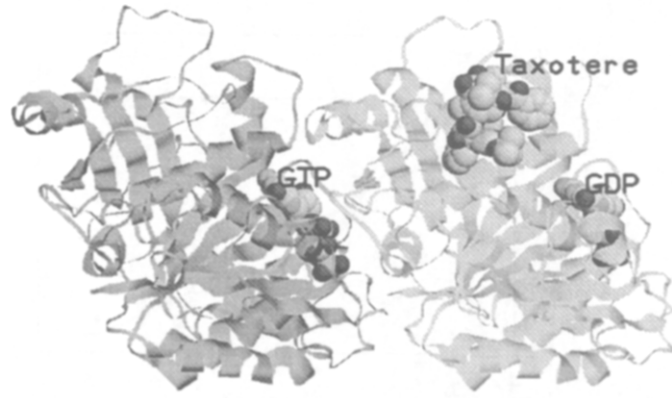

Figure 3. A ribbon diagram of the tubulin molecule produced from the [9] crystallographic data shows the similarity between the α-subunit (up half) and the β-subunit (lower half). The stick outlines near the base of each subunit indicate the location of GTP when bound.

the same organism. In humans at least six distinct α isotypes and seven β isotypes of tubulin have been identified. What is intriguing and, so far, unexplained, is the correlation between localization of certain isotypes and the functions performed by microtubules assembled from them. For example, the β_1 and β_4 are not found in cell nuclei but are present along with β_2 in the mitotic spindle. It has been suggested that, the interaction of tubulin with extrinsic proteins may direct the architecture and organization of MTs according to the isotypes used [13].

2. ELECTROSTATIC MODELLING OF TUBULIN

The method of distributed multipole analysis (DMA) provides a fairly accurate means of calculating the electrostatic field around a biomolecule. Diatomics, triatomics, and tetratomics are described to high precision with the use of monopoles, dipoles and quadrupoles providing an accurate picture of molecular bonding. In the case of α and β tubulin, each monomer is comprised of approximately 450 amino acids, i.e., on the order of 7000 atoms. In the initial part of our calculations, we present results for the electrostatic potential in vacuum surrounding the protein. Later on, we discuss the effects of solvent with ions.

Nogales *et al.* [9] imaged tubulin heterodimers to atomic resolution establishing that, the structures of α and β tubulin are nearly identical and confirming the consensus speculation. A detailed examination shows that, each monomer is formed by a core of two β-sheets that are surrounded by α-helices. The monomer structure is very compact, but can be divided into three functional domains: the amino-terminal domain containing the nucleotide binding region, an intermediate domain containing the taxol binding site, and the carboxy-terminal domain, which probably constitutes the binding surface for motor proteins.

Calculations of the potential energy were done with the aid of a molecular dynamics package, TINKER [14]. This computer program serves as a platform for molecular dynamics simulations and includes the facility to use several force-field parameter sets, some of which are protein specific. The most common of these parameter sets for proteins are AMBER [15] and CHARMM [16]. AMBER was selected over CHARMM on the rationale that it is a more up-to-date parameter set. The overall performance of the program gave us confidence that the results it provided for tubulin were meaningful. It was determined using TINKER that tubulin is quite highly negatively charged at physiological pH and that much of the charge is concentrated on the C-terminus. (Perhaps as much as 40% of the overall charge.)

Figure 4 shows an experimental titration curve for the net charge on the tubulin $\alpha\beta$ heterodimer (with the C-termini) as a function of pH. We have also been able to obtain a detailed map of the electric charge distribution on the surface of the tubulin dimer (see Figure 5). It is clear that, the

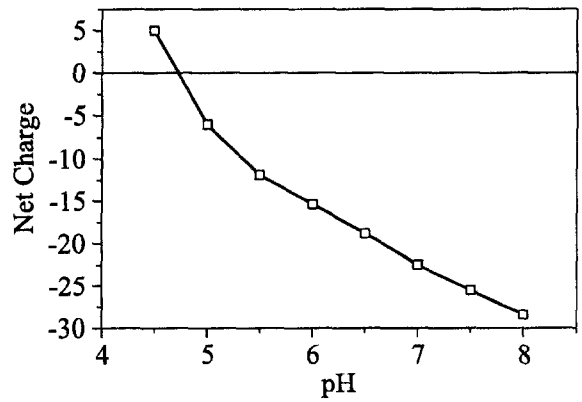

Figure 4. Tubulin titration curve for the tubulin $\alpha\beta$ heterodimer as a function of pH; obtained with no salt and no intra-molecular charge compensation. Figure courtesy of Sackett [17].

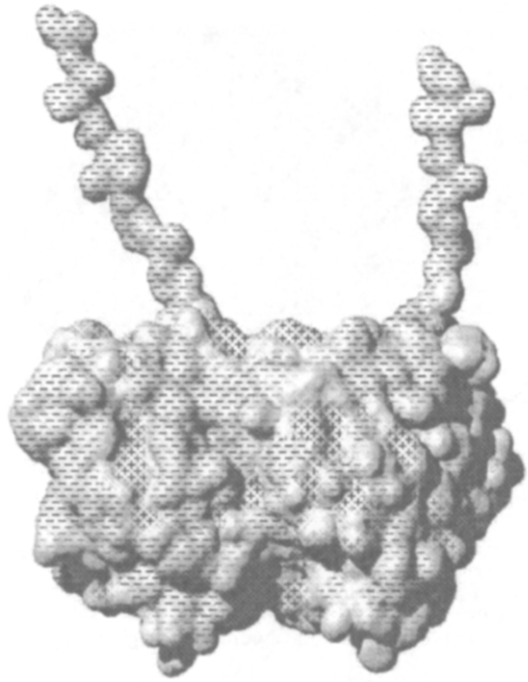

Figure 5. A map of the electric charge distribution on the surface of a tubulin dimer with C-termini tails present. Figure prepared using MOLMOL [18].

C-termini which extend outward carry a significant electric charge. At neutral pH, the negative charge on the carboxy-terminus causes it to remain extended due to the electrostatic repulsion within the tail. Under more acidic conditions, the negative charge of the carboxy-terminal region is reduced by associated hydrogen ions. The effect is to allow the tail to acquire a more compact form by folding (see Figure 6). Although this is probably the largest structural effect which occurs due to changes in the cell's pH, we expect that other structural changes, perhaps the result of post-translational modifications in the process of microtubule assembly, can similarly affect the electrostatics of the tubulin dimer.

In Figure 7, we have constructed a hydrophobicity map showing the location of hydrophobic and hydrophilic regions in the α tubulin monomer. In it, regions of dark minus signs are strongly hydrophobic, the lighter ones less so while increasingly dark plus signs correspond to an increasing level of hydrophylicity.

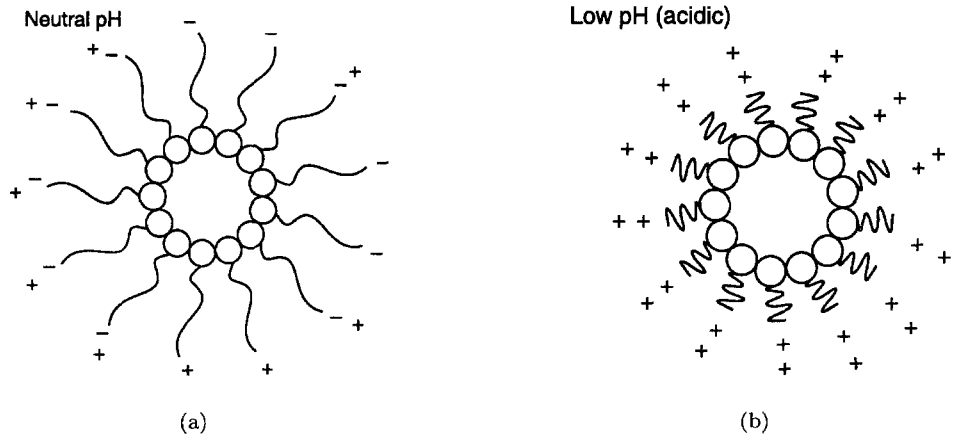

Figure 6. Cross-section of a MT including the carboxy-termini of the tubulin subunits. The folding shown of the carboxy-termini of the tubulin dimer demonstrates the change in the geometry of the molecule with pH. Neutral pH is shown on top, the tail folds at lower pH as the negative charges are screened.

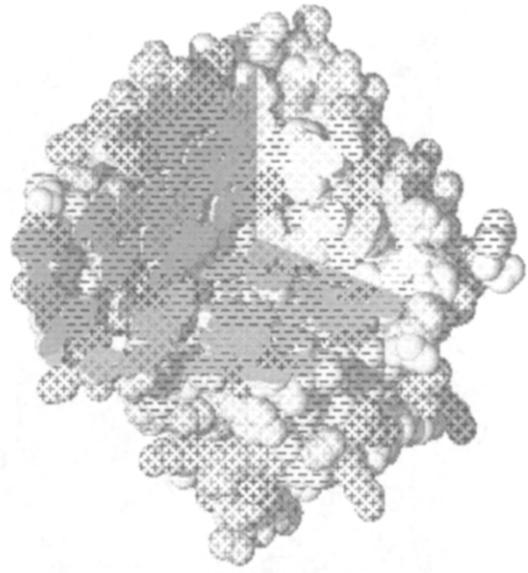

Figure 7. A cut-open view of the α-monomer of tubulin illustrating the location of hydrophobic regions (minus signs) and hydrophilic regions (plus signs).

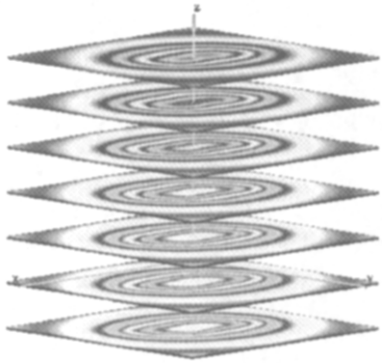
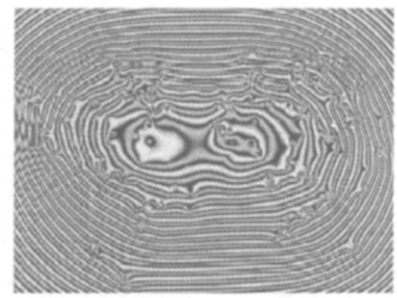
In Figure 8a, we have imaged the electrostatic potential inside the tubulin dimer. It is interesting to note that, the hydrophobic interior of the protein gives rise to a nicely symmetric electrostatic potential with the different rings indicating equipotential surfaces. While the topography of the potential slices taken in the plane perpendicular to the dimer axis is, for the most part, concentric, towards the top layer of the dimer the sampled cross-sections reveal a double-well structure. This may indicate that charged groups present in this region could execute tunneling motions between the two equivalent energy minima. A close-up view of one such cross-section is given in Figure 8b.

In Table 1, we listed the dipole moment of the dimer without the tails (see Figure 9a). The story here, however, is more complicated. As shown in Figure 9, there are several additional sources of dipoles when tubulin is present in an ionic solution. When two dimers are bound within a protofilament, their positively and negatively charged ends form a double layer with a net dipole moment along the protofilament axis (Figure 9b). Beside each tubulin monomer there is a hydrophobic pocket that may develop a double-well structure (see Figure 8). This can give rise to an internal (switchable) dipole moment due to electronic transitions on this positive



(a) Cross-section slicing perpendicular to its axis.



(b) A double-well potential region close to the top of the $\alpha - \beta$ heterodimer.

Figure 8. Images of the electrostatic potential inside a tubulin dimer.

Table 1. Tubulin's electrostatic properties (tail region excluded)[a].

Tubulin Properties	Dimer	α Monomer
Charge (Electron Charges)	−10	−5
dipole (Debyes)		
overall	1714	566
P_x component	337	115
P_y component	−1669	−554
P_z component	198	−6

[a] The x-direction coincides with the protofilament axis. The α monomer is in the direction of increasing x values relative to the β monomer. The y-axis is oriented radially towards the MT centre and the z-axis is tangential to the MT surface.

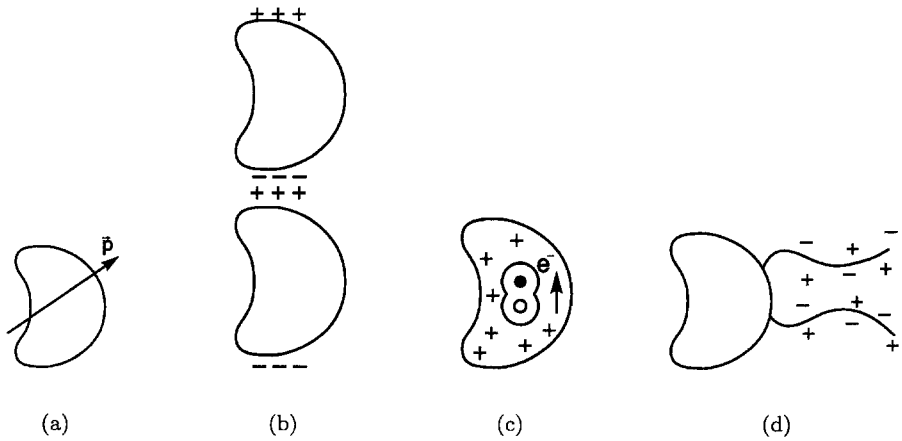


Figure 9. The various contributions to the dipole moment of a tubulin dimer (a) the intrinsic dipole moment of the globular protein, (b) the double layer formed when two dimers are bound in a protofilament, (c) a possible internal dipole created by electronic transitions in the hydrophobic pocket, and (d) a double layer formed by counter ions surrounding the C-termini tails.

background (see Figure 9c). Finally, as is shown in Figure 9d the C-termini which are negatively charged are surrounded by counter ions in solution leading to the formation of double layers. The principal contribution to the dipole moment of a tubulin dimer comes, however, from the location of partial charges on the constituent amino acids.

3. ELECTROSTATIC POTENTIAL AROUND TUBULIN

Having obtained the charge distribution on the tubulin surface, we have attempted to investigate its role in the microtubule lattice formation and its interaction with ions and macromolecules. We have confined our examination largely to the surfaces of tubulin that form the exterior surface and the protofilament-protofilament contacts when assembled into a MT. The first result that may be derived from the electrostatic potential is that there are those regions of the MTs outer surface that are negatively charged and which may attract hydrogen ions.

In calculating the electrostatic potential, 2.0 nm was selected as the cutoff distance for charge, dipole, and van der Waal interactions. The electrostatic potential was calculated for a 12 nm segment of the line, thereby including an additional 2 nm above and below each tubulin molecule. Periodic boundary conditions were then applied in the direction of the protofilament because this is the configuration of the tubulin dimers within a MT. The resulting profiles of the electrostatic potential are shown in Figure 10 and are located about the tubulin dimer as shown in Figure 11. The lateral boundary conditions were not considered in the calculation of the potential.

Consider the profile of the electrostatic potential in Figures 10a and 10b and compare them with the profiles in Figures 10c and 10d. These are left and right sides, respectively, of the

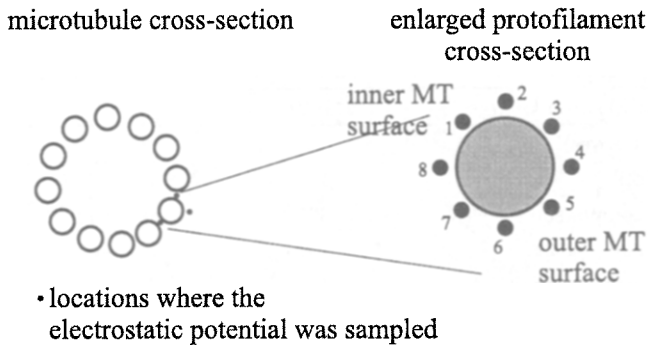

Figure 10. A MT cross-section illustrates where the electrostatic potential was examined along lines parallel to the protofilament axis (perpendicular to the page) in the preceding figure.

a and b are left sides
c and d are right sides

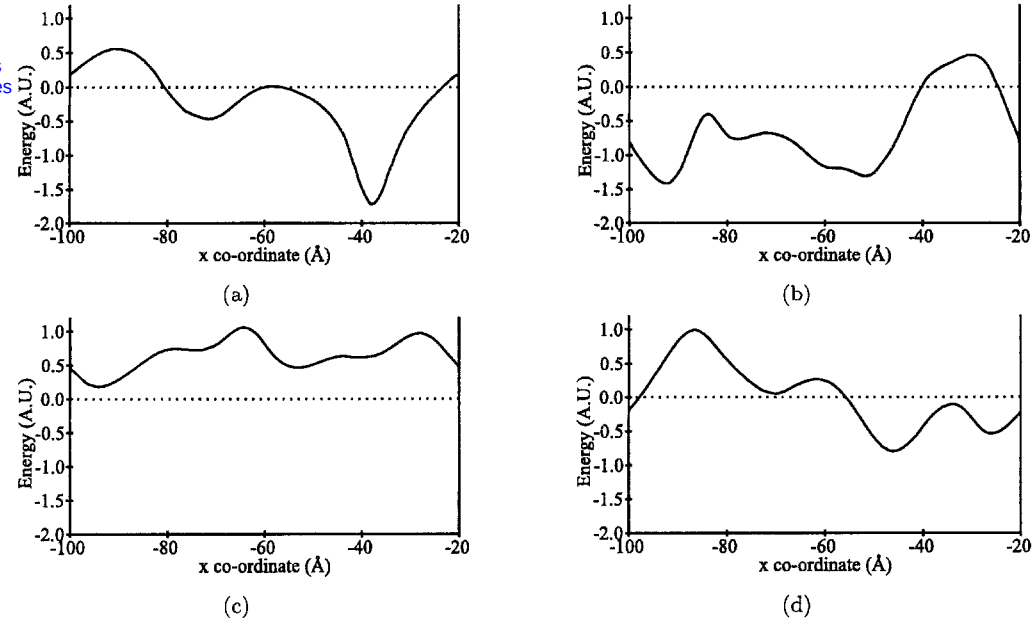

Figure 11. Electrostatic profiles along lines parallel to the protofilament axis. (a) Line 3-MTs interior on the A side of the protofilament-protofilament interface. (b) Line 4-MTs exterior on the A side of the protofilament-protofilament interface. The profile is largely negative indicating the negative surface charge. (c) Line 7-MTs exterior on the B side of the protofilament-protofilament interface. The largely positive surface charge is complementary to the opposite side of the dimer and contributes to protofilament-protofilament binding. (d) Line 8-MTs exterior on the B side of the protofilament-protofilament interface.

tubulin molecule, which interact laterally to hold one protofilament together with neighboring protofilaments. In these figures, each unit of energy represents 14.4 kcal/mol or 0.62 eV. This is roughly the energy available from the hydrolysis of two to three molecules of GTP or just a little more than the hydrolysis of one molecule of ATP. What is interesting is that, the electrostatic potential is largely negative on the left side and positive on the right side. Thus, there is a net electrostatic attraction between tubulin dimers with parallel alignment when their opposite sides face each other. In fact, if the minima in the left side's profile are aligned with the maxima in the electrostatic potential of the right side, we find that the neighboring tubulin dimer will be shifted by 1.4 nm or 5.4 nm which compares reasonably well to the observed 0.9 nm or 4.9 nm offsets that depend on the lattice type. The simple change of a residue on the surface offers the possibility of specifying one shift and locking the resulting MT into either the A or B type lattice. Hence, post-translational modification or more likely the expression of a particular isotype over another could select a specific lattice.

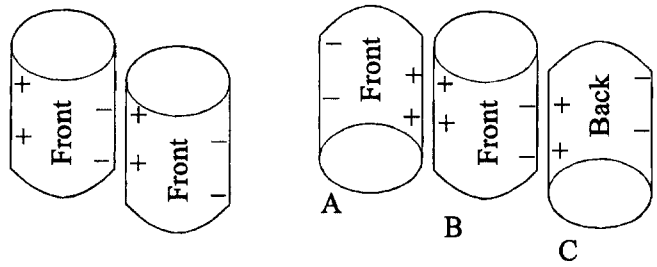

Figure 12. Protofilament-protofilament interaction. At left, tubulin dimers associate such that there is a vertical offset between protofilaments. At right, when the dimer's up-down orientation is reversed, it must also be rotated from front to back since the interaction between A and B is destabilizing but the interaction between B and C is stabilizing.

In the event that, we wish to consider tubulin aggregations such as the zinc(II) ion-induced sheets that were prepared in the tubulin structure determination experiments [9], the protofilaments have an anti-parallel configuration. As a result, proceeding on the premise that electrostatic interactions determine the protofilament-protofilament binding, the zinc(II) ion must work to alter this interaction. Since, the pattern of the electric potential consisting of two electrostatic wells on one side and two electrostatic peaks on the opposite side must be maintained, to explain the efficient binding of the dimers into the lattice of the tubulin sheet or MT, the potential is presumably not tremendously distorted. Since each tubulin dimer will be affected in the same manner, forming anti-parallel protofilaments does require that either the energy profile changes such that each side has a well and peak in the potential or conversely, that there is a small change in the potential which now favors binding where the "front" of the tubulin dimer is presented to an observer along protofilaments with the first orientation while the "back" of the tubulin dimer faces the observer for the protofilaments with the opposite orientation (see Figure 12).

4. ELECTROSTATIC EFFECTS OF MICROTUBULE STRUCTURE

When the previous investigations of the electrostatics of tubulin are brought to bear on the structure of the microtubule, we predict the emergence of a very unusual anti-ferroelectric structure. This is shown in Figure 13 with tubulin's permanent dipoles placed almost perpendicular to the surface of the microtubule cylinder and almost canceling one another due to rotational symmetry. It is tantalizing to speculate that such a dipolar structure may be constructed to facilitate the docking process of motor proteins such as kinesin. Bearing in mind that tubulin is

rotational symmetry = means that each dipole on the opposite ends of the cylindrical structure cancel each other out

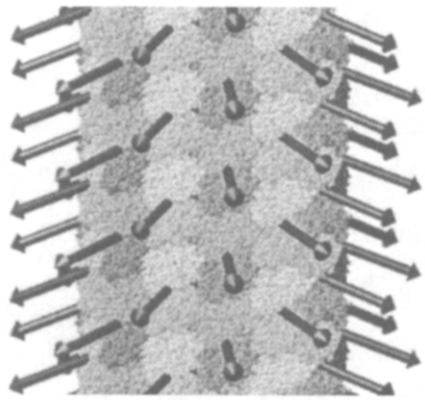

Figure 13. The arrows indicate the orientation of the permanent dipole moments of individual tubulin dimers with respect to the surface of a microtubule. Figure prepared using MOLMOL [18].

(c) another microtubule in the vicinity, and
(d) the dipole-dipole interaction between two microtubules.

Below, we summarize our calculations and Figure 14 illustrates the geometrical details.

A. Microtubule-Charge Interaction

Consider a microtubule with charge per unit area σ on its surface, with a length L, and a diameter $2a$. Suppose a point charge is situated at the points $(d, L_1, -L_0)$ relative to the origin as shown in Figure 14a. We calculate the electric field intensity at the point-charge location assuming the electrical relative permittivity to be ε. Using the formula

$$E = \int_0^L \int_0^{2\pi} \frac{\sigma a \, d\theta \, dx}{4\pi\varepsilon_0\varepsilon(d^2 + a^2 - 2ad\cos\theta - 2aL_1\sin\theta + L_1^2 + (x + L_0)^2)}, \tag{4.1}$$

we assume $d \gg a$ so that $d^2 + a^2 + L_1^2 + (x + L_0)^2$ is much greater than the terms in ad and aL_1. In the angular part of the integration we retain the leading term only and find that

$$E \approx \frac{\sigma a}{2\varepsilon_0 \varepsilon} \frac{1}{\sqrt{d^2 + a^2 + L_1^2}} \left[\tan^{-1} \left(\frac{L + L_0}{\sqrt{d^2 + a^2 + L_1^2}} \right) - \tan^{-1} \left(\frac{L_0}{\sqrt{d^2 + a^2 + L_1^2}} \right) \right]. \tag{4.2}$$

For sufficiently long microtubules

$$E \approx \frac{\sigma a}{2\varepsilon_0 \varepsilon} \frac{1}{\sqrt{d^2 + a^2 + L_1^2}}. \tag{4.3}$$

The results presented for the electrostatic potential in this paper represent "vacuum" results given that, the solvent is not explicitly taken into account. If the surrounding mixture of ions is considered, then the potential due to a point charge does not fall off simply as $1/r$ but instead as $\phi \propto (1/r)e^{-K(r-r_0)}$ where K^{-1} is the Debye length, typically close to 1 nm under physiological conditions [19]. The constant r_0 is the ionic radius. Since we consider locations within several nanometers of the MT surface, they are not completely screened by the ions of the solution.

As an example consider an average length of the microtubule of $L = 5\,\mu$m, $a = 12.5$ nm, and $\sigma = 0.5\,\mathrm{e/nm^2}$ which is consistent with our earlier discussion. With a test charge of $+5$ e located with $L_1 = 0$ and distance 5 nm from the surface we obtain a force of electrostatic attraction of 6 pN in water which is reduced to only 0.5 pN in standard ionic solution with a Debye length of 0.6–1.5 nm depending on the ionic strength. This would indicate that, the maximum distance over which a microtubule can exert an influence on a charged particle is on the order of 5 nm from its surface.

B. Microtubule-Dipole Interaction

Here, we consider a microtubule with a dipole moment per unit area, σ_D, on its surface, each dipole moment being perpendicular to its surface. The test dipole is assumed to be at the point $(d, +L_1, -L_0)$ as we illustrate in Figure 14b. The distance between this latter dipole and a dipole on a small element of area $\sigma_D a\, d\theta\, dx$ at $(a\cos\theta,\, a\sin\theta, x)$ is given by

$$\sqrt{(a\cos\theta - d)^2 + (a\sin\theta - L_1)^2 + (L_0 + x)^2}. \tag{4.4}$$

As a result the test dipole, with dipole moment $\vec{p}$, has a dipolar energy H_E, due to its interaction with the microtubule, given by

$$H_E = \sigma_D \int_0^L \int_0^{2\pi} \frac{a\, d\theta\, dx \left[\hat{n} \cdot \vec{p} - 3\,(\vec{n} \cdot \hat{n})\,(\vec{n} \cdot \vec{p})\right]}{4\pi\varepsilon_0 \varepsilon \left(d^2 + a^2 - 2ad\cos\theta - 2aL_1 \sin\theta + L_1^2 + (x + L_0)^2\right)^{3/2}}, \tag{4.5}$$

where $\hat{n}$ is a unit vector in the direction of the dipole moment of the element of area on the microtubule. That is

$$\hat{n} = \hat{\imath}\cos\theta + \hat{\jmath}\sin\theta. \tag{4.6}$$

Here, $\hat{\imath}$ and $\hat{\jmath}$ are unit vectors along the x and y coordinate axes. On the other hand, $\vec{n}$ is a unit vector along the direction from the surface element to the location of the test dipole. Hence,

$$\vec{n} = \frac{(a\cos\theta - d)\hat{\imath} + (a\sin\theta - L_1)\hat{\jmath} + (L_0 + k)\hat{k}}{\sqrt{(a\cos\theta - d)^2 + (a\sin\theta - L_1)^2 + (L_0 + x)^2}}, \tag{4.7}$$

where $\hat{k}$ is a unit vector along the z coordinate axis parallel to the length of the microtubule. The angular integral in equations (4.5) is evaluated by taking only the leading terms (since on

expansion, using the approximations in Section 4a, terms in $\sin\theta$ and $\cos\theta$ will vanish). Denoting the x, y, and z components of the test dipole by p_x, p_y, and p_z we find

$$\begin{aligned} H_E \approx & \frac{a\sigma_D}{4\pi\varepsilon_0\varepsilon\gamma} \frac{12ad\pi p_x + 12aL_1\pi p_y}{\left(d^2+a^2+L_1^2\right)^2} \\ & \times \left[\sin\left(\tan^{-1}\left(\frac{L+L_0}{\sqrt{d^2+a^2+L_1^2}}\right)\right) - \frac{1}{3}\sin^3\left(\tan^{-1}\left(\frac{L+L_0}{\sqrt{d^2+a^2+L_1^2}}\right)\right)\right. \\ & \left. - \sin\left(\tan^{-1}\left(\frac{L_0}{\sqrt{d^2+a^2+L_1^2}}\right)\right) + \frac{1}{3}\sin^3\left(\tan^{-1}\left(\frac{L_0}{\sqrt{d^2+a^2+L_1^2}}\right)\right)\right] \\ & + a^2\sigma_D 2\pi p_z \left(\left(d^2+a^2+L_1^2+(L+L_0)^2\right)^{-3/2} - \left(d^2+a^2+L_1^2+L^2\right)^{-3/2}\right). \end{aligned} \tag{4.8}$$

Note that, for an infinite cylindrical dipole surface with a uniform value of the dielectric constant in all space, the potential at an arbitrary point in space exterior to the cylinder is zero. However, here we deal with a finite cylinder. More importantly, there is a large difference between the dielectric constant in the medium (close to 80 for H_2O) and inside the protein (in the range of 2 to 4). Since interactions of a test dipole with the layer facing it are through the medium only while those with the layer turned away from it also involve a large portion of the space filled with protein, there will be a non-zero result. For distances comparable to the MT diameter we have introduced an appropriate correction parameter γ which varies between 2 and 3 depending on the distance. We have used the dielectric constant of water for ε.

To get a sense of energies involved in the interaction between a polar molecule in solution and a microtubule a distance of 5 nm away, we consider a 5 μm microtubule whose tubulin dimers possess a dipole moment on the order of 2000 D each, the latter may include an additional contribution from a double layer of water and ions. Assume first that a macromolecule carrying a dipole moment of 200 D along the x axis is situated in the equatorial plane of the cylinder where $L_1 = L_0 = 0$. Using equation (4.8) we obtain the energy of the dipole-dipole interaction, in this case to be a disappointing 0.03 meV which is much less than the energy of thermal fluctuations. However, repeating this calculation for a fictitious tubulin dimer in solution whose 2000 D dipole moment is oriented along the y axis and which is located so that $L_1 = 1\,\mu$m above the plane, everything else remaining the same as before (with $\gamma = 3$), we find that the interaction energy is now just above 2 meV—a value smaller than room temperature thermal fluctuations. Clearly, this indicates a minimal role of the dipolar structure of microtubules in promoting orientational order. This effect may become significant, however, as the assembling molecule approaches the surface for docking both on account of short distances and the decreasing dielectric constant [19]. Notice that, it transpires from equation (4.8) that, the interaction with the z-component of the dipole (which is along the microtubule axis) is very small.

C. Charged Microtubule-Charged Microtubule Interaction

In this section, we consider the force of interaction between the charge distributions, assumed uniform, on two parallel microtubules. We assume there is a charge σ per unit area on each, and consider two elements of area $a\,d\theta\,dx$ and $a\,d\theta'\,dy$, respectively. The square of the distance between the elements (see Figure 14c) is given by $(x-y)^2 + D^2$ where $D^2 = (a\sin\theta - a\sin\theta')^2 + (d - a\cos\theta - a\cos\theta')^2$. The force, F_1, is given by

$$F_1 = \int_0^{2\pi}\int_0^{2\pi}\int_0^{L}\int_0^{L} \frac{\sigma^2 a^2}{4\pi\varepsilon_0\varepsilon\left[(x-y)^2+D^2\right]}\,dx\,dy\,d\theta\,d\theta'. \tag{4.9}$$

Assuming that $d^2 + (x-y)^2$ is very much greater than the other terms in the denominator of equation (4.9) we may expand and retain only leading terms in $\sin\theta, \cos\theta, \sin\theta'$, and $\cos\theta'$. When

integrated over θ and θ' these will vanish giving

$$F_1 \approx \int_0^L \int_0^L \frac{(2\pi)^2\sigma^2 a^2}{4\pi\varepsilon_0\varepsilon\left[(x-y)^2+d^2+2a^2\right]}\,dx\,dy. \tag{4.10}$$

We now change the variables from x, y to $z = x - y$ and $w = x + y$ with a Jacobian of $J = 1/2$. The integral part of equation (4.10), namely

$$I = \int_0^L \int_0^L \frac{dx\,dy}{(x-y)^2+d^2+2a^2}, \tag{4.11}$$

then becomes

$$I = \frac{1}{2}\int_0^L \int_{-w}^{w} \frac{dz\,dw}{z^2+d^2+2a^2} + \frac{1}{2}\int_L^{2L} \int_{w-2L}^{-w+2L} \frac{dz\,dw}{z^2+d^2+2a^2}. \tag{4.12}$$

The integrals in equation (4.12) then become elementary and therefore, F_1 is given by

$$F_1 \approx \frac{2\pi a^2\sigma^2}{\varepsilon_0\varepsilon}\left\{\frac{L}{\sqrt{d^2+2a^2}}\tan^{-1}\left(\frac{L}{\sqrt{d^2+2a^2}}\right) + \ln\left[\cos\left(\tan^{-1}\frac{L}{\sqrt{d^2+2a^2}}\right)\right]\right\}. \tag{4.13}$$

We have estimated this effect by using the same charge density as before and the length of each microtubule to be $5\,\mu$m. The distance between two neighboring microtubules cannot be less than 35 nm measuring it between the centres due to the repulsion between the C-termini. The force of repulsion in equation (4.13) for $d = 40$ nm in an aqueous environment is found to be staggering 0.2×10^6 pN. However, when Debye screening due to ions at a concentration of 150 nM is included the result is reduced to 9 pN. This is a significant number that may explain various ordering effects in microtubule bundles or asters.

D. Dipole-Dipole Interactions Between Two Microtubules

Consider the interaction between the dipole moment densities on two microtubules and suppose on each the dipole moment per unit area is σ_D. We consider an element on one microtubule with coordinates $(a\cos\theta, a\sin\theta, x)$ and an element at $(d + a\cos\theta', a\sin\theta', y)$ on the other. (The positioning of elements in space is the same as in Figure 14c.) Once again d is the distance between the axes of the microtubules which will be assumed parallel and a is their radius. The force between them becomes

$$F_2 = \int_0^L\int_0^L\int_0^{2\pi}\int_0^{2\pi} \frac{\sigma_D^2\left[\hat{n}_x\cdot\hat{n}_y - 3\left(\vec{n}\cdot\hat{n}_x\right)\left(\vec{n}\cdot\hat{n}_y\right)\right]d\theta'\,d\theta\,dy\,dx}{4\pi\varepsilon_0\varepsilon\gamma^2\left[(x-y)^2+\left(a\sin\theta-a\sin\theta'\right)^2+\left(d+a\cos\theta'-a\cos\theta\right)^2\right]^2}, \tag{4.14}$$

where $\vec{n}$ is a unit vector along the line joining the two elements and given by

$$\vec{n} = \frac{\left(d+a\cos\theta'-a\cos\theta\right)\hat{\imath}+\left(a\sin\theta'-a\sin\theta\right)\hat{\jmath}+(y-x)\hat{k}}{\left[\left(d+a\cos\theta'-a\cos\theta\right)^2+\left(a\sin\theta'-a\sin\theta\right)^2+(y-x)^2\right]^2}. \tag{4.15}$$

The unit vector $\hat{n}_x$ denotes the direction of the dipole moment on the element at $(a\cos\theta, a\sin\theta, x)$ so, that $\hat{n}_x = \cos\theta\hat{\imath} + \sin\theta\hat{\jmath}$.

The direction of the dipole moment on the element at $(d + a\cos\theta', a\sin\theta', y)$ is defined by the unit vector

$$\hat{n}_y = \frac{\left(d+a\cos\theta'\right)\hat{\imath}+a\sin\theta'\hat{\jmath}}{\sqrt{\left(d+a\cos\theta'\right)^2+\left(a\sin\theta'\right)^2}}. \tag{4.16}$$

Assuming that, the square in equation (4.14) may be expanded by factoring out $(x-y)^2+d^2+2a^2$, similarly in equation (4.15) and extracting d^2+a^2 in equation (4.16) we have linearized and retained leading terms as we did in Section 4c. This is done by first performing the angular integrals and then dropping all denominators which involve $(x-y)^2+d^2+2a^2$, d^2+a^2, and $[(x-y)^2+d^2+2a^2][d^2+a^2]$ which we assume are small. The net result is that the force, F_2, becomes

$$F_2 \approx \frac{a^2\sigma_D^2}{4\pi\varepsilon_0\varepsilon\gamma^2}\frac{-2ad^2\pi^2}{\sqrt{d^2+a^2}}\int_0^L dx\int_0^L \frac{dy}{\left((x-y)^2+2a^2+d^2\right)^3}. \tag{4.17}$$

The integrals now become tractable if we change variables again to $z=x-y$ and $w=x+y$. We find that, the resultant force is

$$\begin{aligned} F_2 \approx & \frac{a^3\sigma_D^2 d^2\pi}{\varepsilon_0\varepsilon\gamma^2\sqrt{d^2+a^2}\left(d^2+2a^2\right)^2} \\ & \times\left\{\frac{3}{8}\frac{L}{\sqrt{d^2+2a^2}}\tan^{-1}\left(\frac{L}{\sqrt{d^2+2a^2}}\right)+\frac{1}{8}\sin^2\left[\tan^{-1}\left(\frac{L}{\sqrt{d^2+2a^2}}\right)\right]\right\}. \end{aligned} \tag{4.18}$$

Taking as before the polarization density of 2000 D per dimer and a separation between microtubule centres to be 40 nm and using $L=5\,\mu$m as well as $\gamma=3$ results in the attractive force, F_2, between the two microtubules of 330 pN which is very significant. Moving the distance between microtubules to 90 nm (which is the mean separation between axonal microtubules) reduces the attraction force by a factor of 4000 to a mere 0.08 pN. It is also worth emphasizing that a combined action of monopole-monopole and dipole-dipole forces will have a competitive nature with Coulomb repulsion on short distances due to negative charges of the microtubular surfaces and an attractive dipole-dipole interaction that evidently extends over a larger range. Hence, it is expected that an equilibrium distance between neighboring microtubules may be established as a global energy minimum.

5. DISCUSSION AND CONCLUSION

In this paper, we have summarized our calculations regarding the net charges and dipole moments of tubulin and microtubules. These calculations were performed using an atomic resolution structure of tubulin in conjunction with molecular dynamics simulations. We found a large negative charge concentrated on the outer surface of the protein, almost half of which is located on flexible peptide tails attached to the outer face. This charge is undoubtedly instrumental in tubulin-tubulin interactions as well as the interactions of tubulin with motor proteins such as kinesin. Figure 15 shows the results of our force field calculations where two tubulin dimers are placed in each other's neighborhood and allowed to interact electrostatically. The brush strokes represent the direction of the Coulomb force of attraction.

We have also shown that, the microtubule structure, in particular the lateral binding between protofilaments, is consistent with the location of positive and negative segments of the electrostatic potential for optimal binding. It is worth mentioning that, a recent paper [20] showed the electrostatic surface of the whole microtubule following computations involving the Poisson-Boltzmann equation. From these calculations a dramatic difference between the plus and minus ends of a microtubule has been revealed. It is very likely that, this difference leads to the well-known difference is polymerization kinetics involving these two ends. In our paper, we have also considered the role of electrostatics in the interactions between microtubules and other charged or polarized molecules. In particular, in spite of Debye screening, a microtubule can exert a Coulomb force on a charged particle that is up to 5 nm away from its surface. The dipole-dipole forces that have been found are negligible for the most part. However, they can be felt by dipoles that are perpendicular to the microtubule surface and removed from the equatorial plane. When two microtubules are found in the same vicinity, they can exert significant forces of repulsion even

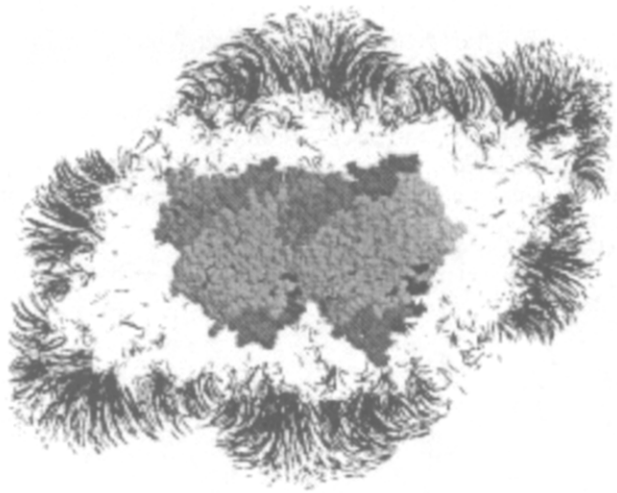

Figure 15. A view of the attractive regions about a tubulin dimer as would be experienced by another dimer. The smallest principal moment of inertia of the dimers is perpendicular the page, the middle one is aligned vertically, the largest principal moment horizontally. See, text for more details. Figure prepared using [11].

in the presence of ionic screening. Since the negatively charged C-termini protrude perpendicularly to the microtubule surface this effect is additionally increased and explains the existence of the so-called "zone of exclusion" [21].

In conclusion, our calculations demonstrate a significant role played by charge and dipole forces in both the formation of microtubules and their interactions with other proteins and possibly drug molecules. The latter observation may lead to a fruitful search for microtubule binding drugs such as derivatives of taxol. In addition, there has already been progress in understanding cell division by the inclusion of electrostatic interaction mechanisms as shown in a recent paper [22].

Abstract. Microtubules are cylindrically shaped cytoskeletal biopolymers that are essential for cell motility, cell division and intracellular trafficking. Here, we investigate their polyelectrolyte character that plays a very important role in ionic transport throughout the intra-cellular environment. The model we propose demonstrates an essentially nonlinear behavior of ionic currents which are guided by microtubules. These features are primarily due to the dynamics of tubulin C-terminal tails which are extended out of the surface of the microtubule cylinder. We also demonstrate that the origin of nonlinearity stems from the nonlinear capacitance of each tubulin dimer. This brings about conditions required for the creation and propagation of solitonic ionic waves along the microtubule axis. We conclude that a microtubule plays the role of a biological nonlinear transmission line for ionic currents. These currents might be of particular significance in cell division and possibly also in cognitive processes taking place in nerve cells.

1 Introduction

Microtubules (MTs) are major cytoskeletal protein polymers assembled from the protein called tubulin that plays a number of crucial biological roles in all eukaryotic cells [1]. The role of MTs in cell division has been extensively discussed in the cell biology literature. In this paper, we focus on the importance of MTs in the process of ionic current regulation within biological cells. Many years ago Matsumoto *et al.* [2] revealed that axoplasmic MTs and 260 K proteins in the structure underlying the axolema play a role in generating Na^+ currents in squid giant axons. Another seminar paper [3] considered the importance of Ca^{++} ionic currents in cell division and emphasized that MTs in the mitotic apparatus might be controlled by the local Ca^{++} concentration which should be tuned by nearby endoplasmic reticulum (ER). Spindle MTs appear to be very sensitive to Ca^{++} concentration increases in such a way that MT depolymerisation occurs when the concentration is raised above 1 μM. It was suggested that during anaphase Ca^{++} release from ER activates MT depolymerisation and this facilitates movement of chromosomes to the spindle poles [4]. Here, we postulate that localized Ca^{++} ionic currents along MTs serve as triggers for the onset of their depolymerisation. The synchronously regulated separation of sister chromatid pairs in mitotic spindles has been recently described by Matsson [5,6] using an elegant nonlinear theoretical model. We propose that the process of MT depolymerisation involved in cell division is finely orchestrated by Ca^{++} influx from ER which propagates along MTs as a nonlinear wave.

The structure of MTs is cylindrical and it typically involves 13 parallel protofilaments *in vivo*, see fig. 1. The building block of a MT is a tubulin dimer (TD) that contains approximately 900 amino acid residues comprising some 14000 atoms with a combined mass of 110 kDa (1 Da is the atomic unit of mass, 1 Da = 1.7×10^{-27} kg). The TD is made up of two structurally slightly different monomers called α and β tubulin, respectively. Each TD in the MT has a length of 8 nm along the MT cylinder axis, a width of about 6.5 nm and the radial dimension of 4.6 nm. The inner core of the cylinder, known as the lumen, is approximately 15 nm in diameter. The surface of MTs is mostly characterized by a so-called B-lattice structure [7], see fig. 2.

Between neighboring protofilaments there are two distinct types of nanopores (NP). NP-1, see fig. 2, left panel, is located where an inter-dimer β/α interface of one TD lies next to the inter-dimer β/α interface of the adjacent TD molecule. The so-called NP-2 arises where an intra-dimer interface of one dimer lies next to the intra-dimer interface of an adjacent TD of a neighboring protofilament, see fig. 2, right panel. Freedman *et al.* [8] used HOLE and AMBER programs to estimate the effective radius of the narrowest points within these NPs and found them to be 0.4 nm and 0.47 nm for type-1 and type-2 NPs, respectively.

The biological relevance of NPs in MT is still largely unknown. However, it has been experimentally determined

[a] e-mail: dalsek@yahoo.com

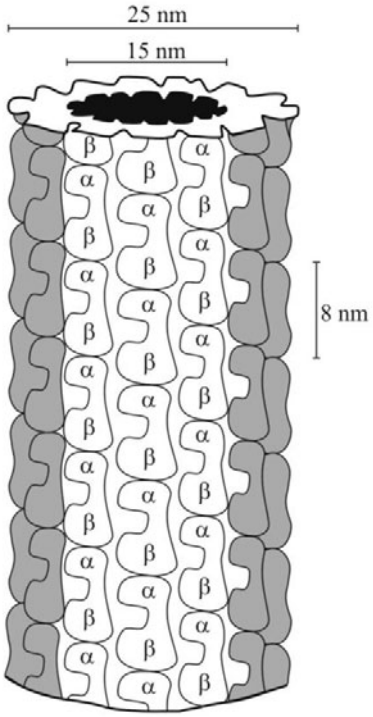

Fig. 1. A MT hollow cylinder of 13 parallel protofilaments with denoted characteristic dimensions: outer and inner diameters of 25 nm and 15 nm, respectively, and tubulin dimer length of 8 nm.

that the molecules of some chemotherapy drugs such as paclitaxel and epothilone diffuse through MT NPs to their corresponding binding sites mostly positioned in the lumen [9]. Thus, it can be safely assumed that these NPs, on the basis of their size, should be quite permeable to the counter-ions from the ionic clouds covering outer and inner sides of the MT wall. This paper will theoretically examine the role of these NPs in the regulation of ionic currents along MTs within the regime comparable to transmission lines used in electric engineering applications. We have earlier made preliminary attempts to evaluate MTs as nonlinear transmission lines. The first stage was a model which disregards the role of NPs but includes the nonlinear electric capacity of MTs [10]. The outcome of this model was the appearance of stable localized kink-like pulses of cations propagating along MTs. The next step was extended by the inclusion of NPs [11]. This approach was based on the simple conical geometry pattern of NPs considered earlier by the group of Eisenberg [12]. This preliminary description of NPs in our model has led to the emergence and propagation of ionic pulses analogous to the celebrated Korteveg de Vries (KdV) solitons and was arrived at using reasonable values of model parameters.

This paper is intended to develop a much more realistic model based on the sophisticated simulations performed by Freedman *et al.* [8]. We briefly state the main results of the simulations reported in [8] which are relevant for the model considered here. Based on the modified version of the Poisson-Boltzmann equation, the conductances of NPs are determined in terms of Brownian dynamics of ions. For the type-1 NP, inner and outer cationic conductances were calculated to be 2.93 nS and 1.22 nS, respectively, while for type-2 NP the respective values of 7.80 nS and 4.98 nS were found. Interestingly, it was demonstrated that both types of NPs are impermeable to anions whose respective conductances are 0.044 nS and 0.012 nS for type-1 and type-2 NPs. Freedman *et al.* [8] also explained in great detail how the constriction zones of NPs, due to the presence of negative ASP and THR residues, prevent the passage of more negative ions through the NPs. Similar asymmetric conductance has been found in various experiments involving ion channels, for example Omp F porin [13].

We now focus on the second, an even more important constituent of MTs in the context of the present model. Each tubulin monomer of the MT lattice has a short C-terminal alpha-helix H12 followed by a highly acidic amino acid sequence projecting out of the MT outer surface which is referred to as a tubulin tail (TT). Geometrically, these TTs are hair-like projections of 4–5 nm length, see fig. 3. Their approximate molecular masses are 5.5 kDa and 6.7 kDa for α and β tubulin, respectively. TTs are of great functional importance because they participate in the binding of proteins through which MT interact with many cellular structures such as motor proteins (kinesin and dynein) and a plethora of microtubule associated proteins (MAPs) [14]. Satarić and Tuszynski [15] developed a model of nonlinear waves created by tilting excitations of TTs emphasizing their possible role in the control of motor protein traffic along MTs. In α tubulin the TT consists of the last 10 residues in their sequence, while in β tubulin the corresponding TT is longer comprising 18 residues. The most common isotype of α tubulin has a TT with 5 Glu and 2 Asp residues, while its β counterpart has 9 Glu and 2 Asp residues. The negative charge on TTs is the reason why they are surrounded by a large number of cations required for overall charge neutrality. The important aspect of the aforementioned modeling [8] is the claim that TTs could contribute to ionic currents flowing along MTs by playing the role of small voltage generators (batteries). This claim is based on their larger time-scale thermal fluctuations which result in an oscillatory transfer of ions between the bulk solution and the cloud of counterions located near the MT surface. Here, we partly rely on the results of the simulations reported in [8] and partly on our earlier transmission line analysis [11], in order to elucidate the possible active role MTs play in ionic signaling throughout cytoskeletal networks.

The paper is organized as follows: In sect. 2 we explain the polyelectrolyte character of MTs. In sect. 3 we describe the basic elements of MTs as a biological nanoscale transmission line. In sect. 4 we analyze a nonlinear differential equation of the modified KdV type for the electric potential accompanying a localized ionic wave along an MT. Then, we solve and analyze the pertaining differential equation which exhibits the common features with spherical and cylindrical solitons arising in ion-acoustic waves in plasma. Section 5 provides conclusions stemming from the results of this paper.

2 The biophysical basis for the model

Extensive molecular dynamics simulations were performed on the TD structure and MTs [16,17]. Their results indicate the existence of a highly negatively charged solvent exposed surface of the TD with a net electric charge on the order of (20–25)e per monomer, depending on the isotype of tubulin considered. This net charge is distributed preferentially on the outer surface of the MT at an approximate charge ratio of 2:1 between the outer surface and the rest of the protein. Therefore, we conclude that MTs as highly charged polyelectrolytes are expected to attract a fraction of their surrounding counter-ions in the form of a condensed ionic cloud (IC) preferentially localized around the MT surface.

Manning's theory of polyelectrolyte solutions [18] states that ionic condensation occurs along the stretch of a charged polymer, if a sufficiently high linear electric charge density is present on the polymer's surface. On this basis, it can be concluded that the cylindrical sheath of depleted ions outside the ionic cloud surrounding the MT serves as an electrical shield. The "cable-like" behavior of such a structure can be supported by the protein polymer itself and the "condensed" counter-ions, which are physically "bound" to the polymer. The strength of this interaction has been estimated to be such that even under infinite dilution conditions, the counter-ions are still attached to the polymer and do not diffuse out from its vicinity. Although this theory was originally postulated for such polyelectrolytes as DNA, the same applies to highly charged quasi-one-dimensional, or cylindrical polymers such as actin filaments and MTs. These two cases were studied theoretically in more detail in other publications [8,10,19–22] and we adopt this approximation as valid for the case considered in our paper.

Moreover, experimental confirmation of the novel nonlinear amplification of ionic currents by MTs serves as support for this model [23]. Since our model is directly based on the ionic condensation effect around the MT cylinder, we first evaluate the effective charge density around the MT length. The Bjerrum length, denoted l_B, describes the distance beyond which thermal fluctuations are stronger than the electrostatic interactions between charges in solution whose dielectric constant is ε. Specifically, the following equation is satisfied:

$$\frac{e^2}{4\pi\varepsilon_0\varepsilon l_B} = k_B T; \quad \varepsilon_0 = 8.85 \times 10^{-12}\,\mathrm{F/m}. \tag{2.1}$$

At a physiological temperature ($T = 310\,\mathrm{K}$), taking the elementary charge as $e = 1.6 \times 10^{-19}\,\mathrm{C}$, Boltzmann's constant as $k_B = 1.38 \times 10^{-23}\,\mathrm{J/K}$ and the relative dielectric permittivity of the cytosol as $\varepsilon = 80$, one readily obtains

$$l_B = 0.67 \times 10^{-9}\,\mathrm{m} = 0.67\,\mathrm{nm}. \tag{2.2}$$

Accordingly, every MT should attract an IC of positive counter-ions close to its surface and along TTs, while negative ions of the cytosol are repelled away from the MT surface so that a roughly cylindrical ionic depletion area around TDs and TTs emerges. The thickness of such a depleted area is approximately equal to the Bjerrum length.

In addition, counter-ion condensation occurs when the mean distance between two charges, b, is such that

$$S = \frac{l_B}{b} > 1. \tag{2.3}$$

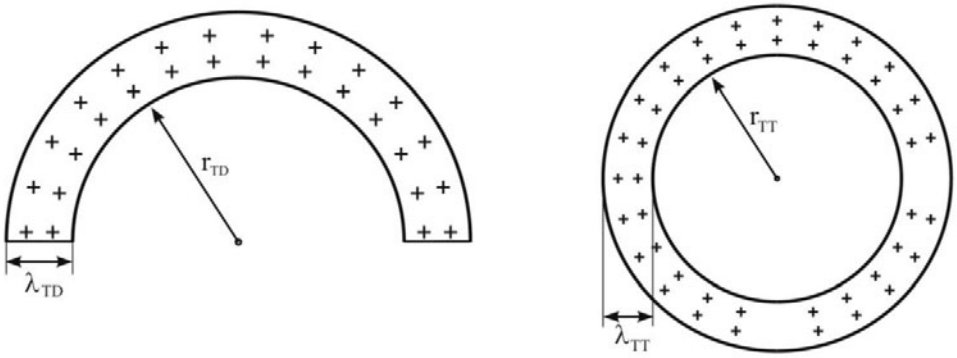

Fig. 4. Schematic representation of the counter-ion charge distributions surrounding a microtubule (left panel) and a C-terminal tail (right panel).

As a reasonable approximation we assume that each β tubulin monomer carries an excess of 24 negative charges in vacuum while each α tubulin monomer carries 22 charges. Moreover, some 30–40% of the net charge is located in areas of tubulin that are not solvent accessible. Therefore, we expect to have 15–18 exposed negative charges per TD, without counting the charges present on the protruding TTs. Since each dimmer is 8 nm long and 13 protofilaments form a MT, we readily find that there is a linear charge of (20–30)e/nm and a linear charge spacing of $b = (0.33\text{–}0.44) \times 10^{-10}$ m which gives S in the range between 16 and 21. As the effective charge q_{eff} is defined as the bare value of net charge divided by S, we estimate it to be $q_{\text{eff}} = (0.43\text{–}0.57)e$/monomer. This quantity has been indirectly measured in experimental assays where MTs were subjected to external electrical fields [23]. However, it should also be noted that this number represents a "far-field" value which could be overly high since it belies additional screening which is achieved by all ions attached to the MT but not all necessarily condensed on it. We conclude that in view of the experimental data, these estimates are acceptable for our continuum model calculations. For this type of model it is important to estimate the thickness of an IC of positive counter-ions around MTs and TTs. This is dictated by the geometry of the surface landscape and by its negative charge distribution.

The occurrence of Manning condensation around the polymer of radius r also depends on the fact that the salt concentration n in the cytosol should be low enough to satisfy the inequality [24]

$$l_{\text{Db}} \gg r, \tag{2.4}$$

where the Debye length l_{Db} is defined by

$$l_{\text{Db}}^{-1} = (8\pi n l_B)^{1/2}. \tag{2.5}$$

Since the radius of a TT is of the order of 0.5 nm and the radius of a TD is of the order of 2.5 nm, while the Debye length for the cytosol is of the order of 10 nm [25], we see that the condition in (2.4) holds for both radii. Thus, we are now able to reliably estimate the respective condensate thickness λ

$$\lambda = A(r l_{\text{Db}})^{1/2}; \quad A < 1, \tag{2.6}$$

where A depends only weakly on the Manning parameter q_0. Taking $A = 1/2$ one finds the corresponding values for the TD (λ_{TD}) and TT (λ_{TT}) as follows:

$$\lambda_{\text{TD}} = 2.5\,\text{nm}; \qquad \lambda_{\text{TT}} = 1.1\,\text{nm}. \tag{2.7}$$

These values will be used in our calculations of the corresponding capacity and resistivity, see fig. 4.

We expect that this IC which is shielded from the cytosol by a depleted layer is an analog of a coaxial cable used in electrical engineering applications, so MTs may effectively act as nonlinear inhomogeneous transmission lines capable of propagating nonlinear dispersive ionic waves within an IC. Independent corroboration of this idea can be found in experimental assays first performed for actin filaments [26] demonstrating that an IC current along a single filament exhibits localized wave patterns similar to solitons in nonlinear electric LC transmission lines. Recently, a similar experiment was conducted on single MTs providing evidence of the amplification of input electrical signals [23]. In our model of IC currents we only consider one of the 13 parallel currents associated with a single protofilament. The elementary unit of this "nanowire" is one tubulin dimer with adjacent NPs (type-1 and type-2) and two associated TTs (α and β). The shape of a tubulin dimer with extended α- and β-TTs is presented in fig. 3, including the charge distribution on its surface. At neutral pH values, the negative charge on each TT causes it to be extended away from the MT surface due to the electrostatic repulsion. When the negative charges of the amino acids within a TT are partly neutralized by counter-ions condensed around, it will cause TTs to contract by folding as shown in fig. 5.

As mentioned earlier, the differences in the structures of α- and β-TTs will cause them to fold differently so that the β-TT is expected to shrink to a greater extent. In addition to these electrostatically generated conformations of TTs, their tilting oscillations due to thermal fluctuations of the environment are also present. Quantitative features of this effect will be presented in the next section. These effects are accompanied by a change in the electrostatic capacity contributed by TTs which inevitably leads

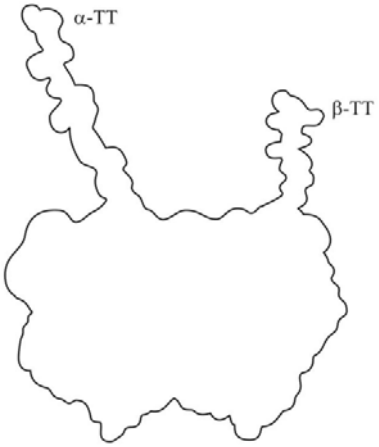

Fig. 5. The shape of TTs, where β-TT is shown to have shrunk due to the surrounding counter-ions, thus diminishing its electrostatic capacity.

to a slightly nonlinear overall capacity of every elementary unit of the ionic current along each filament.

3 The model parameters of an MT as an electric transmission line

Here, we proceed to estimate the electric parameters of an elementary unit of each MT protofilament (EUP). The essential assumption could be that an MT with a condensed IC is separated from the rest of the ions in the bulk solution by a depleted layer which plays the role of a dielectric medium located between the MT and the bulk cytosol. This IC is a conductive medium which dictates the electrical features of MTs. The depleted layer results in the IC and repelled anions playing the roles of "conductive plates" of a cylindrical capacitor. The ions injected from an appropriate cellular compartment are primarily confined to flow along an MT within its IC whose estimated thickness is $\lambda_{\rm TD} = 2.5\,{\rm nm}$.

For example, the opening of inositol (1, 4, 5) triphosphate (IP_3) receptors clustered at specific sites on the ER can lead to large-scale intracellular calcium waves [3,27]. By novel experimental techniques that permit the visualization of subcellular events it has become clear that Ca^{++} dynamics is a highly localized process with respect to these release events and also by the channelling of these waves along cytoskeletal filaments, primarily MTs. We have earlier proposed that such Ca^{++} waves could cause controlled MT depolymerisation during mitosis.

3.1 The capacitance of an EUP

In an earlier paper [10], a detailed Poisson-Boltzmann approach was used to evaluate the capacitance of an elementary ring of an MT which consists of 13 dimers. Here, we

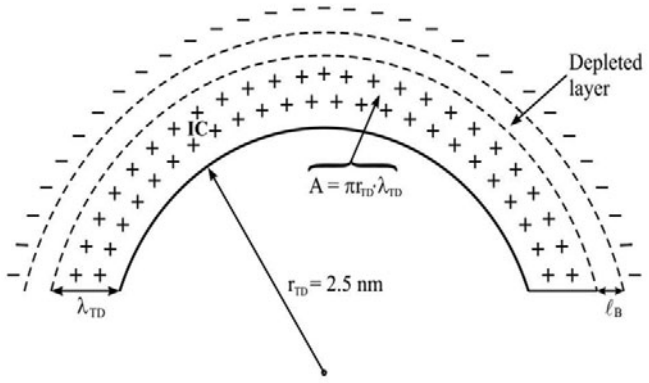

Fig. 6. Schematic illustration of the calculation of the MT capacitance.

adopt the same expression which reads

$$C_0 = \frac{2\pi\varepsilon_0\varepsilon l}{\ln\left(1+\frac{l_B}{R_{\rm IC}}\right)}\,, \tag{3.1}$$

where l stands for the length of a polymer unit and $R_{\rm IC} = r_{\rm TD} + \lambda_{\rm TT}$ for the outer radius of an IC. The other parameters have already been introduced.

We first estimate the EUP capacitance contributed by a TD, see fig. 6. With $l_{\rm TD} = 8\,{\rm nm}$ and $R_{\rm IC} = r_{\rm TD} + \lambda_{\rm TT} = 2.5\,{\rm nm} + 2.5\,{\rm nm} = 5\,{\rm nm}$, we find for TD (including only the outer surface)

$$C_{\rm TD} = \frac{3.14\times 80\times 8.85\times 10^{-12}\times 8\times 10^{-9}}{\ln\left(1+\frac{0.67}{5}\right)}\,{\rm F} = 1.4\times 10^{-16}\,{\rm F}. \tag{3.2}$$

Analogously, we can consider an extended TT as a smaller cylinder with the radius $r_{\rm TT} = 0.5\,{\rm nm}$ and the thickness of its IC equal to $\lambda_{\rm TT} = 1\,{\rm nm}$. Its extended effective length should be $l_{\rm TT}^{\rm eff} = 4.5\,{\rm nm} - 2.5\,{\rm nm} = 2\,{\rm nm}$, meaning that its part close to the tubulin surface is already embedded in the IC accounted for in (3.2). Thus we now estimate the corresponding capacitance as:

$$C_{\rm TT} = \frac{2\times 3.14\times 80\times 8.85\times 10^{-12}\times 2\times 10^{-9}}{\ln\left(1+\frac{0.67}{1.5}\right)}\,{\rm F} = 0.26\times 10^{-16}\,{\rm F}. \tag{3.3}$$

Accounting for the fact that two TTs are present in each tubulin dimer, we finally obtain

$$2\times C_{\rm TT} = 0.52\times 10^{-16}\,{\rm F}. \tag{3.4}$$

The two capacitance values above are considered to correspond to a parallel arrangement with respect to each other, so that the total maximal capacitance of an EUP is readily estimated as

$$C_0 = C_{\rm TD} + 2\times C_{\rm TT} = 1.92\times 10^{-16}\,{\rm F}. \tag{3.5}$$

We have earlier emphasized that TTs capacitance must change with an increasing concentration of condensed

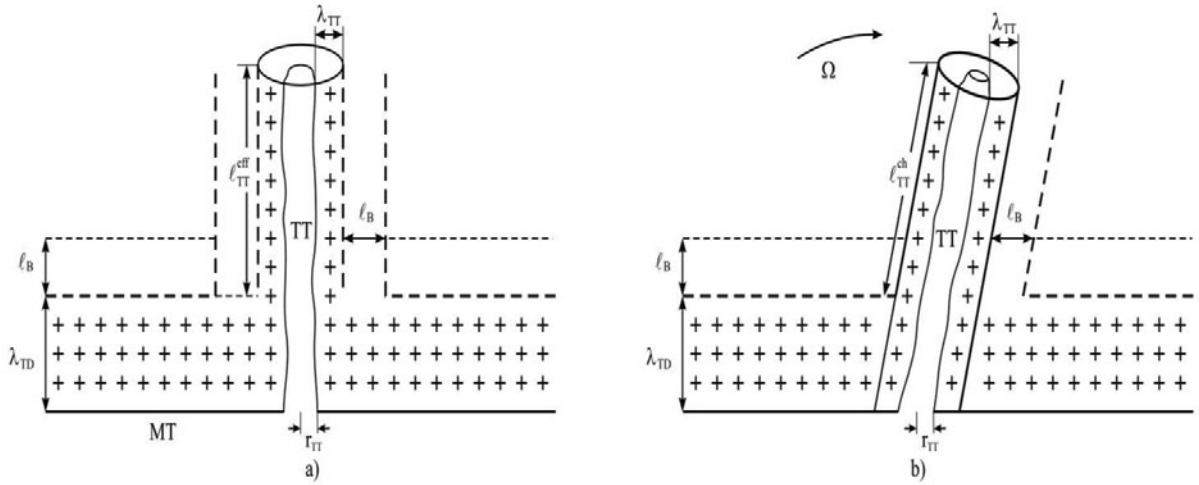

Fig. 7. A comparison between an extended TT (a) and a tilting TT due to oscillations (b).

cations due to the shrinking of flexible TTs. These changes are slightly different due to the different structures of α- and β-type TTs. To include this case we introduce the reduced factor of nonlinearity as follows:

$$b_0 = \frac{b_\alpha b_\beta}{b_\alpha + b_\beta}, \tag{3.6}$$

where b_α and b_β stand for the respective TTs. This implies that the charge of an EUP capacitor diminishes with an increased voltage in a nonlinear way $\Delta C_0 = C_0 b_0 v$, $b_0 v \ll 1$. Additionally, we account for the tilting movements of TTs under the combined action of thermal fluctuations [8] and a changing voltage due to an incoming ionic wave. Thus, the part of EUP capacitance contributed by TTs should also change by TTs tilt as shown in fig. 7. The change of the effective length $l_{\rm TT}^{\rm eff}$ of a TT is an additional factor affecting the capacitance $\Delta C_{\rm TT}$. We assume that this change can be adequately described by the oscillating function

$$\Delta l_{\rm TT}^{\rm eff} = l_{\rm TT}^{\rm eff} \sin[\Omega(t - t_0)] \cong l_{\rm TT}^{\rm eff} \Omega (t - t_0). \tag{3.7}$$

So that the capacitance changes linearly with a change in the effective TTs length $\Delta l_{\rm TT}^{\rm eff}$

$$\Delta C_{\rm TT} = C_0 \Gamma_0 \Omega (t - t_0), \tag{3.8}$$

where the frequency Ω is much lower than the inverse charging time of the EUP capacitor due to the strong viscous damping of the TT tilt, thus justifying the linearization of the above sine function in eq. (3.7). In some sense, this effect is similar in character to the thermal ratchet mechanism combined with an asymmetric ionic potential. Including the two aspects of TTs dynamics described above, the charge of EUP can be expressed as follows

$$Q = C_0[1 - \Gamma_0 \Omega (t - t_0) - b_0 v]v, \tag{3.9}$$

where Γ_0 is a dimensionless parameter.

In the earlier simplified version of the model of ionic currents along MT [10], a proof was given that the order of magnitude of magnetic inductance is so small that its role in these transmission lines can be safely ignored. We accept this statement in the present paper.

3.2 The resistance of an EUP

Regarding the Ohmic resistance, if we ignore ionic current leaks through the depleted layer, the dominant current flows in parallel with the MT axis charging EUP capacitors and partly leaking through NPs. The resistance attributed to this kind of ionic flow can be estimated on the basis of experimental evidence provided by the electro-orientation method performed on MTs *in vitro* [25]. Taking the reported measured value of MT ionic conductivity as

$$\sigma = (0.15 \pm 0.01)\,{\rm S\,m^{-1}}, \tag{3.10}$$

and adopting a simplifying assumption that the resistivity within an IC patch beyond an EUP is homogeneous, the resistance of an EUP with the length $l = 8\,{\rm nm}$ and the cross-sectional area $A = \pi r_{\rm DT} \lambda_{\rm DT} = 3.14 \times 2.5\,{\rm nm} \times 2.5\,{\rm nm} = 19.625\,{\rm nm^2}$, see fig. 6, is estimated as $R_0 = \frac{1}{\sigma}\frac{l}{A} = 2.7 \times 10^9\,\Omega$. This is obviously an extremely high value of resistance which is most likely an over-estimate.

We therefore prefer the computed resistance shown in table 3 of ref. [8], referred to as the outer sheath-outer sheath resistance for complete 13 protofilaments, namely $R_{13} = 4.75 \times 10^6\,\Omega$. The resistance for our EUP will be 13 times greater, *i.e.*

$$R_0 = 6.2 \times 10^7\,\Omega. \tag{3.11}$$

This value appears to be more consistent with the resistance of two NPs which follows from eq. (3.12).

Finally, we could include the conductance of both NPs to account for the leakage of IC cations into the lumen area. Thus we have

$$G_0 = \sigma_1 + \sigma_2 = (2.93 + 7.8)\,{\rm nS} = 10.7\,{\rm nS}; \quad \frac{1}{G_0} = 9.3 \times 10^7. \tag{3.12}$$

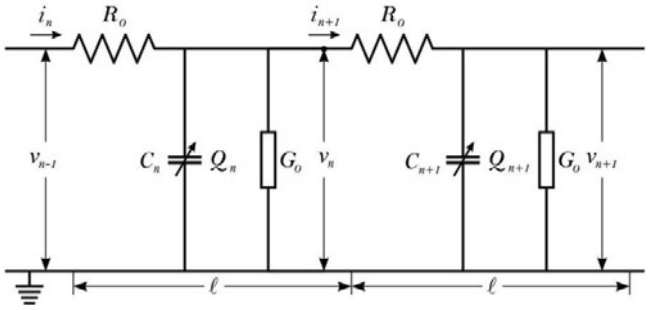

Fig. 8. An effective circuit diagram for the n-th ER with characteristic elements for Kirchhoff's laws.

It is expected that NPs exert greater resistance than the volume of IC around EUP. The above features of EUP electric parameters will lead to biophysical implications of our model. The next section develops the underlying equations governing the ionic flows along MTs.

4 The generalized model of an MT as a nonlinear transmission line

We now construct a simple periodic electric circuit simulating one protofilament of an MT. It consists of a long ladder network composed of a lumped section equal to identical EUPs as represented in fig. 8.

The longitudinal ionic current is represented by the series of resistors with Ohmic resistance R_0 for one EUP, as represented in (3.11). The nonlinear capacity with the charge Q_n for the n-th site of the ladder network is in parallel with the total conductance G_0 of the two TTs expressed by eq. (3.12). This is true if the bulk cytosol and MT lumen are considered to be grounded. This permits the application of Kirchhoff's law as

$$i_n - i_{n+1} = \frac{\partial Q_n}{\partial t} + G_0 v_n, \tag{4.1}$$

$$v_{n-1} - v_n = R_0 i_n. \tag{4.2}$$

Using eq. (3.9) and taking the time derivative results in a nonlinear form of the governing equation since

$$\frac{\partial Q}{\partial t} = C_0 \frac{\partial v_n}{\partial t} - C_0 \Gamma_0 \Omega v_n - C_0 \Gamma_0 \Omega (t - t_0) \frac{\partial v_n}{\partial t} - 2 b_0 C_0 v_n \frac{\partial v_v}{\partial t}. \tag{4.3}$$

Inserting eq. (4.3) into eq. (4.1) we arrive at the explicit system of equations describing the ionic current within IC, and an accompanying voltage

$$i_n - i_{n+1} = C_0 \frac{\partial v_n}{\partial t} - C_0 \Gamma_0 \Omega v_n - C_0 \Gamma_0 \Omega (t - t_0) \frac{\partial v_n}{\partial t} - 2 b_0 C_0 v_n \frac{\partial v_v}{\partial t} + G_0 v_n, \tag{4.4}$$

$$v_{n-1} - v_n = R_0 i_n. \tag{4.5}$$

The next step is to establish the auxiliary function $u(x,t)$ unifying the voltage and its accompanying ionic current as follows:

$$u_n = Z^{1/2} i_n = Z^{-1/2} v_n, \tag{4.6}$$

where the characteristic impedance of EUP is defined in the usual way as

$$Z = \frac{1}{\omega C_0}. \tag{4.7}$$

Since the discrete voltage v_n as well as the associated current i_n change gradually from an EUP to its neighbors, we can safely justify the expansion of u_n in a continuum approximation using a Taylor series with respect to a small spatial parameter l ($l = 8\,\mathrm{nm}$ is the length of an EUP). Then using the travelling-wave form of the function $u(x,t)$ with dimensionless space and time variables (ξ, τ), we eventually get the following inhomogeneous nonlinear partial differential equation (for details see appendix B):

$$\left(\frac{ZC_0 s}{T_0} - 2\right) \frac{\partial u}{\partial \tau} + \frac{1}{3} \frac{\partial^3 u}{\partial \xi^3} + ZC_0 \Gamma_0 \Omega (\xi - \xi_0) \frac{\partial u}{\partial \xi} + 2 \frac{Z^{3/2} b_0 C_0 s}{T_0} u \frac{\partial u}{\partial \xi} + (ZG_0 + Z^{-1} R_0 - ZC_0 \Gamma_0 \Omega) u = 0. \tag{4.8}$$

Here, the characteristic charging (discharging) time of an EUP capacitor C_0 through the resistance R_0, $T_0 = R_0 C_0$, on the basis of eqs. (3.5) and (3.11) yields the value

$$T_0 = 6.2 \times 10^7\,\Omega \times 1.92 \times 10^{-16}\,\mathrm{F} = 1.2 \times 10^{-8}\,\mathrm{s}. \tag{4.9}$$

The characteristic propagation velocity of the ionic wave is defined as follows:

$$v_0 = \frac{8 \times 10^{-9}\,\mathrm{m}}{1.2 \times 10^{-8}\,\mathrm{s}} = 0.67 \frac{\mathrm{m}}{\mathrm{s}}. \tag{4.10}$$

The dimensionless speed, space and time variables are chosen to be, respectively,

$$s = \frac{v}{v_0} \leq 1; \quad \xi = \frac{x}{l} - \tau; \quad \tau = s \frac{t}{T_0}. \tag{4.11}$$

Imposing that the condition

$$\frac{ZC_0 s}{T_0} > 2 \tag{4.12}$$

holds, we then estimate the characteristic impedance of EUP as

$$Z > \frac{2R_0}{s} \quad \text{or} \quad Z > 1.24 \times 10^8\,\Omega \quad \text{for} \quad s = 1. \tag{4.13}$$

For $s = 1$ one obtains the cutoff frequency

$$\omega_{\max} = 4.3 \times 10^7\,\mathrm{s}^{-1} \qquad \text{or} \qquad \nu_{\max} = 6.8 \times 10^6\,\mathrm{Hz}. \tag{4.14}$$

This indicates that the characteristic frequency matches the order of magnitude of frequency Ω which describes

$$W(\xi,\tau)=\frac{u_0}{\cosh^2\left\{\left[\frac{\alpha u_0}{4\beta}\exp(-2\gamma_0\tau)\right]^{1/2}\left[\xi-\xi_0\left(1-\exp(\gamma_0\tau)\right)+\frac{\alpha u_0}{3\beta}\left(1-\exp(3\gamma_0\tau)\right)\exp(-2\gamma_0\tau)\right]\right\}}, \tag{4.28}$$

$$u(\xi,\tau)=\frac{u_0\exp(-2\gamma_0\tau)}{\cosh^2\left\{\left[\frac{\alpha u_0}{4\beta}\exp(-2\gamma_0\tau)\right]^{1/2}\left[\xi-\xi_0\left(1-\exp(\gamma_0\tau)\right)+\frac{\alpha u_0}{3\beta}\left(1-\exp(3\gamma_0\tau)\right)\exp(-2\gamma_0\tau)\right]\right\}}. \tag{4.29}$$

the TTs oscillations. We now establish the compact form of eq. (4.8) as

$$\frac{\partial u}{\partial\tau}+\beta\frac{\partial^3 u}{\partial\xi^3}+\alpha u\frac{\partial u}{\partial\xi}+\gamma(\xi)\frac{\partial u}{\partial\xi}+\delta u=0, \tag{4.15}$$

where the abbreviations were introduced as follows:

$$\left.\begin{aligned}
&\alpha=\frac{2Z^{3/2}b_0C_0s}{T_0\left(\frac{ZC_0s}{T_0}-2\right)};\quad \beta=\frac{1}{3\left(\frac{ZC_0s}{T_0}-2\right)};\\
&\delta=\frac{ZG_0+Z^{-1}R_0-ZC_0\Gamma_0\Omega}{\left(\frac{ZC_0s}{T_0}-2\right)};\\
&\gamma(\xi)=\frac{ZC_0\Gamma_0\Omega(\xi-\xi_0)}{\left(\frac{ZC_0s}{T_0}-2\right)}=\gamma_0(\xi-\xi_0);\\
&\gamma_0=\frac{ZC_0\Gamma_0\Omega}{\left(\frac{ZC_0s}{T_0}-2\right)}.
\end{aligned}\right\} \tag{4.16}$$

We can further perform the following transformation of space-time variables $(\xi,\tau)\to(\rho,\theta)$:

$$\left.\begin{aligned}
&\rho(\xi,\tau)=(\xi-\xi_0)\exp(-\gamma_0\tau),\\
&\theta(\tau)=-\frac{1}{3\gamma_0}\exp(-3\gamma_0\tau),\\
&u(\xi,\tau)=W(\rho,\theta)\exp(-2\gamma_0\tau),
\end{aligned}\right\} \tag{4.17}$$

so that eq. (4.15) takes the simplified form

$$\frac{\partial W}{\partial\theta}+\alpha W\frac{\partial W}{\partial\rho}+\beta\frac{\partial^3 W}{\partial\rho^3}+\frac{\kappa}{\theta}W=0, \tag{4.18}$$

where the new parameter κ reads

$$\kappa=\frac{2}{3}-\frac{\delta}{3\gamma_0}. \tag{4.19}$$

If we assume that the Ohmic losses in this circuit are balanced by the "thermal ratchet" action of TTs, then the last term in eq. (4.15) vanishes so that

$$\frac{2}{3}-\frac{\delta}{3\gamma_0}=0;\quad \delta=2\gamma_0. \tag{4.20}$$

This gives the following condition:

$$ZG_0+Z^{-1}R_0=3ZC_0\Gamma_0\Omega;\quad Z=\frac{1}{\omega C_0}. \tag{4.21}$$

Furthermore, if we impose the simple condition

$$\left(\frac{ZC_0s}{T_0}-2\right)=1,\quad \text{with}\quad s=1,$$

we then obtain the values

$$Z=1.87\times10^8\,\Omega\quad\text{and}\quad\omega=2.7\times10^7\,\mathrm{s}^{-1}. \tag{4.22}$$

Subsequently, equating $\omega=\Omega=2.7\times10^7\,\mathrm{s}^{-1}$ we estimate the parameter Γ_0 directly from eq. (4.21) as

$$\Gamma_0=\frac{G_0}{3C_0\omega}+\frac{C_0R_0\omega}{3}=0.07+0.11=0.18. \tag{4.23}$$

Eventually, the spatial inhomogenity parameter is found to be

$$\Gamma_0\,\Omega=4.8\times10^6\,\mathrm{s}^{-1}, \tag{4.24}$$

which is one order of magnitude smaller than the inverse characteristic time $T_0^{-1}=1.83\times10^7\,\mathrm{s}^{-1}$, thus justifying eq. (3.7). In such a case ($\kappa=0$), eq. (4.18) reduces to the modified nonlinear KdV equation with spatial inhomogeneity which exhibits a single bell-shaped soliton solution subjected to the distortion due to the Ohmic dissipation. In reality, the condition in eq. (4.20) seems to be reasonably met. Otherwise, if $\kappa=1$ or $\kappa=2$, eq. (4.18) reduces to a nonlinear spherical (cylindrical) KdV equation which has already been derived in the context of ionic-acoustic plasma waves [28,29]. In general, by introducing the new transformation [30]

$$F=W\exp\left(\sigma\int\frac{\mathrm{d}\theta}{\theta}\right), \tag{4.25}$$

and substituting to eq. (4.18) we obtain

$$\frac{\partial F}{\partial\theta}=\Lambda(\theta)\cdot F\frac{\partial F}{\partial\xi}+\beta\frac{\partial^3 F}{\partial\xi^3}=0, \tag{4.26}$$

where the new function $\Lambda(\theta)$ reads

$$\Lambda(\theta)=\alpha\exp\left(-\alpha\int\frac{\mathrm{d}\theta}{\theta}\right). \tag{4.27}$$

The solution of (4.18) with $\kappa=0$ is expressed as

see equation (4.28) *above*

so that the function $u(\xi,\tau)$ has the form

see equation (4.29) *above*

If we use the set of estimated and chosen parameters in eqs. (3.5), (3.11), (3.12), (4.21) and (4.24), we readily see that all dimensionless parameters (4.16) lie between zero and one ($\beta = 0.33$, $\gamma_0 = 0.17$, $\delta = 0.34$) staying within the same order of magnitude. This suggests that we should inspect numerically the behavior of the solution of eq. (4.29) when the parameters α, β, γ_0, ξ_0 take slightly different values which is done next.

Analyzing the set of plots in fig. 9 we can see the competition between nonlinearity α and the dispersion β, as well as the role of inhomogenity γ_0. In the case represented in fig. 9b we have balanced all parameters. The soliton solution preserves its width but its amplitude decays rather rapidly so that over the length of about $500l$ it becomes negligible. The above view shows the deceleration of the soliton solution along its path. Figure 9c shows the case with increased nonlinearity ($\alpha = 0.5$). It is remarkable that it exhibits not only a higher localization but also a slower decay of its amplitude. The advantage of this case lies in the fact that the velocity of the soliton solution decreases very slightly. We estimate its average velocity as follows:

$$\Delta x \approx 400l = 400 \times 8\,\mathrm{nm} = 3.2\,\mu\mathrm{m},$$
$$\Delta t = 1000T_0 = 10^3 \times 1.2 \times 10^{-8}\,\mathrm{s} = 1.2 \times 10^{-5}\,\mathrm{s},$$
$$v = \frac{\Delta x}{\Delta t} = 0.26\frac{\mathrm{m}}{\mathrm{s}}\,.$$

The range of this soliton is $3.2\,\mu$m which is of the order of the cell's diameter. Therefore, it appears that the ionic pulse with such parameter values could be efficiently transferred within the cell.

5 Conclusions and discussion

In this paper we have developed a nonlinear model of ionic currents along MTs in the context of the polyelectrolyte character of these cytoskeletal filaments. We have taken into account the role of two aspects of this cylindrical biopolymer, its NPs and very sensitive TTs. Both of them are responsible for the nonlinear character of the overall electrical capacitance of MTs. Segmenting an MT into identical EUPs and estimating the values of corresponding electrical parameters, we were able to establish the difference equations of lumped EUP sections, eq. (4.1) and eq. (4.2). On the basis of a gradual change of voltage along MT protofilaments we imposed a continuum approximation limit leading to the nonlinear KdV type equation in (4.15) with dissipative and inhomogeneity terms, δ and $\gamma(\xi)$, eq. (4.16). This sort of equation was derived earlier within non-uniform plasma applications where ion acoustic solitons were identified, both in the cases of cylindrical and spherical geometry.

Our solution, eq. (4.29), was analysed numerically for the set of parameters in fig. 9. It is apparent that the solitonic wave loses its energy due to Ohmic resistance but it preserves the stable localised form. In the case presented in fig. 9c with an increased nonlinearity parameter, the solitonic pulse exhibits greater robustness and it progresses with an almost constant velocity and only a slight decay of its initial amplitude. This demonstrates the role of flexible TTs which could be of decisive importance for the stable localized character of ionic pulses along MTs. Interestingly, TTs are the structural elements of tubulin with the greatest diversity across cells and biological species which could be of functional significance. Moreover, it was earlier shown that MTs posses ferroelectric properties creating an intrinsic electric field [31]. It is expected that this intrinsic electric field within an MT provides the necessary electrostatic energy which may compensate for the losses due to viscosity and thus enable the near lossles propagation of solitonic pulses over long distances along MTs.

We expect that this type of localized ionic waves could play a fundamental role in many cellular processes. First the process of cell division, in the context described by Hepler [3,4], needs the synchronized depolymerisation of MTs. This can be caused by the localized Ca^{++} waves described by our model which could reach MT plus ends and trigger the onset of massive detachment of TDs from MT tips [32]. If this process were to be based on pure diffusion of Ca^{++} ions through the bulk cytosol, the resulting depolymerisation would be prone to frequent mistakes making this process very unreliable which known not to be the case.

In a very interesting paper Duke [33] explained that in hair bundles (kinocilium) in the inner ear consisting of MT doublets, the myosin motor-driven oscillation are controlled by Ca^{++} ions directed from ion channels along MTs. These ions cause a fraction of myosin motors to detach and thus tune the oscillations of kinocilium as reaction to a corresponding acoustic signal. This mechanism can also be seen in the context of localized Ca^{++} waves described in the present paper.

Finally, the experimental work of Priel *et al.* [23] demonstrated that the electrical signal amplification resulting from the presence of MTs can be directly attributed to nonlinear ionic currents guided by MTs in close similarity to the framework developed by our present model. In fact, these measurements inspired the authors to consider the role MTs can play as bio-transistors taking part in cognitive processes which is another interesting application of nonlinear ionic conductance of MTs.

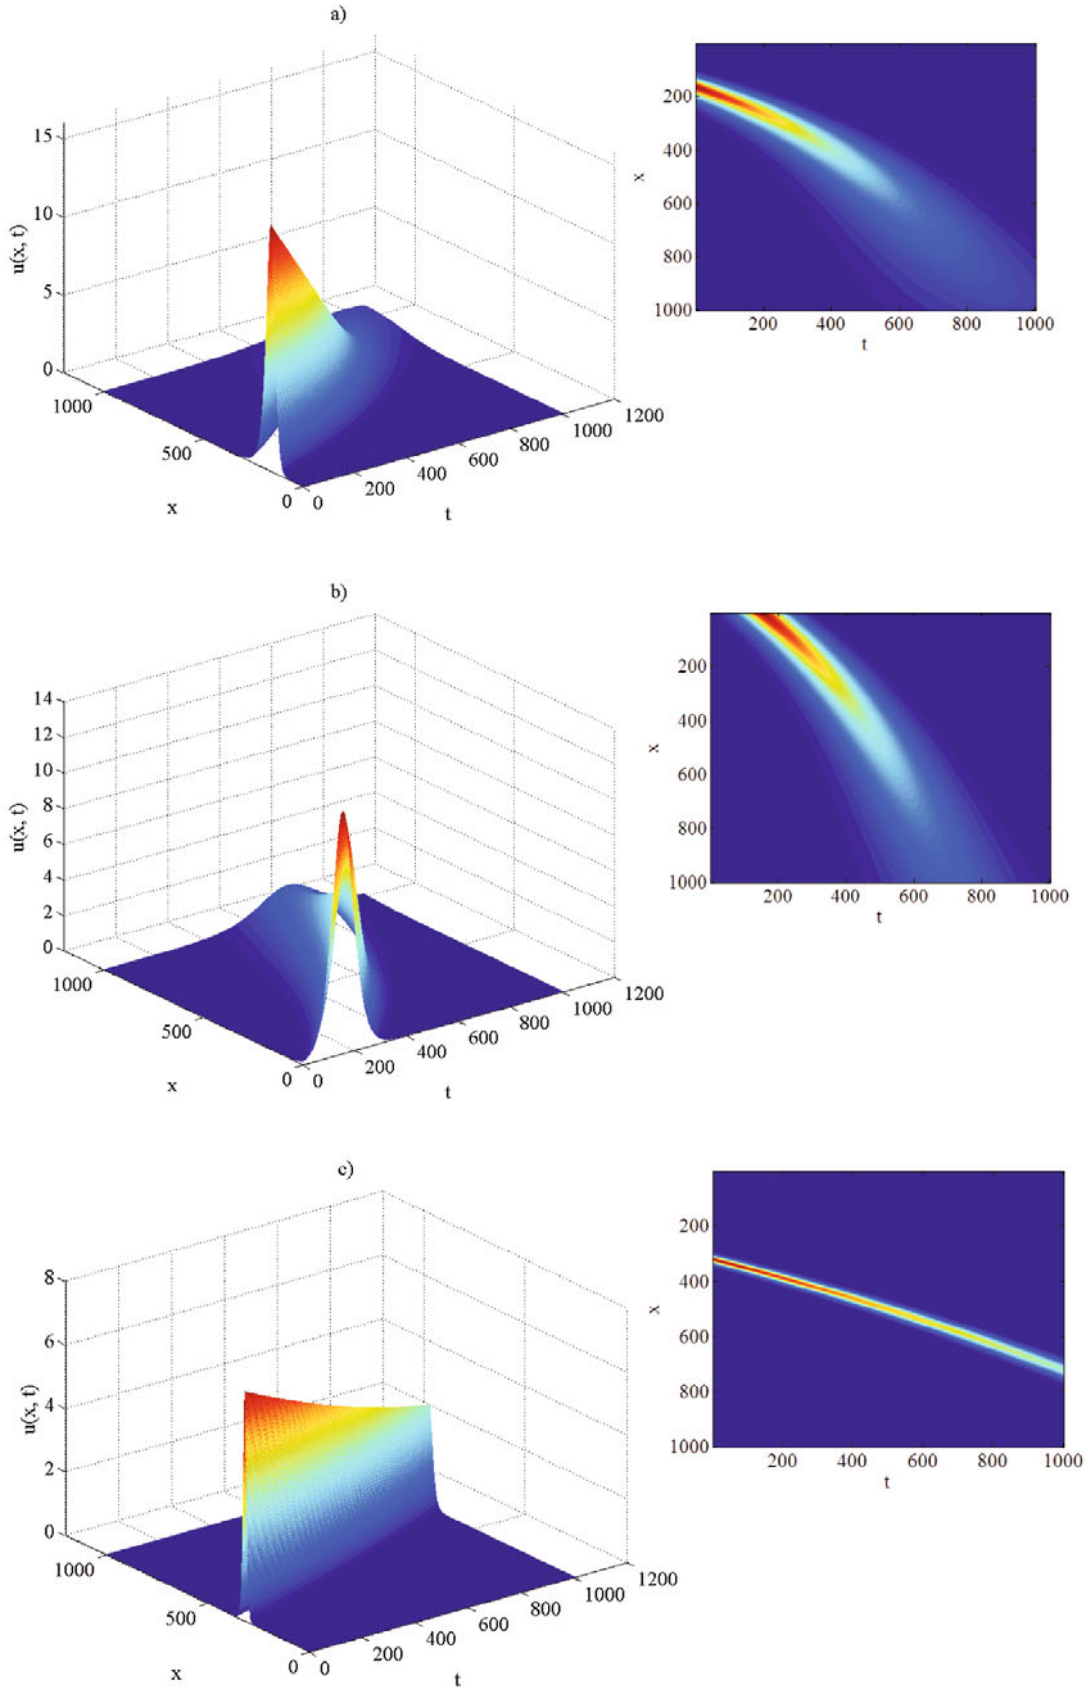

Fig. 9. Numerical solutions of $u(\xi, \tau)$ for: a) $\alpha = 0.2$; $\gamma_0 = 0.17$; $\beta = 0.33$; $\xi_0 = 0.1$. b) $\alpha = 0.1$; $\gamma_0 = 0.1$; $\beta = 0.1$; $\xi_0 = 0.1$. c) $\alpha = 0.5$; $\gamma_0 = 0.1$; $\beta = 0.1$; $\xi_0 = 0.1$.

Appendix B.

Using a Taylor series as follows:

$$u_{n\pm1} = u \pm l\frac{\partial u}{\partial x} + \frac{l^2}{2!}\frac{\partial^2 u}{\partial x^2} \pm \frac{l^3}{3!}\frac{\partial^3 u}{\partial x^3} + \frac{l^4}{4!}\frac{\partial^4 u}{\partial x^4} \pm \frac{l^5}{5!}\frac{\partial^5 u}{\partial x^5} + \ldots, \tag{B.1}$$

and applying on eqs. (4.4) and (4.5) this system now reads

$$-\frac{\partial u}{\partial x} - \frac{l}{2}\frac{\partial^2 u}{\partial x^2} - \frac{l^2}{6}\frac{\partial^3 u}{\partial x^3} - \frac{l^3}{24}\frac{\partial^4 u}{\partial x^4} - \frac{l^4}{120}\frac{\partial^5 u}{\partial x^5} - \frac{ZG_0}{l}u - \frac{ZC_0}{l}\frac{\partial u}{\partial t} + \frac{ZC_0\Gamma_0\Omega}{l}u + \frac{ZC_0\Gamma_0\Omega}{l}(t-t_0)\frac{\partial u}{\partial t} + 2\frac{Z^{3/2}b_0C_0}{l}u\frac{\partial u}{\partial t} = 0, \tag{B.2}$$

$$-\frac{\partial u}{\partial x} + \frac{l}{2}\frac{\partial^2 u}{\partial x^2} - \frac{l^2}{6}\frac{\partial^3 u}{\partial x^3} + \frac{l^3}{24}\frac{\partial^4 u}{\partial x^4} - \frac{l^4}{120}\frac{\partial^5 u}{\partial x^5} - \frac{Z^{-1}R_0}{l}u = 0. \tag{B.3}$$

Adding up the last two equations and retaining the terms up to the order of the third derivative, due to smallness of l^4, we obtain

$$-2\frac{\partial u}{\partial x} - \frac{l^2}{3}\frac{\partial^3 u}{\partial x^3} - \frac{ZC_0}{l}\frac{\partial u}{\partial t} + \frac{ZC_0\Gamma_0\Omega}{l}(t-t_0)\frac{\partial u}{\partial t} + 2\frac{Z^{3/2}b_0C_0}{l}u\frac{\partial u}{\partial t} - \frac{1}{l}(ZG_0 + Z^{-1}R_0 - ZC_0\Gamma_0\Omega)u = 0. \tag{B.4}$$

Then the standard travelling wave with speed v, for the unified function $u(x,t)$, can be employed as follows:

$$\left.\begin{aligned} &u(x,t) = u\left(\frac{x}{l} - v\frac{t}{l}\right) = u\left(\frac{x}{l} - \frac{v}{v_0}v_0\frac{t}{l}\right) = \\ &u\left(\frac{x}{l} - s\frac{t}{T_0}\right) = u(\xi), \\ &\xi = \frac{x}{l} - \tau; \quad \tau = s\frac{t}{T_0}; \quad v_0 = \frac{l}{T_0}; \quad s = \frac{v}{v_0}. \end{aligned}\right\} \tag{B.5}$$

In that respect, the set of the following transformations holds:

$$\frac{\partial u}{\partial x} = \frac{1}{l}\frac{\partial u}{\partial \xi}; \quad \frac{\partial^3 u}{\partial x^3} = \frac{1}{l^3}\frac{\partial^3 u}{\partial \xi^3}; \quad \frac{\partial u}{\partial t} = \frac{s}{T_0}\frac{\partial u}{\partial \tau} = -\frac{s}{T_0}\frac{\partial u}{\partial \xi}. \tag{B.6}$$

Using the transformations given by eqs. (B.5) and (B.6) and retaining the first derivatives of τ and going over to space derivatives of ξ in the inhomogeneous (fourth) term and nonlinear (fifth) term of eq. (B.4), we readily find

$$\left(\frac{ZC_0 s}{T_0} - 2\right)\frac{\partial u}{\partial \tau} + \frac{1}{3}\frac{\partial^3 u}{\partial \xi^3} + ZC_0\Gamma_0\Omega(\xi - \xi_0)\frac{\partial u}{\partial \xi} + 2\frac{Z^{3/2}b_0C_0 s}{T_0}u\frac{\partial u}{\partial \xi} + \left(ZG_0 + Z^{-1}R_0 - ZC_0\Gamma_0\Omega\right)u = 0. \tag{B.7}$$

Received 5 September 1997

We discuss possible quantum mechanical aspects of MicroTubules (MT), based on recent developments in quantum physics. We focus on potential mechanisms for "energy-loss-free" transport along the microtubules, which could be considered as realizations of Fröhlich's ideas on the rôle of solitons for superconductivity and/or biological matter. In particular, by representing the MT arrangements as *cavities*, we present a novel scenario on the formation of macroscopic (or mesoscopic) quantum-coherent states, as a result of the (quantum-electromagnetic) interactions of the MT dimers with the surrounding molecules of the ordered water in the interior of the MT cylinders. Such states decohere due to dissipation through the walls of the MT. Transfer of energy without dissipation, due to such coherent modes, could occur only if the decoherence time is larger than the average time scale required for energy transfer across the cells. We present some generic order of magnitude estimates of the decoherence time in a typical model for MT dynamics. Our conclusion is that the quantum coherent states play a rôle in energy transfer if the dissipation through the walls of the MT cavities is fairly suppressed, corresponding to damping time scales $T_r \geq 10^{-4}$–10^{-5} sec, for moderately large MT networks. We suggest specific experiments to test the above-conjectured quantum nature of the microtubular arrangements inside the cell. These experiments are similar in nature to those in atomic physics, used in the detection of the Rabi-Vacuum coupling between coherent cavity modes and atoms. Our conjecture is that a similar Rabi-Vacuum-splitting phenomenon occurs in the absorption (or emission) spectra of the MT dimers, which would constitute a manifestation of the dimer coupling with the coherent modes in the ordered-water environment (dipole quanta), which emerge due to "super-radiance".

1. Introduction

MicroTubules (MT) appear to be one of the most fundamental structures of the interior of living cells.[1] These are paracrystalline cytoskeletal structures which seem to play a fundamental rôle for the cell *mitosis*. It is also believed that they play an important rôle for the transfer of electric signals and, more general, of energy in the cell.

In this latter respect it should be mentioned that energy transfer across the cells, without dissipation, had been conjectured to occur in biological matter by Fröhlich,[2] already some time ago. The phenomenon conjectured by Fröhlich was based on his one-dimensional superconductivity model: in one dimensional electron systems with holes, the formation of solitonic structures due to electron–hole pairing results in the transfer of electric current without dissipation. In a similar manner, Fröhlich conjectured that energy in biological matter could be transfered without dissipation, if appropriate solitonic structures are formed inside the cells. This idea has lead theorists to construct various models for the energy transfer across the cell, based on the formation of kink classical solutions.[3]

In the early works no specific microscopic models had been considered.[3] Recently, however, after the identification of the MT as one of the most important structures of the cell, both functionally and structurally, a model for their dynamics has been presented in Ref. 4, in which the formation of solitonic structures, and their rôle in energy transfer across the MT, is discussed in terms of classical physics. In Ref. 5 we have considered the *quantum aspects* of this one-dimensional model, and argued on the consistent quantization of the soliton solutions, as well as the fact that such semiclassical solutions may emerge as a result of "decoherence" due to environmental entanglement, according to recent ideas.[6]

The basic assumption of the model used in Ref. 5 was that the fundamental structures in the MT (more specifically of the brain MT) are Ising spin chains (one-space-dimensional structures). The interaction of each chain with the neighboring chains and the surrounding water environment had been mimicked by suitable potential terms in the one-dimensional Hamiltonian. The model describing the dynamics of such one-dimensional sub-structures was the ferroelectric distortive spin chain model of Ref. 4.

The one-dimensional nature of these fundamental building blocks, then, opens up the way for a mathematical formulation of the chain as a *completely intergrable* field theory model, characterized by an infinite-number of conservation laws. The latter are associated with global excitation modes, completely *delocalised* in the chain space-time. This integrability structure proves sufficient in providing a satisfactory solution to memory coding and capacity.[5] Such features might turn out to be important for a model of the brain as a *quantum computer*.

This formulation allowed the authors of Ref. 5 to employ the so-called Liouville (noncritical) string theory approach to decoherence,[7] which is a formalism to treat such completely integrable spin systems embedded in a "two-dimensional quantum

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

gravity environment". At this point we should stress that such an environment does not *necessarily* represent realistic space-time effects. As stressed in Ref. 5, an external stimulus may distort the neighboring space-time of the unpaired spins of the MT dimers, and such a distortion may be *effectively* described by a two-dimensional "metric" in the Liouville picture of MT,[5] which should not be necessarily identified with a relatistic four dimensional space time metric.[a]

The coupling of the MT chain with its "environment" may lead, according to the analysis of Ref. 5, to the formation of *macroscopic quantum coherent solitonic* states. Then, the details of the environment would play a crucial rôle in determining the time scales over which such coherent states could be sustained *before collapsing to classical ground states.*

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

Such analyses have yield important results in the past,[6,10–12] concerning the passage from the quantum to classical world. In particular, in Ref. 6 it was suggested that quantum coherent states may appear as a result of decoherence, depending on the nature of the environment.[13] Such states are minimum entropy/uncertainty states, which propagate "almost classically" in time, in the sense that their shape is retained during evolution. Such "almost classical" states are termed "pointer states" by Zurek.[6] In view of the results of Ref. 12, concerning the localization of the wave function in open (stochastic) quantum-mechanical systems, the emergence of pointer states, as a result of decoherence, may be interpreted as implying that the localization process of the state vector had stopped at a stage where it is not complete, but is such that the resulting (minimum-entropy) state is least susceptible to the effects of the environment.

Not all environments admit such pointer states.[13] Here lies one of the advantages of viewing the MT system of chains as a completely integrable Liouville-string theory. The model possesses a pointer basis,[14] which in Ref. 5 has been identified with the quantized (via squeezed-coherent states) soliton solutions of Ref. 4. Another advantage lies on the fact that energy is *conserved* on the average in the model, despite the environmental entanglement. This is for purely stringy reasons pertaining to the Liouville approach. The reader may find details in Ref. 7. Physically this means that such a formalism is capable of describing *energy-loss-free* transport in biological cells, thereby providing a realization of Fröhlich's ideas.[2]

In this article we focus our attention on the *microscopic nature* of such coherent states, and try to understand their emergence by as much "conventional" physics arguments as possible. By "conventional" we mean scenaria based on *quantum electrodynamics*, which are the major interactions expected to dominate at the energy

[a]It is however, possible, that such a distortion involves a sufficient movement of mass so as to create a virtual microscopic singularity in the surrounding space time[8,9,5]; this could then cause collapse of the macroscopic quantum state, leading to *conscious perception.* Such daring assumptions/conjectures have gain some support by the fact that in certain physical models of MT dynamics[5] the estimated time of collapse is of order $\mathcal{O}(1\text{ sec})$, which is in excellent qualitative agreement with a plethora of experimental/observational findings in Neurobiology. In the present work we shall not discuss these issues.

scales of the MT[b] We make an attempt to pick up possible sources of decoherence, consistent with the above-mentioned energy-loss-free transfer scenario in biological cells, and estimate the associated time scales.

The structure of this article is a follows: in Sec. 2 we review briefly the physical one-dimensional model describing MT dynamics, and discuss briefly the mathematical background for obtaining solitonic structures. An important rôle for the existence of the solitonic structures is played by the ordered water in the interior of the MT. The importance of the water in the interior of the MT has been emphasized by S. Hameroff, in connection with information processing, already some time ago.[15,16] In our article we present a scenario for the formation of electric-dipole quantum coherent modes in the water of the MT, inspired by earlier suggestions on "laser-like" behavior of the water.[17–19] Such coherent modes couple with the unpaired electrons of the MT dimers.

In this work we conjecture that such a coupling would result in the so-called Vacuum Field Rabi Splitting (VFRS),[20] a sort of dynamical Stark effect occuring in the emission or absorption spectra of the dimers as a result of the vaccum quantum fluctuations. This phenomenon is characteristic of the behavior of atoms inside quantum electrodynamical cavities, the rôle of which is played in our work by the MT cylindrical structures themselves.

A review of this phenomenon in the atomic physics is given in Sec. 3. The atomic Rabi Splitting is a consequence of the coupling of the atoms with the coherent modes of electromagnetic radiation inside the cavity. It is considered by many as a "proof" of the quantum nature of the electromagnetic radiation.[20] In our work, we consider this phenomenon, if true, as a manifestation of the quantum mechanical nature of the MT arrangement inside the cell.

This is discussed in Sec. 4, where we present a scenario according to which the MT arrangements inside the cell act as fairly isolated *cavities*. The ordered-water molecules in their interior, then, provides an environment, necessary to form coherent quantum modes (dipole quanta),[17–19] whose coupling with the dimers results in VFRS in the respective absorption spectra. Due to dissipation from the cavity walls, there is decoherence of the combined dimer-cavity system coherent state. The resulting decoherence time scales are estimated, for various sources of envirnoments. The main conclusion of our analysis is that in order for the quantum coherent states to play a rôle in dissipationless energy transfer, i.e. the decoherence time to be larger than the scale required for energy transfer in MT — estimated to be of $\mathcal{O}(5 \times 10^{-7}$ sec), for a moderately long MT, in the model of Ref. 4 — the damping time scales of the MT cavities must be $T_r \geq 10^{-4}$–10^{-5} sec.

[b]According to the above discussion, then, quantum gravity entanglement could be, if at all, important for the decoherence of the coherent state formed as a result of the water-dimer coupling. However this would require extreme isolation of the MT system, so that any conventional decoherence due to ordinary environmental entanglement is suppressed. Such isolated MT subsystems have been conjectured to occur in certain parts of brain, in which case quantum gravity plays a rôle in consciousness by inducing a collapse of the coherent-state of the MT dimers.[5,8,9] At present, we do not know whether this is feasible inside the brain.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

Finally, in Sec. 5, we present our conclusions and suggest some experiments to test the above-conjectured quantum mechanical origin of MT arrangements inside the cell. The experiments are inspired by the physics of Rydberg atoms in electromagnetic cavities.[21,22]

2. Review of the Physical Model for Microtubule Dynamics

2.1. *Classical considerations*

MicroTubules (MT) are hollow cylinders comprised of an exterior surface (of cross-section diameter 25 nm) with 13 arrays (protofilaments) of protein dimers called tubulines. The interior of the cylinder (of cross-section diameter 14 nm) contains *ordered water* molecules, which implies the existence of an electric dipole moment and an electric field. The arrangement of the dimers is such that, if one ignores their size, they resemble triangular lattices on the MT surface. Each dimer consists of two hydrophobic protein pockets, and has an unpaired electron. There are two possible positions of the electron, called α and β *conformations.* When the electron is in the β-conformation there is a 29° distortion of the electric dipole moment as compared to the α conformation.

In standard models for the simulation of the MT dynamics, the "physical" degree of freedom — relevant for the description of the energy transfer — is the projection of the electric dipole moment on the longitudinal symmetry axis (x-axis) of the MT cylinder. The 29° distortion of the β-conformation leads to a displacement u_n along the x-axis, which is thus the relevant physical degree of freedom. This way, the effective system is one-dimensional (spatial), and one has the possibility of a quantum integrable system.[5]

Information processing occurs via interactions among the MT protofilament chains. The system may be considered as similar to a model of interacting Ising chains on a trinagular lattice, the latter being defined on the plane stemming from fileting open and flattening the cylindrical surface of MT. Classically, the various dimers can occur in either α or β conformations. Each dimer is influenced by the neighboring dimers resulting in the possibility of a transition. This is the basis for classical information processing, which constitutes the picture of a (classical) cellular automatum.

The *quantum computer character* of the MT network results from the *assumption* that each dimer finds itself in a superposition of α and β conformations.[8] Viewed as a *two-state* quantum mechanical system, the MT tubulin dimers couple to conformational changes with 10^{-9}–10^{-11} sec transitions, corresponding to an angular frequency $\omega \sim \mathcal{O}(10^{10})$–$\mathcal{O}(10^{12})$ Hz. In the present work we assume the upper bound of this frequency range to represent (in order of magnitude) the characteristic frequency of the dimers, viewed as a two-state quantum-mechanical system:

$$\omega_0 \sim \mathcal{O}(10^{12})\ \text{Hz}\,. \tag{1}$$

The scenario for quantum computation in MT presuposes that there exists a macroscopic coherent state among the various chains. Let us now try to understand its emergence. Let u_n be the displacement field of the nth dimer in a MT chain. The continuous approximation proves sufficient for the study of phenomena associated with energy transfer in biological cells, and this implies that one can make the replacement

$$u_n \to u(x,t) \tag{2}$$

with x a spatial coordinate along the longitudinal symmetry axis of the MT. There is a time variable t due to fluctuations of the displacements $u(x)$ as a result of the dipole oscillations in the dimers. At this stage, t is viewed as a reversible variable.

The effects of the neighboring dimers (including neighboring chains) can be phenomenologically accounted for by an effective potential $V(u)$. In the model of Ref. 4 a double-well potential was used, leading to a classical kink solution for the $u(x,t)$ field. More complicated interactions are allowed in the string picture, as explained in Ref. 5. More generic polynomial potential have also been considered in Ref. 5.

The effects of the surrounding water molecules can be summarized by a viscuous force term that damps out the dimer oscillations,

$$F = -\gamma \partial_t u \tag{3}$$

with γ determined phenomenologically at this stage. This friction should be viewed as an environmental effect, which however does not lead to energy dissipation, as a result of the non-trivial solitonic structure of the ground-state and the non-zero constant force due to the electric field. This is a well known result, directly relevant to energy transfer in biological systems.[3]

In mathematical terms the effective equation of motion for the relevant field degree of freedom $u(x,t)$ reads:

$$u''(\xi) + \rho u'(\xi) = P(u)\,, \tag{4}$$

where $\xi = x - vt$, v is the velocity of the soliton, $\rho \propto \gamma$,[4] and $P(u)$ is a polynomial in u, of a certain degree, stemming from the variations of the potential $V(u)$ describing interactions among the MT chains.[5] In the mathematical literature[23] there has been a classification of solutions of equations of this form. For certain forms of the potential, the solutions include *kink solitons* that may be responsible for dissipation-free energy transfer in biological cells.[c] A typical propagation velocity of the kink

[c]In the "string picture of MT" the various solutions are related[5] by appropriate Renormalization-Scheme changes on the world-sheet of the string (generalizaing appropriately the particle like structures). This is reflected in certain *ambiguities* in the form of the string potential $V(u)$; what seems to be a unique phenomenological potential in point-like theory, determining various forms of soliton solutions, may not have such a unique interpretation in the completely-integrable (noncritical) string picture of MT. This suggests that the point-like field theory soliton solutions, discussed above, constitute only a "low-energy" approximation of more complicated (solitonic) ground states of the string. As discussed in the context of Liouville strings in Ref. 5, such *stringy ground states* share similar properties with their point–like theory counterparts as far as dissipation-free energy transfer is concerned.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

solitons of Ref. 4 is $v \sim 2$ m/sec. This implies that for moderately long microtubules, of length $L \sim 10^{-6}$ m, such kinks transport energy in

$$t_{\rm F} \sim 5 \times 10^{-7} \text{ sec}. \tag{5}$$

This scale is larger than the time scale that Fröhlich had conjectured as corresponding to the frequency of the coherent phonons in biological matter ($t \sim 10^{-11}$–10^{-12} s). In this article, however, we shall keep calling the time (5) the Fröhlich scale, since, upon quantization, the kink soliton solutions of Ref. 4 yield quantum coherent states[5] that are very similar to Fröhlich's phonons.

Therefore, in the above "phenomenological" approach to the MT physics, the importance of the water environment can be seen formally as follows: were it not for the friction term (3) there would be no stable solitonic structures in the ferroelectric distortive model of Ref. 4.[d]

2.2. *Quantum considerations*

Let us attempt a microscopic analysis of the physics underlying the interaction of the water molecules with the dimers of the MT. Our investigation points towards the fact that, as a result of the ordered structure of the water environment, there appear *collective* coherent modes, which in turn interact with the dimer structures (mainly through the unpaired electrons of the dimers) leading to the formation of a quantum coherent solitonic state that extends over the whole network of MT. According to the idea put forward in Ref. 5, following Ref. 6, such coherent states should be viewed as the result of *decoherence* of the dimer system due to its interaction/coupling with the water environment.

As we shall argue below, such a coupling could be detected by a phenomenon analogous to what is happening in atoms interacting with coherent modes of the electromagnetic radiation in *Cavities*, namely the *Vacuum-Field Rabi Slitting* (VFRS).[20] Our *conjecture* is that the interior of MT, full of ordered water molecules, can be viewed as a *cavity* rather than a *wave guide*; the cavity structure can be formed by "closing" the ends of the MT, and is a way of providing a fairly isolated system which can sustain coherent modes.

This type of environmental entanglement is described in the Liouville framework by the world-sheet renormalization-group β-function, β^u, of the displacement field, $u(x)$, of the dimers, described above. A non-trivial $\beta^u \neq 0$ expresses deviations from *conformal invariance*, as a consequence of environmental entanglement.[5] The β-function corresponds to an energy-dependent environmental coupling, since its magnitude depends on the energy of the field $u(x)$[5]:

$$\beta^u = \mathcal{O}[(E/M_s)^2] \tag{6}$$

[d]In the (noncritical) Liouville string picture such a coupling is responsible for the appearance of the appropriate "dilaton"-like terms in the world-sheet action, which are essential for consistency of the Liouville string.[24,25,5]

where M_s is a string scale, characteristic of the problem. The scale M_s acts as an ultraviolet cutoff for the energies of the low-energy field theory obtained from the "string", and its size depends on the details of the subsystem $u(x,t)$ as well as the environment.

The Master Equation for the time evolution of the density matrix ρ of the displacement field u in the Liouville approach reads[7,5]:

$$\partial_t \rho = i[\rho, H] + i\beta^u[\rho, u]M_s\,, \tag{7}$$

where H is the Hamiltonian of the dimer chain. The decoherence time in this approach is estimated as[5]:

$$t_{\text{decoh/Liouv}} \sim \frac{1}{\mathcal{N}\beta^u M_s} \tag{8}$$

where $\mathcal{N}$ denotes the number of dimers in the MT chain. The time scale (8) is the time over which the solitonic quantum coherent pointer states are formed in the MT networks, as a result of the ordered-water-induced decoherence.

We now remark that, in the approach of viewing the MT as cavities, the main source of dissipation will then be the leakage of photons or other coherent modes from the cavity. Its rate can be assumed *small* for the MT of the brain, otherwise the incoherent mode will dominate. This dissipation constitutes an ordinary environment, which cannot lead to the formation of pointer states, but instead induces eventual collapse of the solitonic states into completely classical ground states.

Hence, according to the above discussion, there are two stages when decoherence plays an important rôle.

(i) The first stage concerns the coupling of the system of dimers with the coherent modes formed in the ordered water. This coupling pertains to a specific environment which induces decoherence in the dimer sub-system, producing quantum coherent states ("pointer states") according to Refs. 6 and 5. The time scale of this decoherence corresponds to the time scale necessary for the formation of the solitonic coherent states of Ref. 5, see Eq. (8) above.

(ii) The second stage refers to the decoherence due to ordinary dissipation through the walls of the (imperfect) MT cavities. Such an ordinary environment does not admit a pointer basis,[13] but causes collapse of the quantum coherent state of stage (i) down to a classical ground state.

In this article, we shall estimate the decoherence time scales of both stages (i) and (ii) and compare them with the Fröhlich scale. Moreover, we shall propose specific experimental tests for the detection of the quantum-mechanical behavior of the MT arrangements inside the cell. An important feature of all these tests is, as we mentioned previously, the Vacuum-Field Rabi Splitting phenomenon, to a brief description of which we now turn for instructive purposes.

3. On the Rabi Splitting in Atomic Physics and the Quantum Nature of Electromagnetic Radiation

3.1. *Description of the Rabi splitting phenomenon*

In this section we shall recapitulate briefly the VFRS in atomic physics. This phenomenon has been predicted for the emission spectra of atoms inside electromagnetic cavities,[20] in an attempt to understand the *quantized nature* of the electromagnetic radiation. The basic principle underlying the phenomenon is that, in the presence of an interaction among two oscillators in resonance, the frequency degeneracy is *removed* by an amount proportional to the strength of the coupling. In the cavity QED case of Ref. 20, one oscillator consists of a small collection of N atoms, whilst the other is a resonant mode of a high-Q(uality) cavity.[e] Immediately after the suggestion of Ref. 20, a similar phenomenon has been predicted for absorption spectra of atoms in cavities.[27]

By now, the situation has been verified experimentally on a number of occasions.[21] In such experiments one excites the coupled atom-cavity system by a tuneable field probe. The excitation is then found resonant *not* at the "bare" atom or cavity frequencies but at the *split* frequencies of the "dressed" atom-field system. The splitting is enhanced for collections of atoms. For instance, as we shall review below, for a system of N atoms, the split is predicted to be[27]:

$$\text{Rabi splitting} = 2\lambda\sqrt{N}\,, \qquad 2\lambda = \text{Rabi splitting of a single atom}\,. \tag{9}$$

Despite its theoretical prediction by means of quantum mechanical oscillator systems coupled with a *quantized* radiation field mode in a cavity, at present there seems to be still a *debate* on the nature of the phenomenon:

(i) the dominant opinion is that the Rabi splitting is a manifestation of the *quantum nature* of the electromagnetic radiation (cavity field), and is caused as a result of an *entanglement* between the atom and the cavity coherent modes of radiation. It is a sort of Stark effect, but here it occurs in the absence of an external field.[20] This "dynamical Stark effect" is responsible for a splitting of the resonant lines of the atoms by an amount proportional to the collective atomic-dipole amplitude.

(ii) there is however a dual interpretation,[28] which claims that the splitting can be observed in optical cavities as well, and it is simply a result of *classical* wave mechanics inside the cavity, where the atomic sample behaves as a *refractive medium* with a *complex* index, which splits the cavity mode into two components.

Irrespectively of this second classical interpretation, one *cannot deny* the presence of the phenomenon in entangled atom-quantum-coherent mode systems.

[e]The quantity Q is defined as the ratio of the stored-energy to the energy-loss per period,[26] by making the analogy with a damped harmonic oscillator.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

This is the point of view we shall be taking in this work, in connection with our picture of viewing MT filled with ordered water as cavities. We shall try to make specific experimental predictions that could shed light in the formation of quantum coherent states, and their eventual decoherence. As mentioned above, the latter could be due to the interaction of the dimer unpaired spins (playing the rôle of the atoms in the Rabi experiments) with the ordered-water coherent modes (playing the rôle of the cavity fields). Possible scenaria for the origin of such cavity coherent modes will be described below.

Let us first recapitulate briefly the theoretical basis of the Rabi-splitting phenomenon, which will allow the non-expert reader to assess the situation better. We shall present the phenomenon from a point of view that will help us transcribe it directly to the MT case. Consider an atom of a frequency ω_0 in interaction with a single coherent mode of electromagnetic radiation field of frequency ω. The relevant Hamiltonian is:

$$H = \hbar\omega_0 \sum_i S_i^z + \hbar\omega a^\dagger a + \sum_i (\hbar\lambda S_i^+ a + \text{h.c.}), \tag{10}$$

where $a^\dagger$, a are the creation and annihilation cavity radiation field modes, S_i^z, $S_i^\pm$ are the usual spin-1/2 operators, and λ is the atom-field coupling. The atom-field system is not an isolated system, since there is *dissipation* due to the interaction of the system with the surrounding world. An important source of dissipation is the leakage of photons from the cavity at some rate κ. If the rate of dissipation is not too big, then a quantum coherent state can be formed, which would allow the observation of the vacuum-field Rabi oscillations. The density matrix ρ of the atom-field system obeys a Markov-type master equation for the evolution in time t[27]:

$$\partial_t \rho = -\frac{i}{\hbar}[H, \rho] - \kappa(a^\dagger a \rho - 2a\rho a^\dagger + \rho a^\dagger a) \tag{11}$$

The limit $\kappa \ll \lambda\sqrt{N}$ guarantees the possibility of the formation of a quantum coherent state, i.e. this limit describes environments that are weakly coupled to the system, and therefore the decoherence times (see below) are very long. In this limit one can concentrate on the off-diagonal elements of the density matrix, and make the following ("secular") approximation for their evolution[27]:

$$\partial_t \rho_{ij} = -\frac{i}{\hbar}(E_i - E_j)\rho_{ij} - \Gamma_{ij}\rho_{ij}\,, \tag{12}$$

where Γ_{ij} denotes the damping factor, pertaining to the weak coupling of the atom-field system to the environment. The analysis of Ref. 27 pertained to the evaluation of the susceptibility tensor of the system, $\chi_{\alpha\beta}$, which can be calculated by considering its interaction of the system with an external field of frequency Ω. The absorption spectrum is proportional to $\text{Im}\,\chi(\Omega)$. A standard quantum-mechanical

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

computation yields the result[27]:

$$\mathrm{Im}\,\chi(\Omega) = \cos^2\theta \frac{\Gamma_-/\pi}{\Gamma_-^2 + \{\Omega - \omega_0 + \Delta/2 - (1/2)(\Delta^2 + 4N\lambda^2)^{1/2}\}^2} + \sin^2\theta \frac{\Gamma_+/\pi}{\Gamma_+^2 + \{\Omega - \omega_0 + \Delta/2 + (1/2)(\Delta^2 + 4N\lambda^2)^{1/2}\}^2} \tag{13}$$

with $\Delta \equiv \omega_0 - \omega$. In the above expression the damping factors $\Gamma_\pm$ represent the damping in the equation of motion for the off-diagonal element of the density matrix $\langle \Psi_0 | \rho | \Psi_\pm^{S,C} \rangle$ where $\Psi_\pm$ are eigenfucntions of H, classified by the eigenvalues of the operators S^2, and $S^z + a^\dagger a \equiv C$, in particular[27]: $S = N/2$, and $C = 1 - N/2$.

The expression (13) summarizes the effect of Rabi-vacuum splitting in absorption spectra of atoms: there is a doublet structure (splitting) of the absorption spectrum with peaks at:

$$\Omega = \omega_0 - \frac{\Delta}{2} \pm \frac{1}{2}(\Delta^2 + 4N\lambda^2)^{1/2}\,. \tag{14}$$

For resonant cavities the splitting occurs with equal weights

$$\Omega = \omega_0 \pm \lambda\sqrt{N}\,. \tag{15}$$

Notice here the *enhancement* in the effect for multi-atom systems $N \gg 1$. This is the "Vacuum Field Rabi Splitting phenomenon", predicted in emission spectra in Ref. 20. As we have already mentioned, the above derivation pertains to absorption spectra, where the situation is formally much simpler.[27] It is also this latter case that is of interest to us for the purposes of this work.

The quantity $2\lambda\sqrt{N}$ is called the "Rabi frequency".[20] From the emission-spectrum theoretical analysis an estimate of λ may be inferrred which involves the matrix element, $\underline{d}$, of atomic electric dipole between the energy states of the two-level atom[20]:

$$\lambda = \frac{E_{\mathrm{vac}}\underline{d}\cdot\underline{\epsilon}}{\hbar} \tag{16}$$

where $\underline{\epsilon}$ is the cavity (radiation) mode polarization, and

$$E_{\mathrm{vac}} \sim \left(\frac{2\pi\hbar\omega_c}{\varepsilon_0 V}\right)^{1/2} \tag{17}$$

is the r.m.s. vacuum field amplitude at the center of the cavity of volume V, and of frequency ω_c, with ε_0 the dielectric constant of the vacuum[f]: $\varepsilon_0 c^2 = 10^7/4\pi$, in M.K.S. units. As mentioned above, there are simple experiments which confirmed this effect,[21] involving beams of Rydberg atoms resonantly coupled to superconducting cavities.

[f]For cavities containing other dielectric media, e.g. water in the case of the MT, ε_0 should be replaced by the dielectric constant ε of the medium.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

The situation which is of interest to us involves atoms that are *near resonance* with the cavity. In this case $\Delta \ll \omega_0$, but such that $\lambda^2 N/|\Delta|^2 \ll 1$; in such a case, formula (14) yields two peaks that are characterized by dispersive frequency shifts $\propto 1/\Delta$:

$$\Omega \simeq \omega_0 \pm \frac{N\lambda^2}{|\Delta|} + \mathcal{O}(\Delta)\,, \tag{18}$$

whilst no energy exchange takes place between atom and cavity mode. This is also the case of interest in experiments using such Rabi couplings to construct Schrödinger's cats in the laboratory, i.e. macro(meso)scopic combinations "measuring apparatus + atoms" to verify decoherence experimentally. The first experiment of this sort, which confirms theoretical expectations, is described in Ref. 29.

Another important issue, which has been used above, and in Ref. 29, is the *dephasing* of the atom as a result of the above-described atom-field Rabi entanglement. To understand better the situation, let us discuss a more generic case, that of a three-state atom, f, e, g, with energies $E_g > E_e > E_f$. Suppose one is interested in the transition $f \to e$ by absorption, in the presence of atoms in interaction with a cavity mode. Calling $D^+_{ef} \equiv |e\rangle\langle f|$, $D^-_{ef} \equiv |f\rangle\langle e| = (D^+_{ef})^\dagger$, we have the effective Hamiltonian for the transition $f \to e$[30]:

$$H^{ef}_{\rm eff} = \hbar\omega_{\rm eff} D^+_{ef} D^-_{ef}\,, \qquad \omega_{\rm eff} = \omega_{ef} + \frac{\lambda^2 n}{\Delta}\,. \tag{19}$$

where the "effective" frequency $\omega_{\rm eff}$ incorporates the dispersive frequency shifts (18) of the Rabi effect, appropriate for near-resonant atom-cavity-field systems; n is the number of cavity photons.[g]

Consider now an experiment to measure, say, the photon number n in the cavity. The relevant probe P can be the above-described three-state atom, in a superposition of e and f states. In this picture the photon number n is an eigenvalue of the cavity signal operator $a^\dagger_{\rm s} a_{\rm s}$; the interaction Hamiltonian between atom and cavity then reads[30]:

$$H_{\rm I} = \frac{\hbar\lambda^2}{\Delta} a^\dagger_{\rm s} a_{\rm s} D^+_{ef} D^-_{ef}\,. \tag{20}$$

The probe observable is the atomic dipole operator:

$$A_{\rm P} = \frac{1}{2i}(D^+_{ef} - D^-_{ef})\,. \tag{21}$$

The Heisenberg evolution of this operator yields

$$i\hbar \frac{d}{dt} A_{\rm P} = [A_{\rm P}, H^{ef}_{\rm eff} + H_{\rm I}] \tag{22}$$

[g]Notice that the $\sqrt{n}$ characteristic scaling law for the Rabi splitting (15) is *also valid* in the case of interaction of a *single* atom with n cavity oscillator quanta (e.g. a coherent cavity mode).

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

from which it is easily seen that in a time interval t the phase of the probe is changing by:

$$\Delta\phi = \omega_{ef}t + \frac{\lambda^2 n}{\Delta}t\,. \tag{23}$$

The case of interest for the experiment of Ref. 29 is a two-state atom; the resulting phase shift is then obtained from (23) by setting $\omega_{ef} = 0$. In that case, the phase entanglement due to the atom-field Rabi coupling is

$$\Delta\phi_{\mathrm{R}} = \frac{\lambda^2 n}{\Delta}t \tag{24}$$

for a near resonance atom-field system, with a small detuning Δ. Such a situation is encountered precisely in the experiment of Ref. 29, which will constitute our prototype for the extension of the above results to the MT case. Before doing so it is instructive to review briefly the experiment of Ref. 29, where decoherence of an open mesoscopic system ("Schrödinger's cat") *has been demonstrated.*

3.2. *Rabi splitting and decoherence: Experimenal verification*

The experiment consists of sending a Rubidium atom with two circular Rydberg states e and g, through a microwave cavity storing a small coherent field $|\alpha\rangle$. The coherent cavity mode is mesoscopic in the sense of possessing an average number of photons of order $\mathcal{O}(10)$. The atom-cavity coupling is measured by the Rabi frequency $2\lambda/2\pi = 48$ kHz. The condition for Rabi dispersive shifts (18) is satisfied by having a $\Delta/2\pi \in [70, 800]$ kHz.

The set up of the experiment is as follows: The atom is prepared in the superposition of e, g states, by virtue of a resonant microwave cavity R_1. Then it crosses the cavity C, which is coupled to a reservoir that damps its energy (*dissipation*) at a characteristic time scale $T_r \ll 1.5$ ms. Typical cavities, used for atomic scale experiments such as the above, have dimensions which lie in the mm range or at most cm range. In the cavity C a number of photons varying from 0 to 10 is injected by a pulse source. The field in the cavity relaxes to vacuum — thereby causing *dissipation* through leakeage of photons through the cavity — during a time T_r, before being regenerated for the next atom. The experiment is at an effective temperature of $T = 0.6$ K, which is low enough so as to minimize thermal effects. After leaving C, the atom passes through a second cavity R_2, identical to R_1; one then measures the probability of finding the atom in the state, say, g. This would mean decoherence. The decoherence time is measured for various photon numbers; this helps testing the theoretical predictions that decoherence between two "pointer states" of a quantum superposition occurs at a rate proportional to the square of the distance among the states.[6,11,31,32]

Let us understand this latter point better. The coherent oscillator states, characterizing the cavity modes, constitute such a pointer basis: an oscillator in a coherent state is defined by the average number of oscillator quanta n as: $|\alpha\rangle : |\alpha| = \sqrt{n}$.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

Then, consider the measurement of the above-described experiment, according to which there is only a phase entanglement between the cavity and the atom: the combined atom-cavity (meter) system is originally in the state

$$|\Psi\rangle = |e, \alpha e^{i\phi}\rangle + |g, \alpha e^{-i\phi}\rangle \tag{25}$$

According to (24) the dephasing is atomic-level dependent $\phi \propto \lambda^2 tn/\Delta$. Coupling the oscillator to a reservoir, that damps its energy in a characteristic time scale T_r, produces decoherence. According to the general theory[10,31–32] the latter occurs during a time scale inversely proportional to the square of the distance between the "pointer" states D^2:

$$t_{\text{collapse}} = \frac{2T_r}{D^2} \tag{26}$$

This is easy to verify in a prototype toy model, involving only a phase entanglement, i.e. without energy dissipation. To this end, consider the Hamiltonian:

$$H = \hbar\omega a^\dagger a + a^\dagger a\Gamma \tag{27}$$

with $a^\dagger$, a creation and annihilation operators of a quantum oscillator, and Γ a phase damping. The "pointer" states for this problem are characterized by the eigenvalues n of the number operator $a^\dagger a$ which commutes with the Hamiltonian $[a^\dagger a, H] = 0$, i.e. the pointer basis is $\{|n\rangle\}$. The pertinent Markov master equation for the density matrix, ρ, reads:

$$\partial_t \rho = \frac{\kappa}{2}(2a^\dagger a\rho a^\dagger a - \rho a^\dagger a a^\dagger a - a^\dagger a a^\dagger a\rho) \tag{28}$$

Writing $\rho(t) = \sum_{m,n} \rho_{mn}(t)|n\rangle\langle m|$ it is straightforward to determine the time dependence of $\rho_{nm}(t)$ from (28)

$$\rho_{nm}(t) = e^{-\kappa(n-m)^2 t/2}\rho_{nm}(0) \tag{29}$$

which implies that the coherence between two different ($m \neq n$) pointer (number) states is damped at a typical scale given by (26), where $T_r = 1/\kappa$, and the distance D is given by $n - m$ in the above example. As mentioned previously, this inverse D^2-behavior seems to be a *generic* feature of open (decohering) systems, including open string models.[7,5]

In the set up of Ref. 29 the distance D is given by

$$D = 2\sqrt{n}\sin\phi \simeq 2n^{3/2}\frac{\lambda^2 t}{\Delta} \tag{30}$$

for Rabi couplings 2λ, such that $\lambda^2 tn \ll \Delta$. For mesoscopic systems $n \sim 10$, $D > 1$, and, hence, decoherence occurs over a much shorter time scale than T_r; in

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

particular, for $\Delta/2\pi \sim 70$ kHz the decoherence time is $0.24T_r$.[29] This concludes the construction of a Schrödinger's cat, and the associated "measurement process". Notice that the above construction is made in two stages: first it involves an interaction of the atom with the cavity field, which results in a coherent state of the combined "atom-meter", and then *dissipation* is induced by coupling the cavity (measuring apparatus) to the environment, which damps its energy, thereby inducing *decoherence* in the "atom + meter" system. The important point to realize is that the more macroscopic the cavity mode is (i.e. the higher the number of oscillator quanta), the shorter the decoherence time is. This is exactly what was to be expected from the general theory.[6,7,10,11]

4. Rabi Vacuum Coupling in MT and Energy Transfer in the Cell

4.1. *Microscopic mechanisms for the formation of coherent states in MT*

Above we have sketched the experimental construction of a mesoscopic quantum coherent state (a "Schrödinger's cat" (SC)). The entanglement of the atom with the coherent cavity mode, manifested experimentally by the "vacuum Rabi spliting", leads to a quantum-coherent state for the combined atom-cavity system (SC), comprising of the superposition of the states of the two-level Rydberg atom. Dissipation induced by the leakage of photons in the cavity leads to decoherence of the coherent atom-cavity state, in a time scale given by (26). This time scale depends crucially on the nature of the coupled system, and the nature of the "environment". It is the point of this session to attempt to discuss a similar situation that conjecturally occurs in the systems of MT. We believe that understanding the formation of Schródinger's cats in MT networks will unravel, if true, the mysteries of the brain as a (quantum) computer, which might also be related to the important issue of "conscious perception", as advocated in Refs. 5, 8 and 9.

The first issue concerns the nature of the "cavity-field modes". Our point in this section is to argue that the presence of *ordered water*, which seems to occupy the interior of the microtubules,[16] plays an important rôle in producing coherent modes, which resemble those of the ordinary electromagnetic field in superconducting cavities, discussed above.

Let us first review briefly some suggestions about the rôle of the electric dipole moment of water molecules in producing coherent modes after coupling with the electromagnetic radiation field.[17] Such a coupling implies a "laser-like" behavior. Although it is not clear to us whether such a behavior characterizes ordinary water, in fact we believe it does not due to the strong suppression of such couplings in the disordered ordinary water, however it is quite plausible that such a behavior characterizes the ordered water molecules that exist in the interior of MT.[16] If true, then this electric dipole-quantum radiation coupling will be responsible, according to the analysis of Ref. 17, for the appearance of *collective* quantum coherent modes.

The Hamiltonian used in the theoretical model of Ref. 17 is:

$$H_{\rm ow} = \sum_{j=1}^{M} \left[\frac{1}{2I} L_j^2 + \underline{A} \cdot \underline{d}_{ej} \right] \tag{31}$$

where A is the quantized electromagnetic field in the radiation gauge,[17] M is the number of water molecules, L_j is the total angular momentum vector of a single molecule, I is the associated (average) moment of inertia, and d_{ej} is the electric dipole vector of a single molecule, $|d_{ej}| \sim 2e \otimes d_e$, with $d_e \sim 0.2\,\text{Å}$. As a result of the dipole-radiation interaction in (31) coherent modes emerge, which in Ref. 18 have been interpreted as arising from the quantization of the Goldstone modes responsible for the *spontaneous breaking* of the electric dipole (rotational) symmetry. Such modes are termed "dipole quanta" in Ref. 18.

This kind of mechanism has been applied to microtubules,[19] with the conclusion that such coherent modes cause "super-radiance", i.e. create a specific quantum-mechanical ordering in the water molecules with characteristic times much shorter than those of thermal interaction. In addition, the optical medium inside the internal hollow core of the microtubule is made transparent by the coherent photons themselves.[19] Such phenomena, if observed, could verify the coherent-mode emission from living matter, thereby verifying Fröhlich's ideas.

In our picture of viewing the MT arrangements as cavities, these coherent modes are the quantum coherent "oscillator" modes of Sec. 3, represented by annihilation and creation operators a_c, $a_c^\dagger$, which play the rôle of the cavity modes, if the ordered-water interior of the MT is viewed as an isolated cavity.[h] The rôle of the small collection of atoms, described in the atomic physics analogue above, is played in this picture by the protein dimers of the MT chains. The latter constitute a two-state system due to the α and β conformations, defined by the position on the unpaired spin in the dimer pockets. The presence of unpaired electrons is crucial to such an analogy. The interaction of the dipole-quanta coherent modes with the protein dimers results in an entanglement which we claim is responsible for the emergence of *soliton quantum coherent states*, extending over large scale, e.g. the MT or even the entire MT network.

The issue, we are concerned with here, is whether such coherent states are responsible for *energy-loss-free transport*, as well as for *quantum computations* due to their eventual collapse, as a result of "environmental" entanglement of the entire

[h]This was not the picture envisaged in Ref. 17. However, S. Hameroff, as early as 1974, had conjectured the rôle of MT as "dielectric waveguides" for photons,[15] and in Ref. 19 some detailed mathematical construction of the emergence of coherent modes out of the ordered water are presented. In our work in this article we consider the implications of such coherent modes for the system of dimers, in particular for the formation of kink solitons of Ref. 4. Thus, our approach is different from that in Refs. 17 and 19, where attention has been concentrated only on the properties of the water molecules. We should emphasize that the phenomenon of optical transparency due to super-radiance may co-exist with the formation of kink soliton coherent states along the dimer chains, relevant to the dissipation-free energy transfer along the MT, discussed in the present work.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

"MT dimers + ordered water" system. An explicit construction of such solitonic states has been made in the field-theoretic model for MT dynamics of Ref. 5, based on classical ferroelectric models for the displacement field $u(x,t)$ discussed in Sec. 2.[4] The quantum-mechanical picture described here should be viewed as a simplification of the field-theoretic formalism, which, however, is sufficient for qualitative estimates of the induced decoherence.

4.2. *Decoherence and dissipationless energy transfer*

To study quantitatively the effects of decoherence in MT systems we make the plausible *assumption* that the environmental entanglement of the "ordered-water cavity" (OWC), which is responsible for dissipation, is attributed *entirely* to the leakage of photons (electromagnetic radiation quanta) from the MT interior of volume V ("cavity"). This leakage may occur from the *nodes* of the MT network, if one assumes fairly isolated interia. This leakage will cause decoherence of the coherent state of the "MT dimer-OWC" system. The leakage determines the damping time scale T_r in (26).

The dimers with their two conformational states α, β play the rôle of the collection of N *two-level* Rydberg atoms in the atomic physics analogue described in Sec. 3. If we now make the assumption that the ordered-water dipole-quantum coherent modes couple to the dimers of the MT chains in a way similar to the one leading to a Rabi splitting, described above, then one may assume a coupling λ_0 of order:

$$\lambda_0 \sim \frac{d_{\rm dimer} E_{\rm ow}}{\hbar} \tag{32}$$

where $d_{\rm dimer}$ is the single-dimer electric dipole matrix element, associated wiith the transition from the α to the β conformation, and $E_{\rm ow}$ is a r.m.s. typical value of the amplitude of a coherent dipole-quantum field mode.

Given that each dimer has a mobile charge[1]: $q = 18 \times 2e$, e the electron charge, one may *estimate*

$$d_{\rm dimer} \sim 36 \times \frac{\varepsilon_0}{\varepsilon} \times 1.6 \times 10^{-19} \times 4 \times 10^{-9} \sim 3 \times 10^{-18}\,{\rm Cb} \times {\rm \AA} \tag{33}$$

where we used the fact that a typical distance for the estimate of the electric dipole moment for the "atomic" transition between the α, β conformations is of $\mathcal{O}(4\,{\rm nm})$, i.e. of order of the distance between the two hydrophobic dimer pockets. We also took account of the fact that, as a result of the water environment, the electric charge of the dimers appears to be screened by the relative dielectric constant of the water, $\varepsilon/\varepsilon_0 \sim 80$. We note, however, that the biological environment of the unpaired electric charges in the dimer may lead to further suppression of $d_{\rm dimer}$ (33).

The amplitude of the collective modes of the dipole-quanta may be estimated using the formula (17). In our case the "cavity volume" is:

$$V \sim 5 \times 10^{-22}\,{\rm m}^3 \tag{34}$$

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

which is a typical MT volume, for a moderately long MT $L \sim 10^{-6}$ m, considered as an isolated cavity,[i] and ω_c a typical frequency of the dipole quanta collective mode dynamics. To estimate this frequency we assume, following the "super-radiance" model of Ref. 19, that the dominant modes are those with frequencies in the range $\omega_c \sim \epsilon/\hbar$, where ϵ is the energy difference between the two principal energy eigenstates of the water molecule, which are assumed to play the dominant rôle in the interaction with the (quantized) electromagnetic radiation field. For the water molecule:

$$\hbar\omega_c \sim 4\,\text{meV} \tag{35}$$

which yields

$$\omega_c \sim \frac{\epsilon}{\hbar} \sim 6 \times 10^{12}\,\text{s}^{-1} \tag{36}$$

This is of the same order as the characteristic frequency of the dimers (1), implying that the dominant cavity mode and the dimer system are almost in resonance. Note that this is a feature shared by the Atomic Physics systems in Cavities examined in Sec. 3, and thus we may apply the pertinent formalism to our system.

From (17) one obtains for the r.m.s E_{ow} in order of magnitude:

$$E_{\text{ow}} \sim 10^4\ \text{V/m} \tag{37}$$

where we took into account the relative dielectric constant of water $\varepsilon/\varepsilon_0 \sim 80$.

It has not escaped our attention that the electric fields of such order of magnitude can be provided by the electromagnetic interactions of the MT dimer chains, the latter viewed as giant electric dipoles.[4] This may be seen to suggest that the super-radiance coherent modes ω_c, which in our scenario interact with the unpaired electric charges of the dimers and produce the kink solitons along the chains, owe their existence to the (quantized) electromagnetic interactions of the dimers themselves.

We assume that the system of $\mathcal{N}$ MT dimers interacts with a *single* dipole-quantum mode of the ordered water and we ignored interactions among the dimer spins.[j] In our work here we concentrate our attention on the formation of a coherent soliton along a single dimer chain, the interactions of the remaining 12 chains in a protofilament MT cylinder being represented by appropriate interaction terms

[i]Here we consider only a single unit of the MT network. The MT network consists of a large number of such cavities/MT. Our scenario here is to examine soliton formation in a single (isolated) cavity MT, with the only source of dissipation the leakage of photons. This would explain the formation of kinks in a single MT.[4,5] If the entire network of MT is viewed as a cavity, then the volume V is complicated, but in that case the volume can be estimated roughly as $\mathcal{N}_{mt}V$, with V the average volume of each MT, and $\mathcal{N}_{mt}$ the number of MT in the network population. In such a case, the solitonic state extends over the entire network of MT. It is difficult to model such a situation by simple one-dimensional Hamiltonians as in Refs. 4, 5.

[j]More complicated situations, including interactions among the dimers, as well as of the dimers with more than one radiation quanta, which might undoubtedly occur in nature, complicate the above estimate.

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

in the effective potential of the chain MT model of Ref. 4. In a moderately long microtubule of length $L \simeq 10^{-6}$ m there are

$$\mathcal{N} = \frac{L}{8} \simeq 10^2 \tag{38}$$

tubulin dimers of average length 8 nm in each chain.

Then, from (32), (33) and (37), the conjectured Rabi-vacuum splitting, describing the entanglement of the interior coherent modes with the dimers can be estimated to be of order

$$\text{Rabi coupling for MT} \equiv \lambda_{\rm MT} = \sqrt{\mathcal{N}}\lambda_0 \sim 3 \times 10^{11}\,{\rm s}^{-1} \tag{39}$$

which is, on average, an order of magnitude smaller than the characteristic frequency of the dimers (1). In this way, the perturbative analysis of Sec. 3, for small Rabi splittings $\lambda << \omega_0$, is valid. Indeed, as can be seen from (1) and (36), the detuning Δ is of order:

$$\frac{\Delta}{\lambda_0} \sim \mathcal{O}(10)\text{–}\mathcal{O}(100) \tag{40}$$

implying that the condition $\lambda_0^2\mathcal{N}/|\Delta|^2 \ll 1$, necessary for the perturbative analysis of Sec. 3, is satisfied. The Rabi frequency (39) corresponds to an energy splitting $\hbar\lambda_{\rm MT} \sim 0.1$ meV for a moderately long MT.

Having estimated the Rabi coupling between the dimers and the ordered-water coherent modes we now proceed to estimate the average time scale necessary for the formation of the pointer coherent states which arise due to this entanglement.[6,5] This is the same as the decoherence time due to the water-dimer coupling. In such a case one may use the Liouville model of MT,[5] discussed in Subsec. 2.2, which is known to possess pointer coherent states.[14] The relevant decoherence time scale is given by (8).

For an accurate estimate of the decoherence time one should have a precise knowledge of the violations of conformal invariance associated with the water-dimer coupling. Unlike the quantum-gravity induced decoherence case, where a microscopic model for the description of the distortions caused in the environment of the chain by the external stimuli is available,[5] at present a precise conformal-field-theory model for the description of the water-dimer coupling is lacking.

However, for our purposes here, it suffices to use our generic approach to the string-theory representation of MT chains, described in Ref. 5, where a good order-of-magnitude estimate for β^u is provided by (6). We, therefore, merely need to have an estimate of the scales E and $M_{\rm s}$ for the problem at hand.

To estimate the "string" scale $M_{\rm s}$ in our case,[k] where only quantum-electromagnetic interactions enter, we notice that in the standard string theory $M_{\rm s}$

[k]In Ref. 5, where scenaria for gravity-induced conscious perception were discussed, the scale $M_{\rm s}$ was taken to be the Planck scale 10^{19} GeV. In that case decoherence was induced by the coupling of the entire network of brain MT to quantum-gravity fluctuations due to the distortion of the surrounding space time, as result of abrupt conformational changes in the dimers, caused by external stimuli.[9,8,5]

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

acts as an ultraviolet cut-off in the energy of the effective target-sace field theory, in our case the field theory of the displacement field $u(x,t)$. Since in the ferroelectric chain the closest distance separating two unpaired electrons, which are assumed to have the dominant interactions with the water, is the size of a tubulin dimer $\sim d_{\rm min} = 4\,{\rm nm}$, an order of magnitiude estimate of $M_{\rm s}$ is:

$$M_{\rm s} \sim \frac{\hbar v_0}{d_{\rm min}} \sim 1.5 \times 10^{-4}\,{\rm eV}\,, \tag{41}$$

where we took into account that the Liouville model for MT in Ref. 5 is formally a relativistic string model, but with the rôle of the velocity of light played by the sound velocity $v_0 = 1$ Km/sec in organic biological materials. It is interesting to note that this cut-off in energies is less than the kinetic energies of fast kinks, propagating with the valocity of sound. Indeed such energies are of order $E_0 \sim 10^{-2}\,{\rm eV}$. Such fast kinks have been associated in Ref. 5 with quantum gravitational effects, due to abrupt distortions of space time, and hence their exclusion in the approach of the present work, by considering kinks with energies much less than those, as implied by $M_{\rm s}$, is consistent with our considering only electromagnetic interactions among the dimers and its environment.

The above estimate allows us to get an idea of the typical energy scales of the excitations of the MT systems that dominate the ordered-water-dimer coupling, in the above scenario, and lead to decoherence. As discussed in Ref. 5, the dominant part of the energy of a kink in the model of Ref. 4 is of order 1 eV, and thus much higher than the $M_{\rm s}$ (41). Such scales may play a rôle in the decoherence due to quantum-gravity entanglements,[5] which however is much weaker than the electromagnetic ones considered here. On the other hand, as we shall argue now, a typical energy scale for the dimer displacement field $u(x,t)$, much smaller than $M_{\rm s}$, and therefore consistent with our low-energy approach, is provided by the kinetic energy of the kink, which is estimated to be of order[4]

$$E_{\rm kin} \simeq 5 \times 10^{-8}\,{\rm eV} \tag{42}$$

As we shall argue below, this energy scale may be used for our estimate of the time scale (8), which is necessary for the formation of the coherent state due to the water-dimer coupling. We stresss that (42) should not be considered as a typical energy scale associated with the excitation spectrum of the dimers, pertaining to the Rabi splitting discussed above. It is rather an "effective scale", characterising "friction" effects between the dimers and the water environment. The latter are responsible[5] for decoherence and the eventual formation of the kink coherent states, which are minimum-entropy states,[6] least susceptible to the effects of the water environent.

To justify the above estimate, one should notice that the formation of coherent quantum states through decoherence due to friction[6] is the quantum analogue of the "drift velocity" acquired by a Brownian particle in classical mechanics. In the (non-relativistic) conformal-field-theory setting of Ref. 5 such a friction could be described by the formation of point-like defects on the dimer chains, which could

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

be described by appropriate non-relativistic membrane backgrounds in the $(1+1)$-dimensional string theory representation of the MT dynamics. Such membranes are stringy defects, which, for instance, could describe the result of an abrupt conformational change of a given dimer due to its coupling with the water environment. Scattering of stringy excitations $u(x,t)$ off the defect causes "recoil" of the latter, which starts moving with a velocity $v_{\rm d}$. The recoil is due to quantum fluctuations as argued in Ref. 33. Such recoil effects are necessary for energy and momentum conservation in the case of (non-relativistic) heavy membranes, considered in Ref. 33. That model represents a pilot model for discussing decoherence due to water environment in our case.

The important feature to notice is that the "effective mass" of the defect in such a stringy representation turns out to be inversely proprotional to the string-coupling constant $g_{\rm s}$,[33]

$$m_{\rm defect} = (8\sqrt{2}\pi g_{\rm s})^{-1} \tag{43}$$

which, in turn, depends on the vacuum expectation value of the effective "dilaton" field Φ: $g_{\rm s} = e^{-\langle\Phi\rangle}$. In the case at hand, as discussed in Ref. 5, the dilaton field is proprotional to the friction coefficient γ, so that $g_{\rm s} \sim \exp(-\gamma)$ in order of magnitude. Strong friction, therefore, between water molecules and dimers, which may be assumed in our physical model of MT, implies weak string coupling, and hence the non-relativistic approximation for the membranes proves sufficient.

Within the framework of identifying target time with the Liouville mode,[7] then, the analysis of Ref. 33 has shown that the *quantum recoil* degrees of freedom of the membrane defect carry *information* and induce decoherence of the dimer (string) subsystem, corresponding to violations of conformal invariance of order:

$$\beta^{\rm recoil} \sim \mathcal{O}\left(\frac{v_{\rm d}^2}{16\pi g_{\rm s} M_{\rm s}}\right) \tag{44}$$

where $v_{\rm d}^2$ is the recoil velocity of the defect. By energy-momentum conservation, the kinetic energy of the recoiling (non-relativistic) defect is *at most* of the same order as the kinetic energy of the displacement field (42). This would yield a lower bound on the decoherence time (8) estimated on the basis of (44) to be of order:

$$t_{\rm owdecoh} \gtrsim 10^{-10}\,{\rm sec} \tag{45}$$

for a moderately long MT, with $\mathcal{N} = 10^2$ dimers. This is the time scale over which solitonic coherent pointer states in the MT dimer system are formed ("pumped"), according to our scenario. Note that the scale (45) is not far from the original Fröhlich scale,[2] 10^{-11}–10^{-12} sec.

To answer the question whether quantum coherent pointer states are responsible for loss-free energy transport across the MT one should examine the time scale of the decoherence induced by the coupling of the MT to their biological environment as a consequence of dissipation through the walls of the MT cylinders. Such an

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

ordinary environmental entanglement has been ignored in the derivation of (45). It is this environment that will induce decoherence and eventual collapse of the pointer states formed by the interaction of the dimers with the coherent modes in the ordered water. Using typical numbers of MT networks, we can estimate this decoherence time in a way similar to the corresponding situation in atomic physics (26) and (30):

$$t_{\rm collapse} = \frac{T_r}{2n\mathcal{N}\sin^2(\mathcal{N}n\lambda_0^2 t/\Delta)} \tag{46}$$

where we took into account that the dominant (dimer)-(dipole quanta) coupling occurs for ordered-water "cavity" modes which are *almost at resonance* with the dimer oscillators (c.f. Eqs. (36) and (1)), slightly detuned by Δ : $\lambda_0/\Delta \ll 1$, c.f. (40).

We also assume that a typical coherent mode of dipole/quanta contains an average of $n = \mathcal{O}(1)$–$\mathcal{O}(10)$ oscillator quanta. The *macroscopic* character of the Schrödinger's cat dimer-dipole-quanta system comes from the N dimers in a MT (or $\mathcal{N}_{\rm mt}\mathcal{N}$ in MT networks).[5]

The time t appearing in (46) represents the "time" of interaction of the dimer system with the dipole quanta. A reasonable estimate of this time scale in our MT case can be obtained by equating it with the average life-time of a coherent dipole-quantum state, which, in the super-radiance model of Ref. 19 can be estimated as

$$t \sim \frac{c\hbar^2 V}{4\pi d_{\rm ej}^2 \epsilon N_{\rm w} L} \tag{47}$$

with $d_{\rm ej}$ the electric dipole moment of a water molecule, L the length of the MT, and $N_{\rm w}$ the number of water molecules in the volume V of the MT. For typical values of the parameters for moderately long MT, $L \sim 10^{-6}$ m, $N_{\rm w} \sim 10^8$, a typical value of t is:

$$t \sim 10^{-4} \text{ sec} \tag{48}$$

We remark at this point that this is considerably larger than the average life-time of a coherent dipole quantum state in the water model of Ref. 17. Indeed in that model, the corresponding life-time is estimated to be:

$$t \sim \frac{2\pi}{\omega_0} \tag{49}$$

where $\omega_0 \sim 1/I$, is a typical frequency of resonating electromagnetic mode in the ordered water. For a typical value of the water molecule moment of intertia[17] this yields a time-scale associated with the coherent interaction $\mathcal{O}(10^{-14}$ sec).

The time scale T_r, over which a cavity MT dissipates its energy, can be identified in our model with the average life-time (47) of a coherent-dipole quantum state:

$$T_r \sim t \sim 10^{-4} \text{ sec} \tag{50}$$

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

which leads to a naive estimate of the quality factor for the MT cavities, $Q_{\rm MT} \sim \omega_{\rm c} T_{\rm r} \sim \mathcal{O}(10^8)$. We note, for comparison, that high-quality cavities encountered in Rydberg atom experiments dissipate energy in time scales of $\mathcal{O}(10^{-3})$–$\mathcal{O}(10^{-4})$ sec, and have Q's which are comparable to $Q_{\rm MT}$ above. Thus, it is not unreasonable to expect that conditions like (50), characterizing MT cavities, are met in Nature.

From (46), (39) and (50), one then obtains the following estimate for the collapse time of the kink coherent state of the MT dimers due to dissipation:

$$t_{\rm collapse} \sim \mathcal{O}(10^{-7})\text{–}\mathcal{O}(10^{-6}) \text{ sec} \tag{51}$$

which is larger or equal than the Fröhlich scale (5) required for energy transport across the MT by an average kink soliton in the model of Ref. 4. The result (51), then, implies that Quantum Physics may be responsible for dissipationless energy transfer across the MT.

We close this section by remarking that if the condition $T_{\rm collapse} \gtrsim 5 \times 10^{-7}$ sec is not met, then the above picture, based on mesoscopic coherent states, would be inconsistent with energy-loss free energy transport, since decoherence due to environmental entanglement would occur before energy could be transported across the MT by the preformed quantum soliton. In such a case energy would be transported due to different mechanisms, one of which is the classical solitons scenario of Refs. 4 and 3. However, even in such cases of fast decoherence, the Rabi coupling predicted above could still exist and be subjected to experimental verification.

5. Outlook: Possible Experimental Tests Using Micro-Tubules as Cavities

In the present work we have put forward a conjecture concerning the representation of the MT arrangements inside the cell as *isolated* high-Q(uality) *cavities*. We presented a scenario according to which the presence of the ordered water in the interior of the cylindrical arrangements results in the appearance of electric dipole quantum coherent modes, which couple to the unpaired electrons of the MT dimers via Rabi vacuum field couplings, familiar from the physics of Rydberg atoms in electromagnetic cavities.[20] In quantum optics, such couplings are considered as experimental proof of the quantized nature of the electromagnetic radiation. In our case, therefore, if present, such couplings could indicate the existence of the coherent quantum modes of electric dipole quanta in the ordered water environment of MT, conjectured in Refs. 18 and 17, and used in the present work.

Some generic decoherence time estimates, due to environmental entanglement of the MT cavities, have been given. The conclusion was that only in *fairly isolated* cavities, which we conjecture exist inside the biological cells, decoherence occurs in time scales which are in agreement with the Fröhlich scale ($\sim 5 \times 10^{-7}$ sec) for energy transfer across the MT via the formation of kink solitonic structures. In such a case, *dissipationless energy transfer* might occur in biological systems, an in particular in MT which are the substratum of cells, in much the same way as frictionless electric

Int. J. Mod. Phys. B 1998.12:517-542. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 01/21/15. For personal use only.

current transport occurs in superconductors, i.e. via *quantum coherent modes* that extend over relatively large spatial regions. A phenomenological analysis indicated that for moderately long MT networks such a situation could be met if the MT cavities dissipate energy in time scales of order $T_r \sim 10^{-4}$–10^{-5} sec. This lower bound is comparable to the corresponding scales of atomic cavities,[21] $\sim 10^{-4}$ sec, which, in turn, implies that the above scenaria, on dissipationless energy transport as a result of the formation of quantum coherent states, have a good chance of being realized at the scales of MT, which are comparable to those in Atomic Physics.

We have conjectured in this work that an indirect verification of such a mechanism would be the experimental detection of the aforementioned Vacuum field Rabi coupling, $\lambda_{\rm MT}$, between the MT dimers and the ordered water quantum coherent modes. This coupling, if present, could be tested experimentally by the same methods used to measure VFRS in atomic physics,[21] i.e. by using the MT themsleves as *cavity environments*, and considering tunable probes to excite the coupled dimer-water system. Such probes could be pulses of (monochromatic) light, for example, passing through the hollow cylinders of the MT. This would be the analogue of an external field in the atomic experiments described above, which would then resonate, not at the bare frequencies of the coherent dipole quanta or dimers, but at the *Rabi splitted* ones, and this would have been exhibited by a double pick in the absorption spectra of the dimers.[21] By using MT of different sizes one could thus check on the characteristic $\sqrt{N}$-enhancement of the Rabi coupling for MT systems with N dimers.

The technical complications that might arise in such experiments are associated with the absence of completely resonant cavities in practice. In fact, from our discussion in this article, one should expect a slight detuning Δ between the cavity mode and the dimer, of frequency ω_0. As discussed in Sec. 3, the detuning produces a split of the vacuum-Rabi doublet into a cavity line $\omega_0 + \lambda^2/\Delta$ and an "atomic line" $\omega_0 - \lambda^2/\Delta$. In atomic physics there are well established experiments[21,22] to detect such splittings. In fact, detection of such lines is considered as a very efficient way of "quantum non-demolition" measurement[30] for small microwave photon numbers. Such atomic physics experiments, therefore, may be used as a guide in performing the corresponding biological experiments involving MT (as cavities), as suggested in the present work.

We believe that such experimental set-ups will help in sheding some light on the issue of the quantum mechanical nature of the MT arrangements, and even on the processes of the transmission of electric signals (stimuli) by the neuronic systems. Clearly much more work needs to be done before even tentative conclusions are reached, concerning the nature of the MT arrangements. However, we believe that the present work constitutes a useful addition to the programme of understanding the nature of the MT arrangements inside the cell, and the associated processes of energy transfer across the cells.

ABSTRACT

Microtubules are hollow cylindrical polymers composed of the highly negatively-charged (~23e), high dipole moment (1750 D) protein α, β- tubulin. While the roles of microtubules in chromosomal segregation, macromolecular transport and cell migration are relatively well-understood, studies on the electrical properties of microtubules have only recently gained strong interest. Here, we show that while microtubules at physiological concentrations increase solution capacitance, free tubulin has no appreciable effect. For a particular microtubule concentration, we were able to quantify these effects by determining the capacitance and resistance of a single 20 μm-long microtubule to be 1.86×10^{-12} F and $1.07 \times 10^{12}\Omega$, respectively. Further, we observed a decrease in electrical resistance of solution, with charge transport peaking between 20-60 Hz in the presence of microtubules, consistent with recent findings that microtubules exhibit electric oscillations at such low frequencies. Our results show that in addition to macromolecular transport, microtubules also act as charge-storage devices through counterionic condensation across a broad frequency spectrum. We conclude with a hypothesis of an electrically-tunable cytoskeleton where the dielectric properties of tubulin are polymerization-state dependent.

KEYWORDS: *microtubules, biological nanowires, intracellular charge storage, intracellular ion conduction*

INTRODUCTION

Microtubules (MTs) are cylindrical polymers composed of the heterodimers of protein α, β- tubulin that play a variety of well-recognised intracellular roles, such as maintaining the shape and rigidity of the cell, aiding in positioning and stabilisation of the mitotic spindle for allowing chromosomal segregation, acting as 'rails' for macromolecular transport and forming cilia and flagella for cell movement. Since the tubulin dimer possesses a high negative electric charge of ~23e and a large intrinsic high dipole moment of 1750 D [1-2], MTs have been implicated in electrically-mediated biological roles [3-6]. They have been modelled as nanowires capable of enhancing ionic transport [7-8], and simulated to receive and attenuate electrical oscillations [4, 9-11]. In solution, MTs have been shown to align with applied electric fields [2, 12-16]. Recently, MTs have also been modelled as the primary cellular targets for low-intensity (1-2 V), intermediate-frequency (100-300 kHz) electric fields that inhibit cancer cell proliferation, in particular glioma [17-19]. Indeed, MTs have been reported to decrease buffer solution resistance [12-13], leading to a conductance peak at TTField-like frequencies [20]. While these studies show that MTs are highly sensitive to external electric fields, answers to the questions 'How do MTs effect a solution's capacitance?' and 'What is the capacitance of a single MT?' are still elusive and crucial to the determination of the dielectric properties of living cells. The tubulin concentration in mammalian cells varies in the micromolar range (~10-25 μM) [21-22]. *In vitro*, polymerizing tubulin at such high concentrations can lead to the formation of entangled meshworks, confounding quantification of the individual MT response to electric fields. Electro-rotation, dielectrophoresis and impedance spectroscopy are thus performed using low concentrations of tubulin, in the nanomolar regime, to enable robust observation of individual MTs.

MT formation and stability are known to be optimal in buffers with ionic strength between 80 and 100 mM [23-24]. A background of BRB80 (which consists of 80 mM PIPES, 2 mM $MgCl_2$ and 0.5 mM EGTA), is thus used to study the dynamics and mechanical properties of MTs. To study their electrical properties however, the usage of such high ionic-strength solutions has historically been problematic because any dielectric attenuation caused by MTs is overwhelmed by the noise and high conductivity from the background. In the low-frequency regime (1 Hz-100 kHz), two approaches have thus far been used to estimate the dielectric properties of MTs and tubulin. One is to electrically observe low concentrations of MTs (tubulin concentration in the nanomolar regime) in the presence of low ionic strengths [12-13, 20, 25-26]. Such studies overlook the intrinsic ionic concentration of mammalian cytosol, which varies between 200 to 500 mM depending on the cell type [27-28]. Another approach to electrically interrogate MTs is to dry them: the conductivity of the buffer is nullified by evaporation, leaving polymeric tubulin behind [29-30] In a physiological situation however, MTs are solvated by the highly conductive and noisy cytosol.

In this paper, we report on our efforts overcome the barrier posed by a high ionic strength by performing electrochemical impedance spectroscopy (EIS) on cellular concentrations of tubulin. We have been able to successfully observe differences in impedance using a background of BRB80, which contains within an order of magnitude of physiologically measured ionic concentrations. Surprisingly, we find that MTs increase the solution capacitance of BRB80 whereas free tubulin does not, implicating a difference in electrical properties based only on the morphology of this protein solute. We also report a 'reversal' in the resistive behaviour of MTs compared to BRB80, with a reduction in solution resistance peaking at 20-60 Hz, a finding consistent with recent reports showing that polymerized tubulin quasi-resonantly responds to electric oscillations at ~39 Hz [9-10]. Using an equivalent circuit model for MTs, we experimentally

determine the capacitance and resistance of the MT meshwork to be 1.27×10^{-5} F and 9.74×10^{4} Ω at physiological concentrations of tubulin. Using approximations, we quantify the capacitance and resistance for an individual MT as 1.86×10^{-12} F and 1.07×10^{12}Ω. Our values are in agreement with previous calculations and indicate that the polymerization of tubulin into MTs alters spatial and temporal charge distribution, altering the electrical properties through charge storage in the cell.

RESULTS

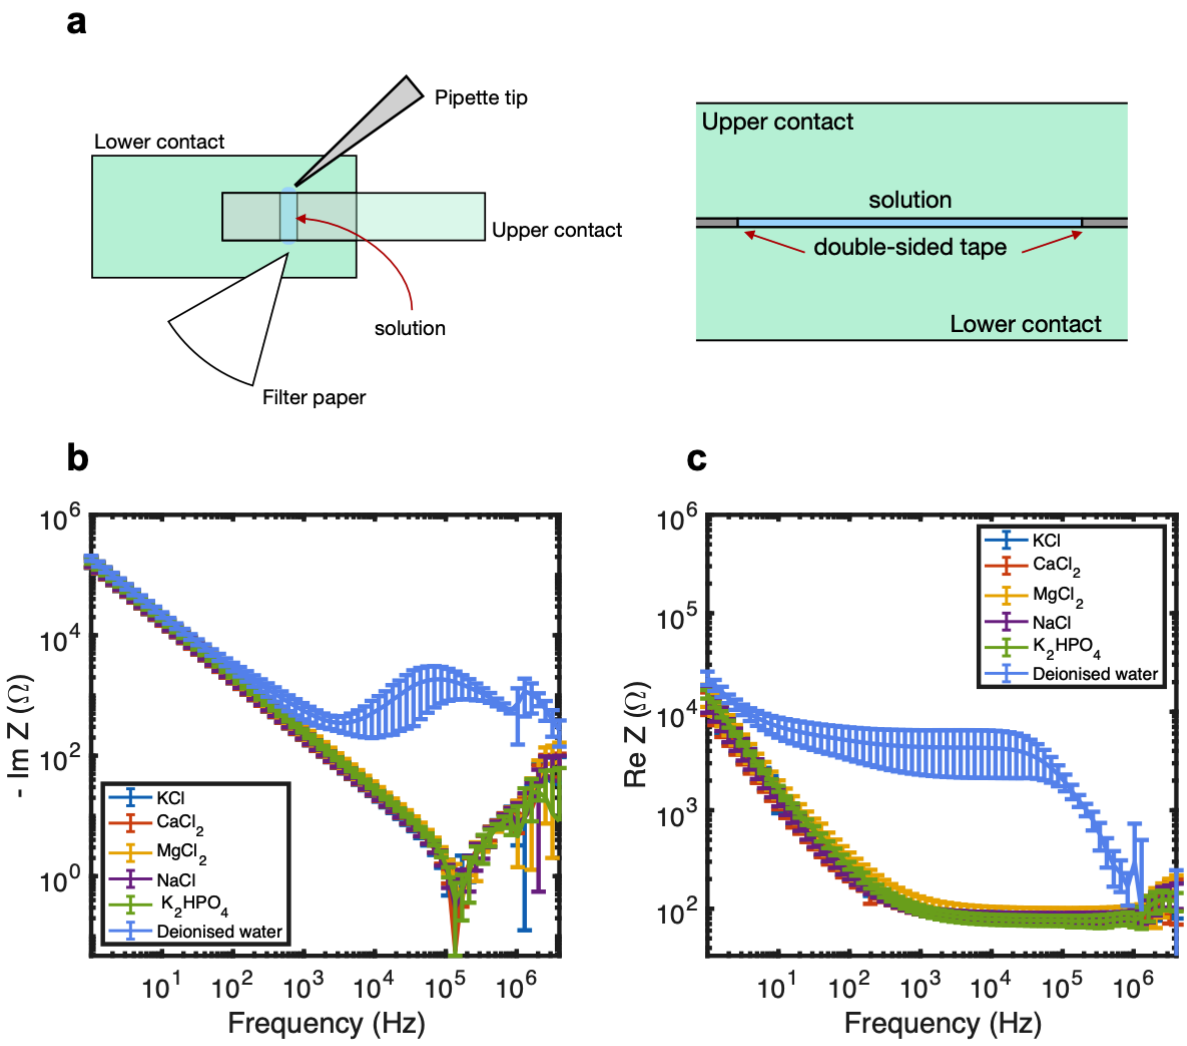

Figure 1. A parallel-plate contact device to measure the impedance properties of MTs compared to tubulin. The operation of the parallel plate device showing (a) top view (left) and side view (right). The upper and lower contacts, double-sided tape and solution are labelled in green, gray and blue, respectively. (b) Imaginary component of impedance for electrolytic solutions at 100 mM and de-ionized water. (c) Real component of impedance for electrolytic solutions at 100 mM and de-ionized water. Data display average values collected between 15 and 21 times. Error bars represent standard deviation. For measurement setup and perfusion protocols, see Materials and Methods.

A parallel-plate contact device can accurately measure dielectric properties of ionic solutions such as the cytosol

To determine the differences in the dielectric properties of solution caused by the presence of MTs, we aimed to create an electrode geometry that would be experimentally robust and easily modelled. We fabricated an FTO-coated parallel-plate contact device (Figure. 1a, Materials and Methods), which allowed EIS using a solution-exchange method.

We started by performing EIS on electrolytes found in the cytosol and observed a decrease in the imaginary component of impedance as a function of decreasing input frequency (Figure. 1b). The total impedance of our system was given by:

$$Z = \mathrm{r_c} + \frac{\mathrm{r_s}}{1+(\mathrm{r_s}\omega\mathrm{C})^2} + j(\omega\mathrm{L_c} - \frac{\mathrm{r_s}^2\omega\mathrm{C}}{1+(\mathrm{r_s}\omega\mathrm{C})^2}) \quad (1)$$

Here, Z is the impedance, ω is the angular frequency (given by $2\pi f$ where f is the input voltage frequency), C is the system capacitance, $\mathrm{L_c}$ is the cable inductance, $\mathrm{r_s}$ and $\mathrm{r_c}$ are the solution and cable resistances respectively. We also observed a decrease in the real component of impedance as a function of decreasing input frequency (Figure 1c). Such a trend is expected from Warburg impedance [32-33] and follows the equation:

$$Z_{complex} = \frac{A_\omega}{\sqrt{\omega}} + \frac{A_\omega}{j\sqrt{\omega}} \quad (2)$$

where $Z_{complex}$ is complex impedance and A_ω is the Warburg coefficient. Our circuit simplifies to the equation below if we ignore the effect of cable inductance ωL_c, at frequencies below 10^5 Hz:

$$Z = r_c - j\frac{1}{\omega C} \quad (3)$$

Our results emulated previous data [34-36] and validated the experimental setup for further analysis.

3.2 MTs increase solution capacitance compared with background, while unpolymerized tubulin does not have a significant effect

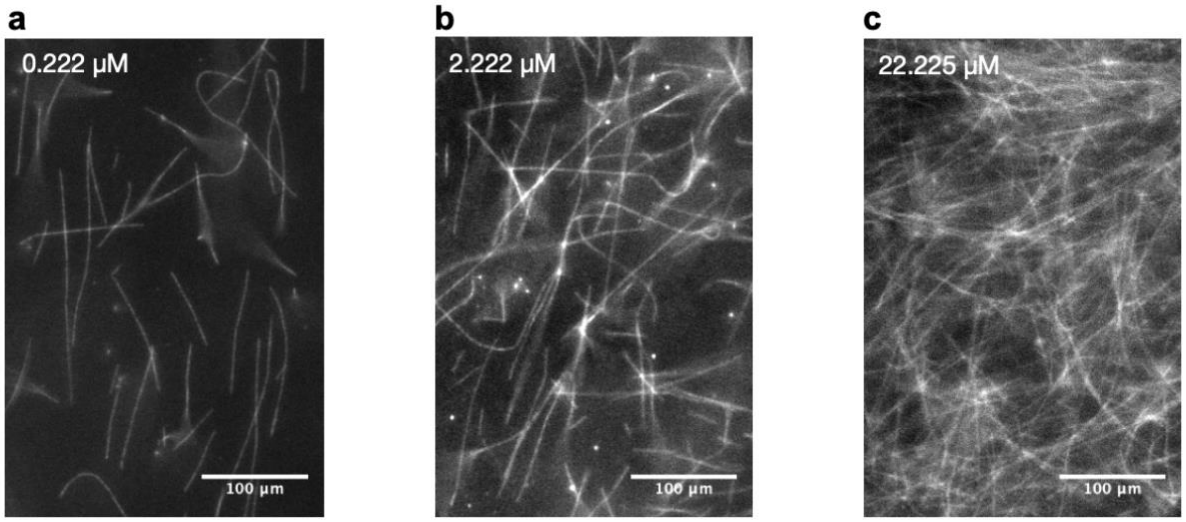

Figure 2. Microtubule imaging at different tubulin concentrations. Polymerization was performed using 45 µM tubulin, and MTs were stabilized with 50 µM paclitaxel, and subsequently diluted to a final concentration of (a) 0.222 µM tubulin (b) 2.222 µM tubulin (c) 22.225 µM tubulin, respectively. For imaging setup and polymerization protocols, see Materials and Methods.

We reconstituted and polymerized fluorescent tubulin from a stock of 45.45 μM tubulin solution (Materials and Methods). MTs were stabilised using 50 μM paclitaxel [37-38] and imaged using an epi-fluorescence microscope. On diluting MT concentration across three orders of magnitude (0.222, 2.222 and 22.225 μM tubulin), we observed that while individual MTs at low concentrations were separated by large distances, those at cellular concentrations formed enmeshed networks reported previously (Figure 2 a, b, c) [39]. Such interconnected MT meshworks are utilized by molecular motors for long-range macromolecular transport [40-41]. Here, their presence demonstrated successful MT polymerization for electrical characterization.

We performed EIS on BRB80, BRB80T (BRB80 supplemented with 50 μM paclitaxel; background for all MT-containing solutions), and MT-containing solutions in increasing order of concentration (Figure S3 a, b). We subtracted impedance values obtained for BRB80T alone from those in MT containing solutions, to determine the MT contribution to impedance. Our results showed that with an increasing MT concentration, the value of imaginary impedance became more negative, resulting in positive impedance differences (Figure 3a, b, c, d). This effect was highest at 1 Hz and decreased with a decreasing input frequency (Figure S4 a, b, c, d, e, f). Experiments with unpolymerized tubulin at the same concentrations were performed using the identical procedure, but using BRB80C (BRB80 was supplemented with 50 μM colchicine) as a background, to prevent MT nucleation [42-43]. Results with tubulin did not show an appreciable deviation at any concentration. Based on the above we can conclude that polymerization of tubulin into MTs alters their ensemble electrical properties, increasing the solution's capacitance on forming MTs and their meshworks. An increase in the solution's capacitance due to MTs has

previously been modelled, [7, 44-45] indicating an increase in charge storage as free tubulin polymerizes.

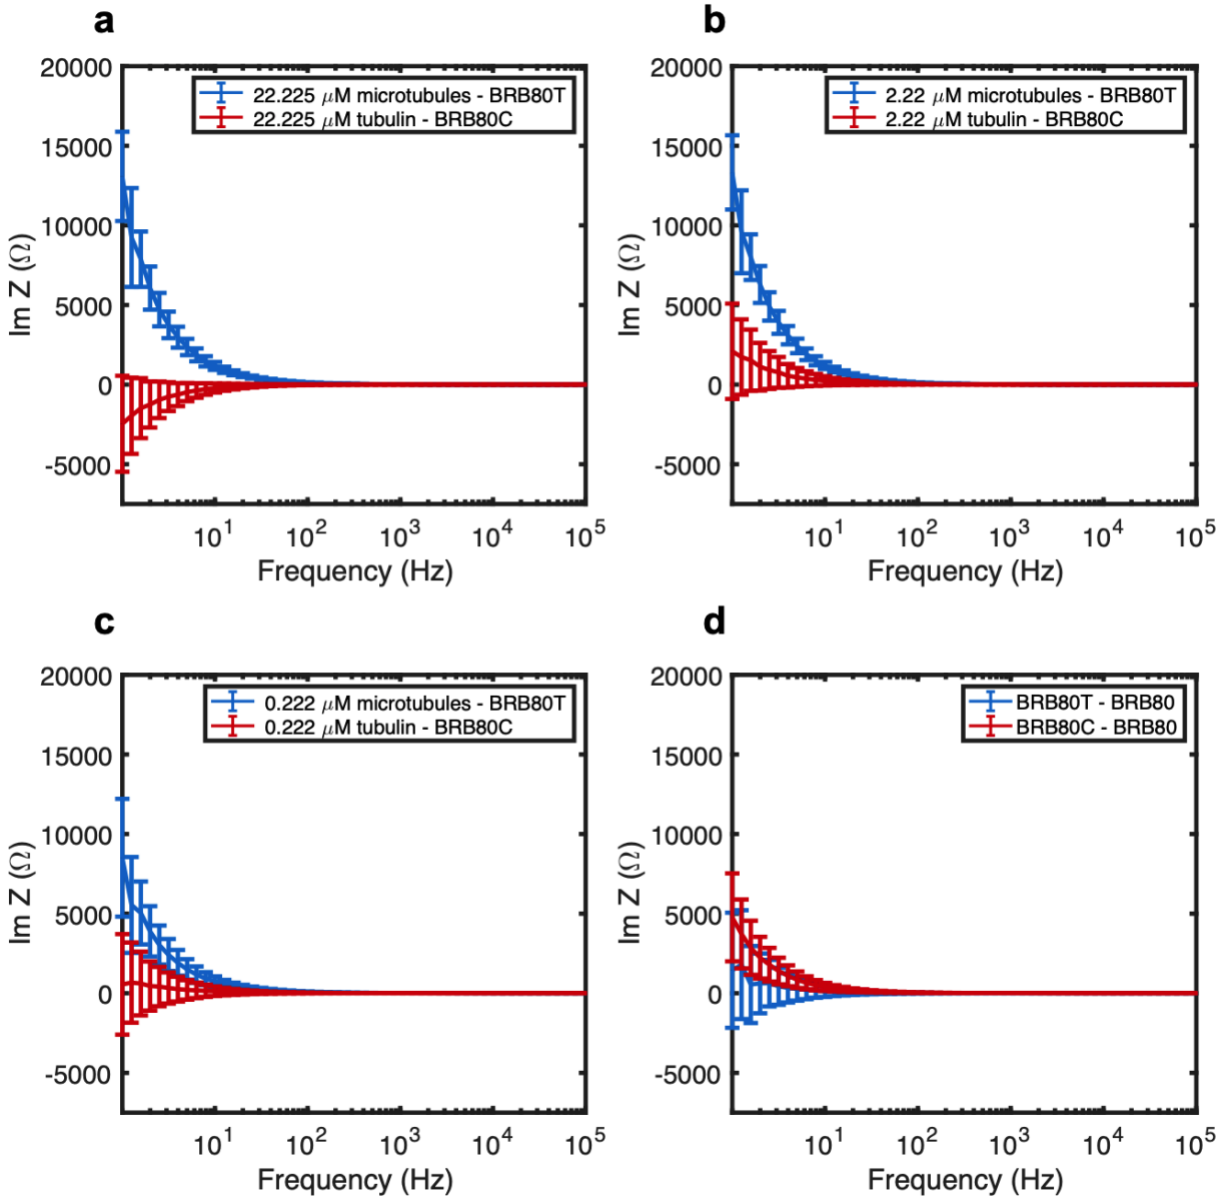

Figure 3. Mean differences in the imaginary component of impedance as a function of decreasing input AC frequency at total tubulin concentrations of (a) 22.225 μM (n = 22 experiments for tubulin, n = 21 for MTs), (b) 2.222 μM (n = 35 experiments for tubulin, n = 49 for MTs) (c) 0.222 μM (n = 35 experiments for tubulin, n = 49 for MTs), (d) comparison of the effects of paclitaxel

(BRB80T) and colchicine (BRB80C, n = 49 experiments for BRB80T, n = 35 for BRB80C, n = 84 experiments for BRB80). Error-bars represent standard deviation.

Microtubules increase solution resistance compared to background with this effect's reversal observed at low frequencies

Next, we looked for differences between MTs and tubulin in the real component of impedance (solution resistance). Previous studies using nanomolar tubulin concentrations and low ionic strengths (1-12 mM) have indicated that MTs enhance charge-transport in solutions [13, 20, 46]. To evaluate if this observation held true at physiologically relevant tubulin concentrations and at higher ionic strengths, we also analyzed the real component of impedance. Addition of both MTs and tubulin generally led to solution led to an increase in resistance (Figure S7 a, b, c, d), with MTs having a higher resistance at low frequencies (1-20 Hz) compared to unpolymerized tubulin. Unexpectedly, a 'reversal' of this behaviour was observed at higher frequencies as MTs began to lower solution resistance compared to tubulin (Figure S5 a, b, c, d, e, f). The reversal took place gradually between 10 and 300 Hz, with a peak between 20 and 60 Hz (Figure 4 a, b, c). Interestingly, within this range, we also found that the addition of MTs lowered solution resistance compared to background buffer BRB80T.

A reversal frequency in resistance between MTs and tubulin has not been reported before and displays the utility of our 'cell-like' approach, because the extent of this reversal decreased with decreasing concentration and was not displayed in the imaginary component of impedance or when BRB80C and BRB80T were compared. It is worth noting that recent findings using this approach showed that MT bundles and tubulin sheets generate electrical signals at ~39 Hz [9-10], and predicted

an increase in solution conductance in the range that we observe, indicating that the conductance behaviour at such frequencies was due to MT- generated electrical oscillations.

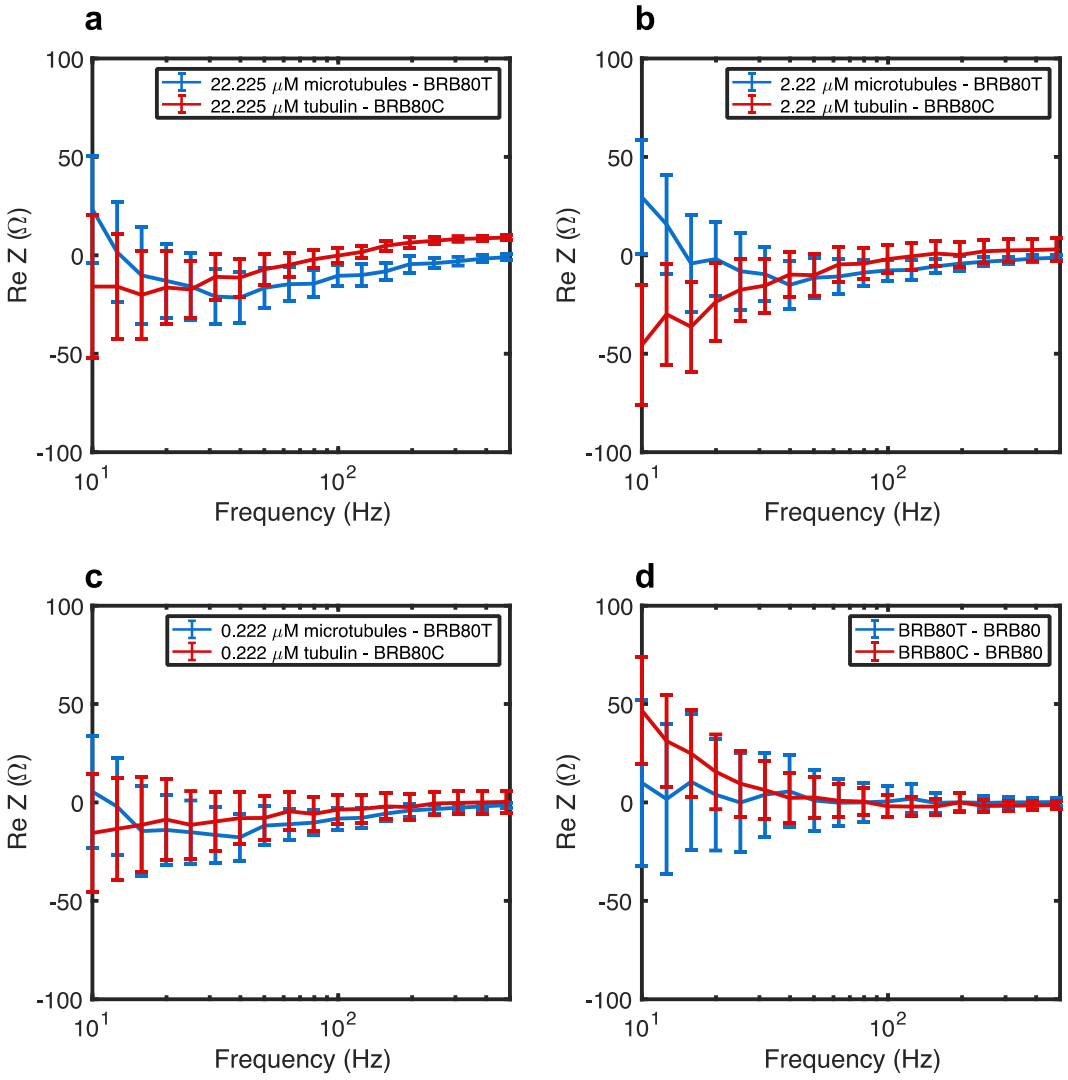

Figure 4. Mean differences in the real component of impedance as a function of decreasing input AC frequency at total tubulin concentrations of (a) 22.225 μM, (b) 2.222 μM, (c) 0.222 μM, (d) comparison of the effect of paclitaxel and colchicine on impedance. Error-bars represent standard deviation.

The microtubule meshwork can be described as an RC circuit in parallel

Using our experiments, our next aim was to quantify the electrical properties of a single MT. Impedance difference curves appeared linear on log-log plots with a slope of approximately negative unity, suggesting that the MT meshwork resulted in the addition of a capacitive element to the solution. We examined several combinations but a parallel RC circuit to represent the entire MT meshwork provided that best fit to observed curves (Figure 5):

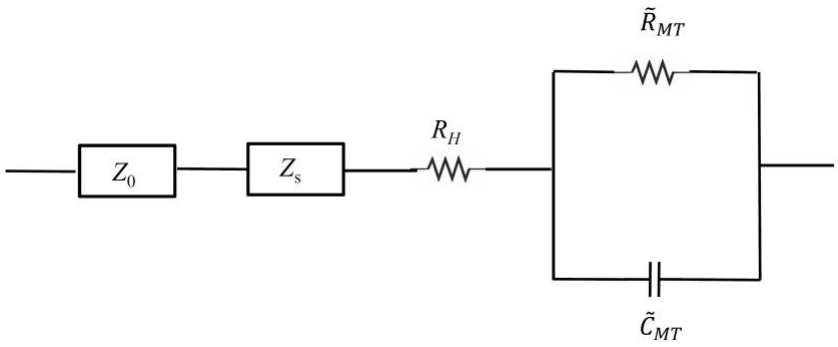

Figure 5. The equivalent electrical circuit model representing the microtubule meshwork as a parallel RC circuit, with meshwork resistance $\tilde{R}_{MT}$ and capacitance $\tilde{C}_{MT}$. The external element has impedance Z_0, while solution has impedance Z_s. R_H is the small constant resistance that is ascribed to small fraction of unpolymerized tubulin that is present in MT containing solutions.

We modelled the impedance caused by external circuit elements and BRB80T as Z_0 and Z_s respectively, as shown in Fig 5. The net impedance of the background BRB80T was thus given by:

$$Z_{\mathrm{buffer}} = Z_0 + Z_\mathrm{s} \tag{4a}$$

Denoting the impedance, resistance and capacitance of the entire MT meshwork by $\tilde{Z}_{\mathrm{MT}}$, $\tilde{R}_{MT}$ and $\tilde{C}_{MT}$ respectively, the impedance for the circuit with MTs is given by:

$$Z_{\mathrm{MT+buffer}} = Z_0 + Z_{\mathrm{s}} + R_{\mathrm{H}} + \tilde{Z}_{\mathrm{MT}} \tag{4b}$$

where,

$$\frac{1}{\tilde{Z}_{\mathrm{MT}}} = \frac{1}{\tilde{R}_{\mathrm{MT}}} + \mathrm{j}\omega\tilde{C}_{\mathrm{MT}}$$

Additionally, the impedance differences between solutions with and without MTs are given by:

$$\Delta Z = Z_{\mathrm{MT+buffer}} - Z_{\mathrm{buffer}} = R_{\mathrm{H}} + \tilde{Z}_{\mathrm{MT}} \tag{5}$$

where

$$\tilde{Z}_{\mathrm{MT}} = \frac{\tilde{R}_{\mathrm{MT}}}{1 + (\omega\tilde{C}_{\mathrm{MT}}\tilde{R}_{\mathrm{MT}})^2} - \mathrm{j}\frac{\omega\tilde{C}_{\mathrm{MT}}\tilde{R}_{\mathrm{MT}}{}^2}{1 + (\omega\tilde{C}_{\mathrm{MT}}\tilde{R}_{\mathrm{MT}})^2} \tag{6}$$

We subsequently fit experimental impedance difference curves shown in Figure 3 and Figure S7 to real and absolute value of imaginary parts of ΔZ using R_{H}, $\tilde{R}_{MT}$ and $\tilde{C}_{MT}$ as our fit parameters. Here, R_{H} is a resistance ascribed to the nominal fraction of unpolymerized tubulin present in MT containing solutions. The fitted curves are displayed in Figure 6 and the optimal fit parameters are listed in Table 1 (see Materials and Methods for details).

Tubulin] (μM)	$\widetilde{\boldsymbol{C}}_{\boldsymbol{MT}}$ **(F)**	$\boldsymbol{\delta\widetilde{C}_{MT}}$ **(F)**	$\widetilde{\boldsymbol{R}}_{\boldsymbol{MT}}$ (Ω)	$\boldsymbol{\delta\widetilde{R}_{MT}}$ (Ω)	$\widetilde{\boldsymbol{R}}_{\boldsymbol{H}}$ (Ω)	$\boldsymbol{\delta\widetilde{R}_{H}}$ (Ω)

0.222	2.01×10^{-5}	3.38×10^{-7}	9.97×10^{4}	2.82×10^{4}	0.41	31.95

Table 1. Fit parameters attained by fitting the real and imaginary components of impedance to equation 6. Fit parameters represent effective capacitance $\tilde{C}_{MT}$, and resistance $\tilde{R}_{MT}$ introduced into

the solution through the addition of the MT meshwork at different concentrations. R_{H} is the small constant resistance that is ascribed to small fraction of unpolymerized tubulin that is present in MT containing solutions. $\delta\tilde{R}_{MT}$, $\delta\tilde{C}_{MT}$ and $\delta\tilde{R}_{H}$ correspond to 95% confidence intervals for the fit parameters. Corresponding graphs are displayed in Figure 6.

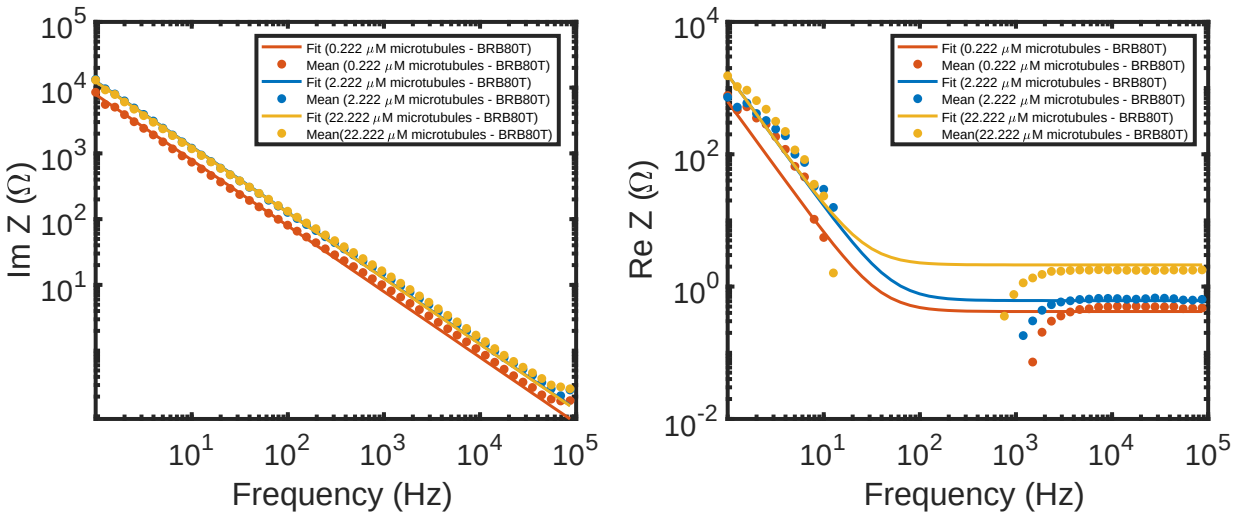

Figure 6. Mean differences of (a) imaginary and (b) real impedance curves for 0.222 μM, 2.222 μM and 22.222 μM, are fitted with the model described in Eq. 5 and Figure 5. Fit parameters and confidence intervals are displayed in Table 1. For detailed fitting methodology, see Materials and Methods.

Experimentally derived values for the capacitance and resistance of a single microtubule match theoretical predictions.

To determine the capacitance and resistance of a single MT from corresponding meshwork mean values, we made two assumptions. (1) The average length of an MT was taken as 20 μm based on visual inspection and (2), MTs were oriented in parallel to one another at 0.222 μM concentration (Figure 2 a). We did not extend the second assumption to concentrations of 2.22 μM and 22.22

μM due to the complex nature of the meshwork, for which a superficial series and/or parallel circuit combination would be inadequate. However, our simple assumptions do provide an upper limit for the capacitance of a single MT. Given the presence of $N = 1.08 \times 10^7$ MTs in our solution volume at the 0.222 μM concentration, the capacitance for a single 20 μm long MT was calculated to be $C_{MT} = \tilde{C}_{MT}/N = 1.86 \times 10^{-12}$ F. We extended our set of assumptions to calculate the resistance of a single 20 μm long MT at 0.222 μM concentration. Here, the total resistance of the MT meshwork would be given by $\tilde{R}_{MT} = R_{MT}/N$ where each MT has resistance R_{MT}, implicating $R_{MT} = \tilde{R}_{MT} \times N = 1.07 \times 10^{12}\Omega$.

To determine if these values were consistent with theoretical predictions, we first calculated the Debye Length λ_D of an MT when present in an ionic concentration $c = 80$ mM to account for an environment consisting of BRB80T.

$$\lambda_D = \frac{\lambda_D^0}{\sqrt{c}} \tag{7}$$

Here, λ_D^0 is a Debye length (calculated to be ~10 nm) in a solution with ionic concentration $c_0 = 1$ mM [13]. Based on the Debye length, the total capacitance of the MT cylinder has been calculated by previous models to be given by [8, 44]:

$$C_{MT,theor} = \frac{2\pi\varepsilon_0\varepsilon l}{\ln\left(\frac{r+\lambda_D}{r}\right)} \tag{8}$$

Substituting the value of λ_D from equation (7) and using the Taylor series expansion for $\ln(1+x)$, we get:

$$C_{MT,theor} = \frac{2\pi\varepsilon_0\varepsilon l}{\ln\left(1 + \frac{\lambda_D^0}{r\sqrt{c}}\right)} \approx \frac{2\pi\varepsilon_0\varepsilon l r\sqrt{c}}{\lambda_D^0} \quad (9)$$

We continued our previous assumption that each microtubule has length $l = 20$ µm, radius r = 12.5 nm and is surrounded by an atmosphere of dielectric constant $\varepsilon = 80$. Placing these values in Equation 9, we calculated the total capacitance of an MT to be 9.8 pF. Interestingly, previous work shows that $\varepsilon < 10$ for tubulin protein [1], enabling an extrapolation of $\varepsilon = 40$ between the protein and the bulk solution [47]. The use of this intermediate value for ε leads to an MT capacitance of 4.9 pF. It is worth noting that both these values are consistent with our experimentally observed value of 1.86 pF per MT.

Fluorescence images (Figure 2 a) showed that MTs orient in the plane of glass surfaces at low concentrations, indicating that resistance to ionic charge transport in solution arose from flow across the porous MT cross section, rather than along their lengths. The lower limit of Ionic current through nanopores present between adjacent tubulin dimers in two-dimensional zinc-induced sheets is previously calculated to be $0.02fA$, at a driving voltage of 5 mV [10]. This leads to a nanopore resistance of $R_{nanopore} = 2.50 \times 10^{14}$ Ω. We note that the conditions of our study vary significantly from those in this reference: Firstly, unlike two-dimensional sheets which present ions with a single resistance, cylindrical microtubules used in our study present both MT entering and MT exiting resistances (Figure 8 a). Secondly, the study utilizing sheets was performed at an ionic concentration of 140 mM, whereas our study was performed at a corresponding concentration of 80 mM. Thirdly and importantly, the resistance calculated above applies to resonant conditions,

with the driving input frequency in the range of 10-100 Hz and would reduce as the input frequency is altered.

We calculated the total resistance for ions entering and exiting transversely through an MT as $R_{MT,enter} = R_{MT,exit} = \frac{R_{nanopore}}{n} = 7.69 \times 10^9\ \Omega$ where n is the total number of nanopores (equal to the number of tubulin dimers) in a 20 μm long MT. We then addressed the first dissimilarity mentioned above, regarding MT entering and exiting impedances, by adding these resistances in series. This leads to total resistance $R_{MT} = R_{MT,enter} + R_{MT,exit} = 1.54 \times 10^{10}\ \Omega$ for ionic movement across the cross section. We also note that theoretically, the total ionic resistance across the cross section has been calculated by [48]:

$$R_{MT,theor} = \frac{\ln\left(1 + \frac{\lambda_D}{r}\right)}{2\pi l\sigma} \approx \frac{\lambda_D}{2\pi l\sigma} \tag{10}$$

Here, the solution conductivity σ is proportional to the ionic concentration c. Additionally, because λ_D depends inversely on the square root of ionic concentration, $R_{MT,theor}$ scales with $\frac{1}{c^{3/2}}$. Thus, to correct for the second dissimilarity arising from the difference in ionic concentration, we multiplied our resistance by a factor of $\mu = \left(\frac{140}{80}\right)^{3/2} = 2.31$. Thus, our computed final value for the resistance across the MT cross section was $\mu \times R_{MT,theor} = 4.71 \times 10^{10}\ \Omega$. We expect the resistance of the MT to be higher in non-resonant conditions (at frequencies >100 Hz), implicating a close match to our experimentally derived value of $1.07 \times 10^{12}\Omega$. As the applied AC voltage oscillates with the frequency it switches electric field direction every half cycle, aiding the movement of in-phase ions across the MT wall, but impeding this flow in out-of-phase ions. Thus, the total resistance is also a function of the input frequency.

Ionic movement to enter the MT cylinder takes place against the potential gradient set up by the tubulin dipole in the MT wall, which could additionally account for the high resistance that we observe.

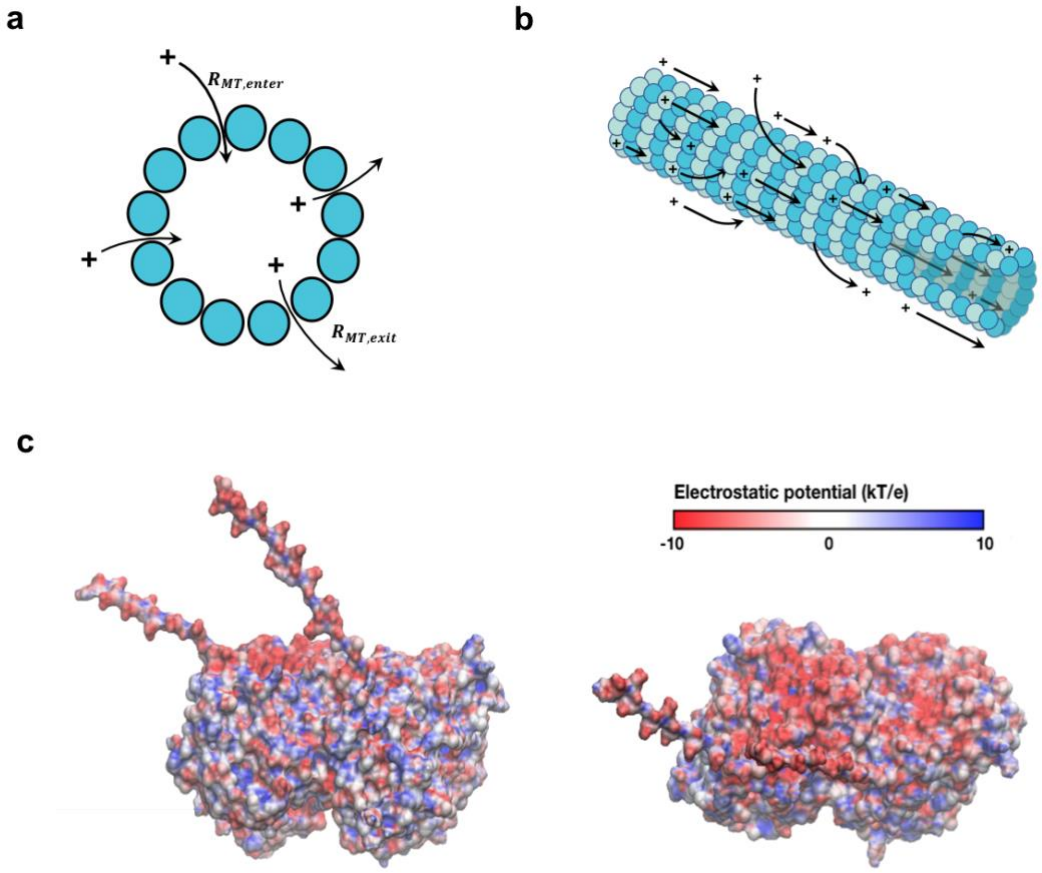

Figure 8. Schematic of charge transport along and across an MT. (a) A representation of charge flow across the MT cross section through nanopores present between adjacent protofilaments. (b) A representation of charge flow through both inner and outer modes along an MT. Arrows depict charge flow via both mechanisms, enabling MT charge storage across a broad spectrum of frequencies, and charge transport at low AC frequencies in the cell. (c) Side view (left) and top view (right) of the tubulin dimer, displaying distribution of electrostatic potential at different

locations. The negatively charged C-termini face towards the solution and contains ~50 % of the total negative charge on a tubulin dimer.

DISCUSSION

Our measurements using a parallel plate contact device reveal interesting electrical properties of MTs at physiological concentrations. Unlike studies exposing MT-containing solutions to non-uniform electric fields [12-14, 20], our device allowed robust quantification of electrical impedance in the presence of spatially uniform electric fields. Our results show that the addition of MTs mimics a parallel RC element placed in series with the high-ionic strength solution, with a nonlinear dependence on the MT number. Unpolymerized tubulin did not alter capacitance significantly, indicating changes in electrical properties of tubulin as it polymerizes.

The physical underpinnings of an increased capacitance

Dense counterion condensation on the MT surface has been previously extensively predicted and simulated due to a variety of reasons [7-8, 44, 49-50]. Firstly, the negative charge of the tubulin dimer attracts counterions in solution, leading to the presence of a double layer and depletion region outside the microtubule surface [7-8, 46, 50]. In addition to this, the charge distribution in the MT protein wall is highly non-uniform, with the outer surface containing approximately four times the charge compared to the inner surface [49]. This asymmetry between the inner and outer electrostatic potentials serves to enhance capacitance and is responsible for the abnormally large dipole moment of the tubulin dimer [1]. The asymmetry also manifests through C-terminal ‘tails’ composed of 10-12 amino-acids, that can extend 4-5 nm outwards from each tubulin monomer. These slender C-termini tails are highly negative, containing about 50 % of the charge of the tubulin dimer [51]. As

they stretch outwards into the solution in a pH and ionic strength dependant manner, they increase the effective area of the tubulin dimer and significantly contribute to the overall MT capacitance [7-8].

Coherent oscillations of these C-terminal tails are modelled to generate solitonic pulses of mobile charge along the outer surface of an MT, creating ionic currents along its' length [7, 44, 52].

Ions from the bulk solution are also modelled to be pumped into the hollow MT lumen through nanopores in its' wall, resulting in charge accumulation inside the cylindrical MT over time [45]. A recent study using molecular dynamics simulations showed that the permeability of the MT lumen was significantly higher for Na^+ and K^+ as opposed to Ca^{2+}, allowing for free movement of selective ions into the MT lumen across its porous surface [49]. To the best of our knowledge, our findings are the first to experimentally quantify this resistance encountered by charge flow across the MT cross section. These results implicate not only ionic movement along the microtubule axis, but also across and inside it, enhancing the modelled roles of MTs as complex subcellular nanowires.

Implications for the cell

Our findings on cell-like complex MT networks at physiological tubulin concentrations indicate a cellular role for MTs as wires that store charge. Neuronal environments where the MT are spontaneously nucleated from free tubulin, such as growth cones, would experience large capacitance changes over short bursts of time. This ability would significantly impact action potentials, that are known to depend strongly on the local charge distributions [53]. Additionally, ionic movement across the MT wall would enhance their roles as attenuators of local cation

distributions. In nonneuronal environments, transient ionic currents around on a MT during mitosis could impact MT dynamics and potentially influence chromosome segregation. Specifically, Ca^{2+} ion storage/flow about an MT would trigger its' depolymerization, whereas waves of Mg^{2+} or lowering in the local pH (increasing H^{+}) would lead to MT stabilization [54-55]. The attraction of Zn^{2+} or Mn^{2+} ions in the vicinity would lead to formation of two-dimensional tubulin polymers [56-57]. Properties of the cytoplasm such as polarizability and relative permittivity would get severely attenuated due to the presence of MTs in the vicinity. Due to the polymerization state of tubulin altering solution capacitance, our findings implicate a temporal evolution of capacitance and ionic flows as the ratio of MTs to free unpolymerized tubulin changes [58-60]. MT lattice defects, that take place when a tubulin dimer is missing in an MT wall [61-62], would cause a large ionic flux to develop at the defect site. Such localised shifts in charge distributions would be most significant at the MT end, where large localized charge fluxes would form due to sudden changes in both ionic resistance and capacitance. Free/polymerized tubulin would thus regulate local and global electrical properties, creating spatially dynamic gradients of charge storage and flux. We envision a cytoskeleton that, in addition to transporting macromolecules, stores and transports ionic signals and electrical information across the cytoplasm (Figure 8 b).

Our findings can be coupled with a vast array of bio-nanodevices that utilize MTs and MAPs (microtubule-associated proteins) for construction of bio-nanotransporters and bio-actuators (Diez 2003; Hess 2018; Li 2018; Kapitein 2018; Yokokawa 2012). In specific conditions, MAP-MT systems are capable of repositioning organelles (Kapitien 2017), directionally transporting microtubules (Yokokawa 2004; Isozaki 200) and even drive their movement within zero-mode waveguides (Yokokawa 2018) and inorganic nanotubes (Li 2014). Charge storage and transport

along MTs can be coupled to mechanical MAP-based movement to develop a wide range of nano-actuators and nano-sensing devices.

Future work

When compared to cells, the rates of MT nucleation and polymerization are significantly lower in BRB80. This difference can be attributed to the absence of MAPs and macromolecular crowding [63-64]. Mammalian cells contain high concentrations of K^+ ions (140-300 mM) [27-28], which, in addition to MAPs and molecular crowding agents, would be included in a future study to attain physiological equivalence. Raw data from complex impedance will be used to derive properties of individual MTs such as the dielectric constant, refractive index, polarizability and Debye relaxation time through the Clausius-Mossotti equation. To improve the present two-contact parallel-plate device, a four-contact device will lower electrode polarization effects and enable quantification of the relative permittivity of MT and tubulin containing solutions. Our device geometry will also be used to perform DC (direct-current) measurements, determine the contribution of MTs to impedance relaxation time and evaluate the voltage dependence of capacitance on MT-containing solutions. Interestingly, this aspect has been discussed previously: the inductance of a single protofilament is calculated to be <1 fH [8]. Further investigation is required to experimentally confirm these predictions.

CONCLUSIONS

We used EIS to compare the complex impedance of MT- and tubulin-containing solutions. A high ionic strength buffer (BRB80) created a high noise, low impedance background, which was countered through the use of physiological concentrations of tubulin. While the presence of MTs

increased solution capacitance, unpolymerized tubulin did not have any appreciable effect. We used an RC circuit to model the MT meshwork across three orders of concentrations, and found at physiological levels, the capacitance and resistance of the meshwork is to be 1.27×10^{-5} F and 9.74×10^{4} Ω . In a study that is the first of its' kind to the best of our knowledge, we determined the capacitance of a single MT to be 1.86×10^{-12} F. We used our lowest, 0.222 μM concentration, for this calculation and assumed that MTs were oriented in parallel to one another. We envision a dual electrical role for MTs in the cell: that of charge storage devices across a broad frequency spectrum (acting as storage locations for ions), and of charge transporters (bionanowires) at specific, low frequencies between 20 and 60 Hz. Our findings also indicate that the electrical properties of tubulin dimers change as they polymerize, revealing the potential impact of MT nucleation and polymerization on the cellular charge distribution. Our work shows, that by storing charge and attenuating local ion distributions, microtubules play a crucial role in governing the bioelectric properties of the cell.

MATERIALS AND METHODS

Tubulin reconstitution

Before reconstituting tubulin solution from lyophilized protein powder, G-PEM buffer was prepared by adding 2.5 μL GTP to 247.5 μL BRB80 (Cytoskeleton Inc; BST01). 180 μL of G-PEM buffer was pipetted into lyophilized tubulin powder (Cytoskeleton Inc; T240). 20 μL of MT cushion buffer (60% glycerol in BRB80) was subsequently added. All steps were performed on ice.

Rhodamine-labelled tubulin solution was prepared by adding 4 μL of G-PEM buffer to labelled tubulin powder (Cytoskeleton Inc; TL590m) and subsequently adding 1 μL of MT cushion buffer.

A final tubulin stock solution of 45.45 μM was thus prepared, and a final labelling ratio of 1:15 was used. Finally, aliquots were snap-frozen and stored at -80 °C.

MT polymerization and stabilization

MT polymerization was performed by incubating 45.45 μM tubulin aliquots in a 37 °C water bath for 30 minutes. BRB80 solution was heated alongside tubulin during the first 15 minutes of polymerization. Subsequently, BRB80 was incubated at room temperature, and paclitaxel solution (Cytoskeleton Inc, TXD01; 2 mM stock) was thawed at room temperature alongside it. After 30 minutes of tubulin polymerization brought to completion, 100 μL of BRB80 was added to 5 μL of 2 mM paclitaxel. For preparing 0.222 μM MTs, 99.5 μL of this solution was added to 0.5 μL tubulin solution. For 2.222 μM MTs, 95 μL of this solution was added to 5 μL tubulin solution. For 22.225 μM MTs, 5 μL of this solution was added to 5 μL of tubulin solution. For preparing BRB80T, 45 μL of this solution was added to 45 μL of BRB80.

For tubulin stabilization, 2 μL of colchicine stock solution (Sigma-Aldrich, C9754; 5 mM in DMSO) was added to 100 μL BRB80. For preparing 0.222 μM tubulin, 99.5 μL of this solution was added to 0.5 μL unpolymerized tubulin solution. For 2.222 μM tubulin, 95 μL of this solution was added to 5 μL unpolymerized tubulin solution. For 22.225 μM tubulin, 5 μL of this solution was added to 5 μL of unpolymerized tubulin solution. For preparing BRB80C, 45 μL of this solution was added to 45 μL of BRB80.

Fluorescence imaging of MTs

Imaging was performed on a Zeiss Examiner.Z1 microscope using a Hamamatsu EMCCD C9100 camera, a Zeiss plan-Apochromat 1.4 NA 63x lens. After pipetting MT solution (2-5 μL) onto a glass slide (VWR 48382-173) a coverslip (VWR 48393-070) was placed on the solution, allowing it to spread. The microscope used an EXFO X-Cite 120 fluorescence source and excitation and

emission filters of 535 nm and 610 nm, respectively. Exposure times between 50 ms and 300 ms were used for imaging to validate the presence of MTs.

Electrode design and device construction

Each 'plate' in the parallel-plate contact device was formed by FTO (Fluorine-doped Tin Oxide)-coated glass slides (Sigma Aldrich, 735140). The slides were cleaved to dimensions of 1.5 mm x 10 mm x 50 mm for the upper contact and 1.5 mm × 27 mm × 50 mm for the lower contact. The cleaving dimensions were set using 3D printed devices that were placed as holders (The Shack, University of Alberta; Figure S1). The slides were sonicated and subjected to Reactive Ion Etching (RIE) using a 5-minute exposure to oxygen plasma (Oxford Instruments, NGP80) to remove surface particulate matter. 70 μm thick double-sided tape was used as a spacer, which formed a chamber of dimensions 3 mm × 1.25 cm × 70 μm. The top electrode was placed using a separate 3D-printed holder device (Figure S1). Once the device was constructed using the above protocol, solution was perfused into the chamber using a pipette and a filter paper for suction (Video S1). We used flat copper electrode clips in a three-electrode configuration to connect to our capacitor device. The counter electrode was connected to the lower electrode, and the working and reference electrodes were connected to the top electrode of our device.

Impedance measurements

Experiments were conducted using Electrochemical Impedance Spectroscopy (EIS) on a Zahner Zennium impedance analyzer. The parallel-plate contact device was placed into the 3D-printed holder for stabilisation (Figure S1). The contacts from the machine were connected to the parallel-plate device using flat-faced copper alligator clips. A three-electrode configuration was used: the counter electrode was attached to the lower contact of the parallel-plate device, whereas the working electrode was attached to the upper contact with the reference electrode orthogonally

clipped onto the clip of the working electrode. Within the Thales Z3.04 environment, the Potentiostat Mode was ON; the stabilisation delay was set to 1 s, the rest potential drift tolerance was set to 250 μV, V_{rms} was set to 5 mV. Solutions were perfused into the experimental chamber using a micropipette tip at one opening, and a filter paper at the other opening for suction, similar to protocols used for TIRF (Total Internal Reflection Fluorescence) microscopy[31]. The frequency range of the EIS measurement was set from 4 MHz to 1 Hz, and data were subsequently collected.

Data analysis

MT and tubulin samples were analyzed using data from five to seven days of experiments. Each day consisted of three to seven solutions for each concentration being tested, with one frequency sweep per solution. Readings of each sweep were saved as a .csv file, and next sample was loaded by solution exchange method. Water was run as the first solution for each day of experiments. BRB80T was run prior to MT solutions, and BRB80C were run prior to the free tubulin containing solutions. MT- and free tubulin-containing solutions were run on separate days, in increasing order of concentration. MATLAB (The Mathworks; Natick, MA) scripts were used for data analysis. Fitting to the real and imaginary components of impedance was performed using the function lsqnonlin. Initial guess values for the MT meshwork resistance and capacitance were 10^5 F and 10^{-5} Ω, respectively, based on visual inspection of raw data. The initial guess values for the nominal series resistor, R_H, were set at 1.78, 0.6 and 0.4 Ω for with tubulin concentrations of 0.222, 2,222 and 22.222 μM respectively. The 95% confidence intervals were determined using the function nlparci. Error propagation was performed assuming no relationship between various days of data collection.

AUTHOR INFORMATION

Author contributions.

AK, JT and KS designed the paper. AK, SP, AB and UM collected the data. AK, SP, AB, KS and JP analysed and validated the data. AK, VR, KS and JT wrote the paper. AK, SP and JP made figures for the paper. KS, JT and JL provided resources for experimentation and analysis.

PHYSICAL REVIEW B VOLUME 16, NUMBER 6 15 SEPTEMBER 1977

Optical spectrum of a Hubbard chain

Pierre F. Maldague
IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598
(Received 18 April 1977)

The optical absorption of the one-dimensional Hubbard model is calculated by three different methods. Linear chains of five atoms and rings of five and seven atoms containing four electrons are treated numerically. The infinite-chain problem is solved first in the t-matrix approximation of Lyo and Holstein. It is shown that in this approximation, most of the high-frequency absorption is due to a bound state which lies above the band continuum. Finally, the absorption is evaluated in the memory-function formalism of Götze and Wölfle, which reduces to ordinary perturbation theory at high frequency. The three approaches are in qualitative agreement, and the differences between them can be explained by the nature of the approximations involved. Applications to tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) and the platinum salt $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ (KCP) are discussed.

I. INTRODUCTION

The goal of this paper is to calculate the optical absorption of a one-dimensional, interacting system of electrons. Our work was motivated by the infrared and optical anomalies recently observed in the quasi-one-dimensional metals tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) and $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ (KCP). It has been suggested by Torrance *et al.*[1] that the optical spectra of many TCNQ salts could be interpreted in terms of a strongly correlated Hubbard model, in which the long-range part of the Coulomb interaction is neglected. An unexplained anomaly has also been found[2] near the plasma edge of KCP; although it could plausibly be attributed to interband transitions,[3] the possibility that the electron-electron interaction plays a role in these anomalies cannot be discarded. Such experiments point out the need for a reliable theory of optical-absorption processes in correlated one-dimensional systems. In the present paper, we discuss three different methods to calculate the absorption spectrum of the Hubbard model. The first method consists in calculating the spectra of finite chains numerically; this brute-force approach can only be used for relatively short chains. The second method is based on the t-matrix approximation introduced by Lyo and Holstein,[4,5] who used it to calculate the low-frequency conductivity of the Hubbard model. We find that, in this approximation, most of the absorption is due to a bound state which lies above the band continuum, and which was neglected in their calculation (which is justified in the low-frequency limit considered by these authors). Finally, we calculate the optical conductivity in the memory-function approximation of Götze and Wölfle.[6] This approach is exact in the weak-coupling limit, since it reduces to ordinary perturbation theory at high frequency. Our purpose in using this last approach is twofold. First, it provides a test for the validity of the t-matrix approach in the weak-coupling limit. Second, it allows us to check the accuracy of the memory-function approximation when extrapolated to higher values of the coupling. We find that although the result of such an extrapolation has the correct order of magnitude, the memory-function approximation cannot be trusted for couplings which are not very weak. The failure of this approximation is related to that of the first Born approximation in the two-body scattering problem.

Three basic conclusions can be drawn from our results. First, the remarkable agreement between the numerical spectra and the t-matrix results indicates that the optical conductivity is indeed a measure of short-range correlations, which are correctly treated in the t-matrix approximation. This suggests that a similar method could also be used to treat more realistic models of a quasi-one-dimensional conductor. Second, we propose that the validity of the first Born approximation in a one- or two-body problem provides a useful criterion for the applicability of the memory-function approximation to the corresponding many-body problem. Third, we do find an absorption peak at a frequency of order U, the on-site repulsion energy, as suggested by Torrance *et al.* This peak is due to transitions in which the final state contains two electrons sitting at the same site. However, if we use parameters appropriate for TTF-TCNQ and KCP, we find that the optical (and infrared) absorption is quite small; most of the absorption occurs at or near zero frequency. This is especially true for KCP, which has a low carrier density (0.3 hole per Pt atom). Thus, it seems that some of the correlation effects neglected by the Hubbard model must play an important role in the optical anomalies observed in real quasi-one-dimensional conductors. This is hardly surprising, since the Hubbard model assumes (i) one tight-binding band, (ii)

a short-range interaction, and (iii) no electron-phonon interaction. On the other hand, our results do not imply that the correlation effects included in the Hubbard model are negligible; we only show that these effects do not *by themselves* explain the observed anomalies.

In the Hubbard approximation, the electron-electron interaction is represented by a term $\sum_i U\hat{n}_{i\uparrow}\hat{n}_{i\downarrow}$ in the Hamiltonian; U is the repulsion energy experienced by two electrons of opposite spin sitting at the same site i. *A priori*, one expects to see large effects in the conductivity if U is comparable to the half-bandwidth ϵ_0. The magnitude of U has been estimated at ~ 0.3 eV in NMP-TCNQ,[7] which is comparable to the bandwidth in TCNQ compounds. U has been calculated for two electrons on a transition metal atom,[8] and found to be in the range 2–4 eV; this is somewhat less than the estimated bandwidth of KCP. These rough estimates clearly indicate that both KCP and TTF-TCNQ are strongly coupled systems.

The Hamiltonian for the one-dimensional Hubbard model is

$$\hat{H} = -\frac{\epsilon_0}{2}\sum_{i,\sigma}(\hat{a}^\dagger_{i,\sigma}\hat{a}_{1,\sigma} + \hat{a}^\dagger_{i,\sigma}\hat{a}_{i-1,\sigma}) + U\sum_i \hat{n}_{i\uparrow}\hat{n}_{i\downarrow}\,, \quad (1)$$

where $\hat{a}^\dagger_{i\sigma}$ creates an electron with spin σ at site i, $\hat{n}_{i\sigma} = \hat{a}^\dagger_{i\sigma}\hat{a}_{i\sigma}$ and $2\epsilon_0$ is the bandwidth. The two basic parameters of the theory are c, the average number of electrons per site, and $\mu = U/\epsilon_0$, which measures the strength of the interaction. The low-energy excitations of the interacting one-dimensional electron gas have been discussed extensively in the literature. In particular, exactly soluble models yield correlation functions exhibiting power-law singularities in the limit $\omega, q \to 0$.[9] Such results have been used to discredit perturbative treatments, in which the power-law behavior manifests itself through logarithmic (infrared) singularities.[10] Exact methods, however, rely on the Luttinger Hamiltonian,[11] which is characterized by an infinite bandwidth and a linear dispersion relation. While such simplifications of the band structure may not qualitatively affect the low-frequency behavior of the correlation functions, it will be apparent from our results that the finite bandwidth associated with the tight-binding Hamiltonian (1) plays an important role in optical absorption. It is therefore necessary to avoid the simplifications inherent in the Luttinger model, and to use some form of perturbation theory—which raises the specter of logarithmic divergences. There are two reasons, however, why we think that perturbation theory may give better results for the $(q = 0)$ conductivity than for other quantities such as the $2k_F$ electrical susceptibility. First of all, in the high-frequency limit $(\omega \sim \epsilon_0)$ the correlation functions should measure short-range rather than long-range correlations, and one therefore expects that an adequate theory of the optical absorption can be obtained if only short-range correlations are included—which is easily achieved in approximate theories. The second reason is that logarithmic singularities actually disappear from the perturbation-theoretic expression of the conductivity, at least in the simple approximation discussed in this paper. Loosely speaking, the low-energy excitations of the system contribute to normal electron-electron scattering processes, which do not affect the electrical current and do not contribute to the resistivity. The finite-frequency absorption is mainly due to Umklapp processes. In non-half-filled systems, such processes are inelastic and involve high-energy excitations to which a perturbative treatment may be applicable.

We can make the above remarks more precise by looking at the kinematics of electron-electron scattering in one dimension. In a noninteracting system, the crystal momentum k is conserved and there is no optical absorption. In the presence of interactions, a pair of electrons in a state $|k_i, k_i'\rangle$ can be scattered into a state $|k_f, k_f'\rangle$, thereby contributing to the absorption if the initial and final values of the current are different. In the low-frequency limit $\omega \ll \epsilon_0$, one can restrict oneself to elastic collisions. For given transfers of energy ω and crystal momentum q, there are only two possibilities for the initial and final electron states. In the first of these, $k_i' = k_f$ and $k_f' = k_i$; this is a normal process which leaves the total current unchanged. The second possibility is illustrated in Fig. 1. It corresponds to an Umklapp process, in which $k_i' = -\pi/a - k_i$ and $k_f' = \pi/a - k_f$, where a is the lattice constant. In this case, the value of the current does change. However, this process requires that one electron should initially lie in the top half of the band. For systems which are less than half filled $(c < 1)$, this is very unlikely except at high

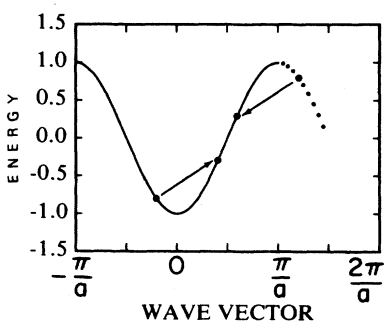

FIG. 1. Energy–wave-vector diagram for a one-dimensional elastic collision. Energy is in units of ϵ_0.

temperature, when the logarithmic divergences of perturbation theory disappear anyway. It follows, then, that for temperatures and frequencies much less than the bandwidth, collisions cannot effectively degrade an electrical current, and the conductivity should look free-carrier-like. A similar reasoning applies to the case $c > 1$.

The above argument breaks down in a strongly correlated system, in which the interaction can excite many electrons out of the Fermi sea. In spite of this, our conclusion about the low-frequency behavior of the conductivity does apply to the limit $U \to \infty$, in which the system becomes equivalent to a noninteracting, spinless fermion gas. In this limit, all of the absorption is concentrated at $\omega = 0$, and the optical absorption vanishes. It is only in the intermediate coupling regime $U \sim \epsilon_0$ that one would expect to see some structure in the low-frequency conductivity.

In Sec. II, we present the general formalism and discuss our numerical spectra. Section III is devoted to the t-matrix approximation. Although this is a low-density approximation, we find that it gives good results even for nearly half-filled systems. In Sec. IV, we discuss the memory function approximation for $\sigma(\omega)$, which reduces to straightforward perturbation theory at high frequency. The good overall agreement between the three approaches gives us confidence that our approximate analysis provides an essentially correct description of the optical spectrum of the infinite Hubbard chain. Of course, our approach breaks down at low frequency, where the detailed structure of the low-lying excitations plays an important role. However, the existence of an exact sum rule for the conductivity of the Hubbard model allows us to indirectly determine the contribution of the zero-frequency absorption peak to the sum rule, which is sufficient for our purposes.

II. FINITE CHAINS AND NUMERICAL RESULTS

This section is devoted to the theory of the optical absorption in a finite chain of N "atoms" or sites. The motivation for the numerical work described later in this section is based on the assumption that the absorption spectra of such finite chains resemble the spectra of infinite chains having the same electron density. There can be no doubt that this is indeed true for large values of N (say, $N = 10^6$). The question is, then, how large an N should be chosen for the assumption to be valid. In principle, this could be checked by calculating the spectra of larger and larger chains, keeping the electron density approximately constant. Unfortunately, the dimension of the Hilbert space grows exponentially with N. Since a knowledge of all the excited states is necessary to describe the spectrum of a chain, one quickly runs into formidable numerical difficulties even for $N \sim 10$. In fact, the numerical results reported here were obtained for only four electrons distributed over up to seven sites. While slightly larger "molecules" could certainly be handled as well, we found that the numerical spectra were in good qualitative agreement with the approximate theories which we developed to treat infinite chains. In particular, all the features of the numerical spectra can be interpreted in terms of physical processes that were included in the approximate treatments. Since the same physical processes are at work in larger chains, it is reasonable to assume that our results reflect the intrinsic properties of the Hubbard model rather than spurious size effects.

For simplicity, we first consider the case of a long chain, in which boundary effects can be neglected. This will enable us to introduce periodic boundary conditions, thereby simplifying the theoretical analysis. In the presence of an oscillating, uniform electric field $Ee^{-i\omega t}$ parallel to the chain, one must add to the Hamiltonian (1) a term representing the coupling to the applied field. This is conveniently done by introducing a vector potential $A(t) = cE/(-i\omega)e^{-i\omega t}$ into the Hamiltonian. Here and in the next two equations, c denotes the speed of light; this is not to be confused with the number of electrons per site, also denoted by c. Some care is needed to preserve gauge invariance in a tight-binding system; if x_i is the position of the ith atom in the chain, then a canonical transformation $\hat{a}'_i = e^{-i(e/c)Ax_i}\hat{a}_i$ should remove the coupling to a static vector potential A. This indicates that in the presence of a time-dependent vector potential $A(t)$, the first term in the Hamiltonian (1) becomes ($\hbar = 1$)

$$\hat{H}'_0 = -\frac{\epsilon_0}{2}\sum_{i,\sigma}(\hat{a}^\dagger_{i,\sigma}\hat{a}_{i+1,\sigma}e^{-ieaA(t)/c} + \hat{a}^\dagger_{i,\sigma}\hat{a}_{i-1,\sigma}e^{ieaA(t)/c}), \tag{2}$$

where a is the lattice constant. Expanding to second order in A, we find that the coupling term is

$$\hat{H}_A = (A/c)\hat{j} + \tfrac{1}{2}(e/c)^2A^2a^2(-\hat{H}_0), \tag{3}$$

where $\hat{H}_0$ is the kinetic energy, i.e., the first term in the Hamiltonian (1) and $\hat{j}$ is the current operator

$$\hat{j} = iea\frac{\epsilon_0}{2}\sum_{i,\sigma}(\hat{a}^\dagger_{i,\sigma}\hat{a}_{i+1,\sigma} - \hat{a}^\dagger_{i,\sigma}\hat{a}_{i-1,\sigma}). \tag{4}$$

We will base our discussion on the fluctuation-dissipation theorem, which relates the conductivity to the equilibrium current-current correlation function χ:

$$\sigma(\omega) = [\chi(\omega) - ne^2/m^*]/i\omega, \tag{5}$$

where $n = cN$ is the number of electrons and m^* is

an effective mass given by[12]

$$1/m^* = -a^2\langle \hat{H}_0 \rangle /n. \tag{6}$$

In the dilute limit, electrons lie near the bottom of the band, and $1/m^* = a^2\epsilon_0$. More generally, in a noninteracting system, one finds $1/m^* = a^2\epsilon_0(\sin\pi c/2)/(\pi c/2)$. The retarded correlation function χ is defined by

$$\chi(\omega) = i\int_0^\infty dt\, e^{i\omega t}\langle[\hat{j}(t),\hat{j}(0)]\rangle\,. \tag{7}$$

In terms of plane wave states, the current $\hat{j}$ is given by

$$\hat{j} = -e\sum_{k,\sigma}\hat{a}^\dagger_{k,\sigma}\hat{a}_{k,\sigma}v_k, \quad v_k = a\epsilon_0\sin ka\,, \tag{8}$$

where k is the (one-dimensional) wave vector, and a is the lattice constant.

Later on in this article, we will use approximations whose validity is restricted to high frequencies. To obtain information about the low-frequency conductivity, we will use the analog of the f-sum rule for a tight-binding system:

$$\frac{2}{\pi}\int_0^\infty \sigma'(\omega)d\omega = ne^2/m^*\,, \tag{9}$$

where σ' denotes the real part of the conductivity and m^* is the effective mass defined in Eq. (6).

Before proving the sum rule, let us consider in some detail the case of a finite chain. The site indices in the Hamiltonian (1) are now restricted by the condition $1 \le i \le N$. If we denote by $|n\rangle$ and E_n the exact eigenstates and energy levels of the many-body Hamiltonian (1), the current-current correlation function (7) becomes

$$\chi(\omega) = \sum_n |\langle 0|\hat{j}|n\rangle|^2\left(\frac{1}{\omega + E_n - E_0 - i\eta} - \frac{1}{\omega - E_n + E_0 + i\eta}\right), \tag{10}$$

where $|0\rangle$ and E_0 denote the ground state and the ground-state energy, respectively. From Eq. (5), the real part of the conductivity is

$$\sigma'(\omega) = \pi\sum_n |\langle 0|\hat{j}|n\rangle|^2\frac{\delta(|\omega| - E_n + E_0)}{E_n - E_0}\,. \tag{11}$$

Thus, the spectrum of a finite chain consists of a series of sharp lines corresponding to transitions from the ground state to the excited states. When N is large, these lines merge into a continuum and σ is a continuous function of the frequency. To compare the spectra of finite and infinite chains, it is convenient to introduce the normalized integrated conductivity $Z(\omega)$, defined by

$$Z(\omega) = \frac{2m^*}{\pi ne^2}\int_0^\omega d\nu\,\sigma'(\nu)\,,$$
$$= \frac{m^*}{n}\sum_{E_n - E_0 < \omega}\frac{|\langle 0|\hat{v}|n\rangle|^2}{E_n - E_0}\,, \tag{12}$$

where $\hat{v}$ is the velocity operator $-\hat{j}/e$. Clearly, the sum rule implies that $Z \to 1$ as $\omega \to \infty$. To prove the sum rule, we observe that the current operator satisfies the equation

$$\hat{j} = ie[\hat{x},\hat{H}], \tag{13}$$

where $\hat{x}$ is the sum of the position operators of the electrons. Therefore,

$$\langle 0|\hat{j}|n\rangle = ie(E_n - E_0)\langle 0|\hat{x}|n\rangle; \tag{14}$$

inserting this into Eq. (11), we find

$$\frac{2}{\pi}\int_0^\infty \sigma'(\omega)\,d\omega = ie\sum_n(\langle 0|\hat{x}|n\rangle\langle n|\hat{j}|0\rangle - \langle 0|\hat{j}|n\rangle\langle n|\hat{x}|0\rangle)\,, \tag{15}$$
$$= -ie\langle 0|[\hat{j},\hat{x}]|0\rangle = -e^2a^2\langle 0|\hat{H}_0|0\rangle,$$

where in the last step we have used the identity [see Eq. (4)]

$$[\hat{j},\hat{x}] = iea^2\frac{\epsilon_0}{2}\sum_{i,\sigma}(\hat{a}^\dagger_{i,\sigma}\hat{a}_{i+1,\sigma} + \hat{a}^\dagger_{i,\sigma}\hat{a}_{i-1,\sigma})\,,$$
$$= -iea^2\hat{H}_0. \tag{16}$$

From the definition (6) of the effective mass, we see that Eq. (16) yields the sum rule (9).

The quantity $Z(\omega)$ was calculated numerically for $N = 5$, $n = 4$, and various values of the interaction constant $\mu = U/\epsilon_0$; the results are illustrated by the dotted lines in Fig. 2. To interpret these spectra, it is instructive to investigate the noninteracting case $\mu = 0$ in some detail. The one-electron wave functions which diagonalize the kinetic energy are easily seen to be

$$\psi_m(k) = \begin{cases}(\frac{2}{5})^{1/2}\sin(\frac{1}{6}\pi km) & (m = 2,4)\\ (\frac{2}{5})^{1/2}\cos(\frac{1}{6}\pi km) & (m = 1,3,5)\end{cases} \tag{17}$$

with corresponding energies $-\epsilon_0\cos\frac{1}{6}\pi m$. Here, k is a site index running from -2 to $+2$. Thus, the ground state of the "molecule" can be represented as in Fig. 3. Since the current operator is odd in k, the only allowed (dipole) transitions from occupied to excited states are $(m = 1) \to (m = 4)$ and $(m = 2) \to (m = 3 \text{ or } 5)$. The corresponding excitation energies are $\Delta E_{14} = \Delta E_{25} = 1.38\epsilon_0$ and $\Delta E_{23} = 0.5\epsilon_0$. These transitions are apparent in the spectrum shown in Fig. 2(a); since these are the only possible transitions, they must exhaust the sum rule (9). The spectrum of an *infinite* noninteracting

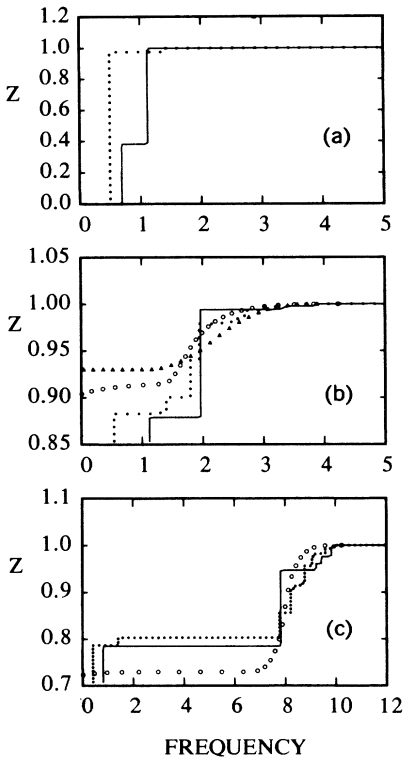

FIG. 2. Normalized, integrated conductivity as defined in Eq. (12) for a Hubbard system with $c = 0.8$ electrons per atom and (a) $U = 0$, (b) $U = \epsilon_0$, (c) $U = 8\epsilon_0$. Continuous curves, five-atom ring; dots, five-atom linear chain; open circles, t-matrix approximation; triangles, memory-function approximation. Frequency is in units of ϵ_0.

chain, on the other hand, would simply be a step function with a discontinuity at $\omega = 0$. Thus, we can look at the finite chain spectrum as a coarse grained approximation to the infinite chain spectrum, with an energy resolution of order $2\epsilon_0/N$. As the interaction parameter μ increases, some of the low-frequency absorption is shifted to higher energy, which would correspond to a peak in the

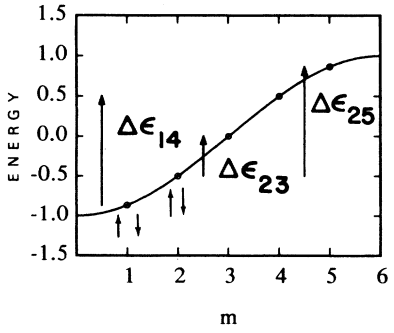

FIG. 3. Ground-state and optical transitions of a noninteracting five-atom linear chain.

real part of the conductivity. This absorption peak occurs at a frequency which increases with μ, and is roughly $U = \mu\epsilon_0$ when $\mu \gg 1$. It must therefore correspond to a transition in which the final state contains two electrons of opposite spin sitting on the same atom. In Sec. III, it will be shown that this transition involves a high-energy "bound state" which is responsible for most of the high-frequency absorption.

The model discussed above has a density of $c = 0.8$ electron per site, which is a nearly half-filled system. In order to increase the number of sites and reduce the value of c, we have also calculated the function $Z(\omega)$ for rings of 5 and 7 sites. The advantage of working with a ring is that periodic boundary conditions can be imposed, and wave-vector conservation ensues. One can then restrict oneself to translation-invariant states, which reduces the dimension of the Hilbert space considerably. Although it is still possible to induce an electric field along the ring by changing the magnetic flux through it, the corresponding "conductivity" is related to the diamagnetic susceptibility of the system and does not satisfy the sum rule (9). Therefore, it is preferable to apply a uniform electric field; the coupling term in the Hamiltonian can again be calculated from Eq. (2), and is given by (c now denotes the speed of light)

$$\hat{H}_{A,r} = \left(\frac{A}{c}\right)\hat{j}_r + \frac{1}{2}\left(\frac{e}{c}\right)^2 A^2 a^2 (-\hat{H}_0) + \frac{\epsilon_0}{4}\left(\frac{e}{c}\right)^2 A^2 a^2 \sum_{k,\sigma} \cos\left(\frac{4\pi k}{N} + 2\psi\right) \times (\hat{a}^\dagger_{k+1,\sigma}\hat{a}_{k,\sigma} + \hat{a}^\dagger_{k,\sigma}\hat{a}_{k+1,\sigma}) , \quad (18)$$

where the current operator is now

$$\hat{j}_r = iea\frac{\epsilon_0}{2^{1/2}} \sum_{k,\sigma} \cos\left(\frac{2\pi k}{N} + \psi\right)(\hat{a}^\dagger_{k+1,\sigma}\hat{a}_{k,\sigma} + \hat{a}^\dagger_{k,\sigma}\hat{a}_{k+1,\sigma}) . \quad (19)$$

In these equations, ψ is a phase angle depending on the orientation of the electric field. The factor $2^{1/2}$ in the last equation provides a convenient normalization. The expectation value of the last term in Eq. (18) in the (translation-invariant) ground state is obviously zero, and the conductivity is again given by Eqs. (5)–(7), in which $\hat{j}$ is replaced by $\hat{j}_r$. The sum rule (9) remains unchanged. Numerical results for rings of five atoms containing four electrons are shown in Fig. 2 (continuous lines), and are in good agreement with the results for the linear chain (dotted lines). In the noninteracting case $\mu = 0$, the spacing between the one-electron energy levels is larger than in the linear case, which results in a poorer energy resolution. The locations

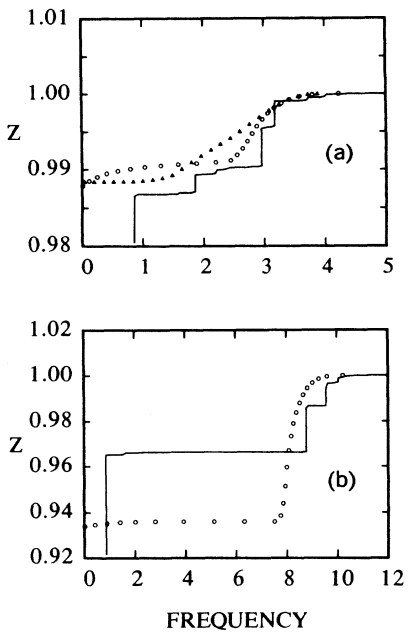

FIG. 4. Normalized, integrated conductivity as defined in Eq. (12) for a Hubbard system with $c = 0.571$ electrons per atom and (a) $U = \epsilon_0$, (b) $U = 8\epsilon_0$. Continuous curves, seven-atom ring; open circles, t-matrix approximation; triangles, memory-function approximation. Frequency is in units of ϵ_0.

and strengths of the main absorption peaks, however, are in good agreement. This indicates that the high-frequency conductivity is relatively insensitive to the boundary conditions, even for $N = 5$. Figure 4 shows numerical results for rings of seven atoms. Note that this yields an electron density $c = 0.571$, which is close to the observed density of TTF-TCNQ.[13] The comparison with the approximate theories of the infinite chain absorption will be carried out in Secs. III and IV.

III. T-MATRIX APPROACH

In the absence of interactions, $\hat{j}$ commutes with the Hamiltonian and the commutator in Eq. (3) vanishes, so that there is no optical absorption and the dc conductivity is infinite. Thus, absorption processes must involve collisions between electrons. In a dilute system, collisions are rare and can be treated "one at a time." Let us therefore consider a system of two electrons having opposite spins and interacting via a Hubbard potential U. If the electrons are in a triplet state, the spatial wave function is antisymmetric and they do not interact. Hence, it will always be assumed that the colliding electrons are in a singlet state. The matrix elements of the two-particle Hamiltonian are

$$\langle k_1, k_2 | \hat{H} | k_1', k_2' \rangle = -\epsilon_0 \delta_{k_1, k_1'} \delta_{k_2, k_2'} (\cos a k_1 + \cos a k_2) + (1/N) \delta_{k_1 + k_2, k_1' + k_2'} U, \tag{20}$$

where $|k_1, k_2\rangle$ and $|k_1', k_2'\rangle$ denote normalized plane wave states. It is convenient to introduce the (dimensionless) "center of mass" and "relative" coordinates $q = \frac{1}{2} a(k_1 + k_2)$ and $\alpha = \frac{1}{2} a(k_1 - k_2)$, so that the kinetic energy of a state $|k_1 k_2\rangle$ takes the simple form $\epsilon_{q,\alpha} = -2\epsilon_0 \cos q \cos\alpha$. If we restrict q and α to the domain $0 < q < \pi$, $-\pi < \alpha < \pi$, q is a conserved quantity. Since we are interested in the singlet state, we limit ourselves to spatially symmetric wave functions. Hence we may further assume that $\alpha > 0$. To find the eigenstates of the two-particle Hamiltonian, we solve the Lippmann-Schwinger equation [a scattering eigenstate with initial quantum numbers q and α is denoted by $|q, \alpha)$, while $|q, \alpha\rangle$ denotes a non-interacting eigenstate].

$$\langle q, \alpha' | q, \alpha) = \delta_{\alpha, \alpha'} + (2/N) U \times \sum_{\alpha'' > 0} \langle q, \alpha'' | q, \alpha) / (\epsilon_{q,\alpha} - \epsilon_{q,\alpha'} - i\eta). \tag{21}$$

This separable equation is immediately solved, with the result that

$$\langle q, \alpha' | q, \alpha) = \delta_{\alpha, \alpha'} + \frac{(1/N) U f(q, \cos\alpha)}{(\epsilon_{q,\alpha} - \epsilon_{q,\alpha'} - i\eta)}, \tag{22}$$

where the "scattering amplitude" $f(q, \cos\alpha)$ is given by

$$1/f(q, \cos\alpha) = 1 + U/(2i\epsilon_0 |\sin\alpha \cos q|). \tag{23}$$

In addition to the scattering states, the Hamiltonian (20) has a bound state $|q, b)$ for arbitrary q. For the repulsive interaction $U > 0$ considered here, the bound state lies *above* the highest band energy $2\epsilon_0$. The ability of a repulsive potential to bind electrons from a tight-binding band was first noted in Ref. 14 in the case of an impurity. The equation for the bound state is analogous to (21) without the inhomogeneous term $\delta_{\alpha,\alpha'}$; the normalized bound-state wave function is found to be

$$\langle q, \alpha | q, b) = \frac{(2U^3/\epsilon_q)^{1/2}}{\epsilon_{q,\alpha} - \epsilon_q}, \tag{24}$$

where the bound state energy ϵ_q is given by

$$\epsilon_q = (U^2 + 4\epsilon_0^2 \cos^2 q)^{1/2}. \tag{25}$$

We now use these results to calculate the correlation function χ for a two-electron system in an eigenstate $|q, \alpha)$, which we will denote by $\chi(q, \alpha, \omega)$. We will then approximate the correlation function for the dilute Hubbard chain by averaging $\chi(q, \alpha, \omega)$ over all the pairs of electrons present in

the system according to

$$\chi(\omega)=\sum_{k_1>k_2}\chi(\tfrac{1}{2}a(k_1+k_2),\tfrac{1}{2}a(k_1-k_2),\omega)n_{k_1,k_2}, \quad (26)$$

where n_{k_1,k_2} is the joint distribution function for a pair of electrons in a singlet state:

$$n_{k_1,k_2}=\langle\hat{S}^{\dagger}_{k_1,k_2}\hat{S}_{k_1,k_2}\rangle,$$

$$\hat{S}_{k_1,k_2}=\frac{1}{2^{1/2}}(\hat{a}_{k_1\uparrow}\hat{a}_{k_2\downarrow}-\hat{a}_{k_1\downarrow}\hat{a}_{k_2\uparrow}). \quad (27)$$

Writing $\chi=\chi'+i\chi''$, one finds from Eq. (7)

$$\chi''(q,\alpha,\omega)=\pi\sum_{\alpha'>0}|(q,\alpha|\hat{j}|q,\alpha')|^2[\delta(\omega+\epsilon_{q,\alpha}-\epsilon_{q,\alpha'})-\delta(\omega-\epsilon_{q,\alpha}+\epsilon_{q,\alpha'})]$$
$$+\pi|(q,\alpha|\hat{j}|q,b)|^2[\delta(\omega+\epsilon_{q,\alpha}-\epsilon_q)-\delta(\omega-\epsilon_{q,\alpha}+\epsilon_q)]. \quad (28)$$

Note that this expression is very similar to that obtained for interband absorption in a semiconductor. The main difference is, of course, that in the present case the optical transitions occur between two- rather than one-particle states. The first term contains the effect of transitions to continuum (scattering) states, and the second term arises from transitions to the bound state. Using the above expressions for the eigenstates of the two-electron Hamiltonian, the matrix elements of the current operator are easily found to be (assuming $\alpha\neq\alpha'$)

$$(q,\alpha|\hat{j}|q,\alpha')=2a(U/N)\tan q f(q,\cos\alpha')f^*(q,\cos\alpha),$$
$$(q,\alpha|\hat{j}|q,b)=(2U^3a^2/\epsilon_q N)^{1/2}f^*(q,\cos\alpha)\tan q. \quad (29)$$

Substituting these matrix elements in Eq. (28) for the correlation function, one finds after some algebra

$$\chi''(q,\alpha,\omega)=2(U/N)a^2\tan^2q|f(q,\cos\alpha)|^2F(q,\alpha,\omega)$$
$$+2\pi(U^3a^2/\epsilon_q N)|f(q,\cos\alpha)|^2\tan^2q$$
$$\times[\delta(\omega+\epsilon_{q,\alpha}-\epsilon_q)-\delta(\omega-\epsilon_{q,\alpha}+\epsilon_q)], \quad (30)$$

where $[\Theta(x)=0$ if $x<0$, 1 if $x>0]$

$$F(q,\alpha,\omega)=\Theta(4\epsilon_0^2\cos^2q-(\omega+\epsilon_{q,\alpha})^2)$$
$$\times\mathrm{Im}f\left(q,\frac{\omega+\epsilon_{q,\alpha}}{2\epsilon_0\cos q}\right)$$
$$-\Theta(4\epsilon_0^2\cos^2q-(\omega-\epsilon_{q,\alpha})^2)$$
$$\times\mathrm{Im}f\left(q,\frac{\epsilon_{q,\alpha}-\omega}{2\epsilon_0\cos q}\right). \quad (31)$$

The first term in the right-hand side of Eq. (30) arises from transitions into continuum two-particle states. This term agrees with the result of Lyo and Holstein.[5] The second term accounts for transitions into the bound state. Since q, α, and k_F are of order c and since $f\sim|\sin\alpha|\sim c$ in the dilute limit, both terms are of order c^4. After integrating over q and α to obtain the real part of the conductivity, these terms are of order c^6 and c^5 respectively (the δ function in the bound state term removes one power of c). This result can be understood by noting that in the dilute limit, electrons sit near the bottom of the band and the dispersion relation is approximately parabolic, leading to momentum conservation and the vanishing of the absorption.

To obtain the current-current correlation function of the system, hence the conductivity, it remains to sum Eq. (31) over the momenta of the incoming particles as specified by Eq. (26). This was done numerically. The open circles in Figs. 2 and 4 show the results for the normalized integrated conductivity $Z(\omega)$, defined in Eq. (12). The corresponding electron densities are $c=\frac{4}{5}$ and $c=\frac{4}{7}$ respectively. In the case $\mu=1$, we have neglected the effect of correlation in the effective mass and in the two-particle distribution function. Thus, we set

$$1/m^*=a^2\epsilon_0\frac{\sin(\pi c/2)}{\pi c/2},$$
$$n_{k_1k_2}=\begin{cases}1 & \text{if } |k_1|,|k_2|<k_F,\\ 0 & \text{otherwise } (\mu \text{ small}).\end{cases} \quad (32)$$

In the strongly interacting case, however, the oscillator strength of the main absorption peak was found to be several times smaller than found numerically for finite chains and rings. This is clearly due to correlation effects, which tend to shift some of the weight of the two-particle distribution function to higher values of the momenta. Since the response function (29) increases rapidly with the reduced momenta q and α, this enhances the absorption. As a crude way to include such effects, we assumed that the particle momenta were uniformly distributed between $-2k_F$ and $+2k_F$.

Thus, we set

$$\frac{1}{m^*} = a^2\epsilon_0 \frac{\sin(\pi c)}{\pi c},$$

$$n_{k_1k_2} = \begin{cases} \frac{1}{4} & \text{if } |k_1|, |k_2| < 2k_F \\ 0 & \text{otherwise } (\mu \text{ large}). \end{cases} \tag{33}$$

This ansatz can be justified as follows. It is easily seen that, in the limit $\mu \to \infty$, the spatial part of the ground-state wave function of the one-dimensional Hubbard model is identical with that of a system of noninteracting, spinless fermions within a factor ± 1. This factor arises because the spinless fermion wave function is odd under the interchange of two spatial coordinates, while the wave function of the Hubbard model is odd under the simultaneous interchange of spatial and spin coordinates. If we concentrate on a pair of neighboring electrons in a singlet state, therefore, the full spatial wave function must behave as a sum of terms of the form $C\left|\sin\frac{1}{2}(k_1-k_2)(x_1-x_2)\right| \times \exp[i\frac{1}{2}(k_1+k_2)(x_1+x_2)]$, where x_1, x_2 denote the coordinates of the two electrons and the two momenta k_1, k_2 are uniformly distributed between $-2k_F$ and $+2k_F$; C is a constant which depends on the remaining coordinates $x_3, \ldots$. Together with the observation that only short-range correlations should be important, we are naturally led to the above ansatz.

With Eqs. (32) and (33), the t-matrix predictions for $Z(\omega)$ are in good agreement with the numerical spectra. The largest discrepancy arises in the case $c = 0.571$, $\mu = 8$ as shown in Fig. 4 (b). We checked that the discrepancy decreases with increasing U. This confirms our interpretation of the main absorption peak in terms of a bound state consisting of two electrons sitting at the same site. Figure 5 shows the dimensionless conductivity σ^*, defined by

$$\sigma^*(\omega) = \frac{2}{\pi}\frac{m^*\epsilon_0}{ne^2}\sigma'(\omega) \tag{34}$$

in the same approximation. Clearly, it is only in the weak coupling limit $\mu \ll 1$ that continuum transitions (open circles) contribute significantly to the absorption; for $\mu \sim 1$ most of the absorption is due to the bound state. It must be noted that the relatively large contribution of continuum transitions to the low-frequency absorption is a spurious effect, due to our neglect of the Pauli principle in the summation over final states in Eq. (28). Restricting the sum over α' to unoccupied states would suppress this contribution. However, this correction is formally of higher order in the electron density c. Since the contribution of continuum transitions to the t-matrix conductivity is small when $\mu \sim 1$, we did not include this refinement in the t-matrix calculation.

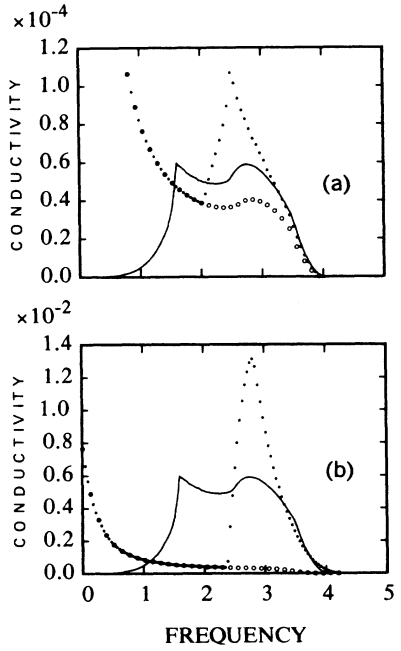

FIG. 5. Dimensionless conductivity [Eq. (34)] calculated in the t-matrix approximation (dotted curves) and in the memory function approximation (continuous curves) for $c = 0.571$ electrons per atom and (a) $U = 0.1\,\epsilon_0$, (b) $U = \epsilon_0$. The open circles represent the contribution of transitions into the continuum to the t-matrix conductivity. Frequency is in units of ϵ_0.

IV. MEMORY-FUNCTION APPROACH

In this section, we will use the memory-function approach of Götze and Wölfle to calculate the conductivity of an infinite Hubbard chain in the weak coupling limit (i.e., $\mu \to 0$). We begin with an outline of the formalism. The memory function $M(\omega)$ is defined in terms of the conductivity by the formula[6]

$$\sigma(\omega) = i(ne^2/m^*)[1/(\omega + M(\omega))]. \tag{35}$$

In particular, $M(\omega) = i/\tau$ in the Drude approximation. Thus, M can be interpreted as a frequency-dependent generalization of the relaxation rate. Just as the conductivity, the memory function is analytic in the upper frequency half-plane. The basic assumption of the theory is that M is a well-behaved function of ω and of the strength of the interaction. One can then expand Eq. (35) at high frequency:

$$\sigma(\omega) = i(ne^2/m^*)[1/\omega - M(\omega)/\omega^2 + \cdots]. \tag{36}$$

Thus, $M(\omega)$ is simply obtained by expanding the conductivity to leading order in the interaction. Extrapolation to all frequencies yields the memory-function approximation. Although we have made no effort toward rigor, it can be show that this approximation is actually the first term of a con-

tinued fraction expansion of the conductivity. In the present context, we view the memory-function approximation as the simplest approximation which satisfies the sum rule (9) and reduces to perturbation theory at high frequency.

From Eqs. (36) and (7), one finds after some algebra that the memory function can be written as

$$M(\omega)=\frac{m^*}{ne^2\omega}\left[\pi(\omega)-\pi(0)\right], \tag{37}$$

where the correlation function π is given by

$$\pi(\omega)=i\int_0^\infty dt\, e^{i\omega t}\langle[\hat{F}(t),\hat{F}(0)]\rangle . \tag{38}$$

Here, the "force operator" $\hat{F}$ is defined according to

$$\hat{F}=-i[\hat{j},\hat{H}]. \tag{39}$$

It is now straightforward to calculate the correlation function (37) to leading order in the interaction U. The force operator (38) is simply

$$2iea\epsilon_0\frac{U}{N}\sum_{k,p,q}\hat{a}^\dagger_{k+q\uparrow}\hat{a}_{k\uparrow}\hat{a}^\dagger_{p-q\downarrow}\hat{a}_{p\downarrow}$$
$$\times\sin\tfrac{1}{2}a(k+p)\{\cos a[\tfrac{1}{2}(k-p)+q]-\cos\tfrac{1}{2}a(k-p)\} \tag{40}$$

so that, to leading order in U, the average in Eq. (38) can be taken in a noninteracting system. The corresponding diagram is shown in Fig. 6. Using the standard rules of perturbation theory, one finds ($M=M'+iM''$)

$$M''(\omega)=\frac{\pi U_a^2}{2\omega\epsilon_0\sin\pi c/2}\int_0^{2\pi/a}\frac{dq}{2\pi}\int_0^\omega\frac{d\Omega}{\pi}\left[2\chi_2(q,\Omega)\chi_0(-q,\omega-\Omega)+2\chi_1(q,\Omega)\chi_1(-q,\omega-\Omega)\right], \tag{41}$$

where

$$\chi_n(q,\omega)=\int_0^{2\pi/a}\frac{dp}{2\pi}\,\delta(\epsilon_p-\epsilon_{p-q}-\omega)$$
$$\times(n_{p-q}-n_p)(v_p-v_{p-q})^n. \tag{42}$$

Here $\epsilon_p=-\epsilon_0\cos ap$ is the electron energy, $v_p=a\epsilon_0\sin ap$ is the velocity, and n_p is the zero-temperature occupation number, $n_p=1$ if $|p|<k_F=\pi c/2a$, $=0$ otherwise. The two-dimensional integral in Eq. (42) is easily evaluated numerically, and the real part M' of the memory function is obtained by using a dispersion relation.

The results for the normalized integrated conductivity $Z(\omega)$ [Eq. (12)] are shown in Figs. 2 and 4, and those for the dimensionless conductivity σ^* [Eq. (34)] in Fig. 5. The absorption predicted by the memory function approximation is of the correct order of magnitude for $\mu=1$. In the weak coupling limit $\mu\ll1$, one would expect the t-matrix and memory function approaches to yield similar results. Figure 5 shows that this is indeed the case for $\mu=0.1$, although (i) the bound-state contribution to the t-matrix is still substantial even though it is formally of order μ^3 [see Eq. (30)], and (ii) the t-matrix absorption is too large at low frequency, as discussed in the previous section. The peak around $\omega=1.6\epsilon_0$ in the memory function approximation curves arises from a singularity in the integrand of the expression (41) for the memory function. This is illustrated in Fig. 7, which shows the domains in the (q,Ω) plane where the susceptibilities $\chi_m(q,\Omega)$ and $\chi_n(-q,\omega-\Omega)$ are nonvanishing [see Eq. (42)].

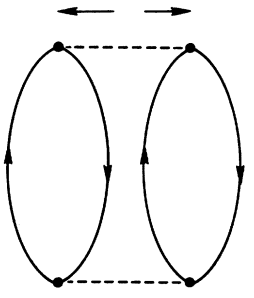

FIG. 6. Feynman diagram for the correlation function π defined in Eq. (38).

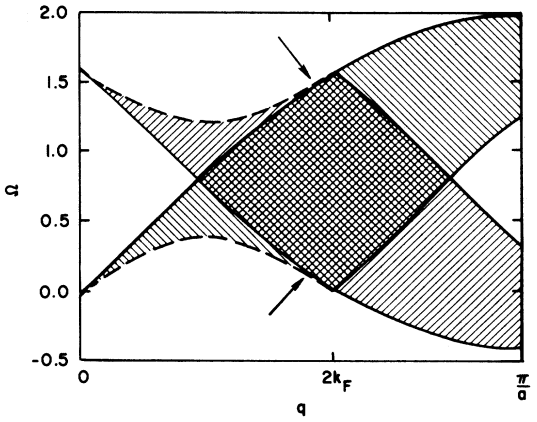

FIG. 7. Domains in which the factors $\chi_m(q,\Omega)$ and $\chi_n(-q,1.58\epsilon_0-\Omega)$ in Eq. (41) are different from zero. The arrows indicate the regions of critical contact, and the dashed lines are the boundaries imposed by the Pauli principle. Ω is in units of ϵ_0.

For certain values of ω, the boundaries of these domains are in critical contact; such values of ω will correspond to singularities in the slope of the memory function, provided that the velocity factor in Eq. (42) does not vanish at the point of critical contact. As discussed in the previous section, our t-matrix approximation neglects the Pauli principle in the summation over final states. The domains shown in Fig. 7 are then enlarged, and the points of critical contact disappear. This explains why the t-matrix curve goes on increasing below the value $\omega = 1.58\epsilon_0$.

Figure 5(b) shows the dimensionless conductivity for $\mu = 1$, and it is clear that the apparent order-of-magnitude agreement between the memory-function approximation and the numerical spectra is due to a fortuitous cancellation of two effects. On the one hand, the memory-function approximation neglects the important bound state contribution. On the other hand, the Born approximation used in the memory-function approximation overestimates the cross-section for scattering into continuum states. In the strong coupling limit, the second effect is stronger and the memory-function approximation breaks down completely.

V. CONCLUSION

The numerical results presented in this paper substantiate the claim made in the introduction that the optical absorption of the one-dimensional Hubbard model with an electron density comparable to that of TTF-TCNQ is small. Thus, for $U = 8\epsilon_0$, we find that the main absorption peak exhausts about 4% of the sum rule. Moreover, within the "energy resolution" $\Delta\omega \sim \epsilon_0$ of our finite chain and ring calculations, we find no low-frequency anomaly in the spectrum. In the case of KCP, we find that the absorption is even smaller; for instance, setting $c = 0.3$ and $U = \epsilon_0$, the t-matrix approximation yields a normalized conductivity $\sigma^*(\omega)$ which is less than 2×10^{-3} for $\omega > 0$. On the positive side, we have shown that the t-matrix approximation is in good agreement with the numerical spectra of finite chains and rings. This indicates that the short-range correlations which are important for the optical conductivity are properly taken into account by that approximation. It also suggests that a similar approximation may be useful in the study of more sophisticated models including both the electron-electron and the electron-phonon interactions.

Received 28 November 1997

Microtubules (MTs) are the largest protein polymers in the cytoskeleton of eucaryotic cells in which they perform various functions. They are important in cell division, cell movement, they seem to be the devices through which are transferred signals in the nervous system. In this paper we continued to investigate the hypothesis that MTs can be viewed as assemblies of dipoles which are carried by the MT subunits, tubulin heterodimers. These assemblies were studied by means of the two-dimensional Ising model for both the A- and B-type arrangements of the tubulin subunits in a MT and the number of protofilaments 12, 13 and 14. We found that depending on these parameters and the magnitudes and orientations of the dipoles a MT may be at body temperature in an ordered phase or in a phase characterized by a random configuration of dipoles. The type of the ordered phase is determined by the above parameters as well, and it can be ferroelectric, antiferroelectric or ferrielectric. The dipolar ordering also depends on the presence of microtubule associated proteins, assuming that they can locally alter the dipolar interactions by binding to a MT, and external electric fields. The model presented here started by Tuszyński[1–3] can be one of the first steps in the theoretical investigation of the electromagnetic features of MTs and their role in the MT behavior.

1. Introduction

Microtubules (MTs) are structural elements of eucaryotic cells.[4] They are hollow tubes formed by the polymerization of tubulin molecules. Each tubulin subunit is a dimer composed of two monomers termed α- and β-tubulin.[5–7] The dimer is approximately 8×10^{-9} m long and its width is about 5×10^{-9} m. The molecules of tubulin bound within a MT arrange themselves into protofilaments. The majority of MTs *in vivo* have 13 protofilaments.[8,9] MTs assembled *in vitro* consist mostly of 13 and 14 protofilaments. Changes in the number of protofilaments occur also within a single MT, even though rather infrequently.[9]

Almost all MTs inside the cell form an array around the centrosome.[4] In a non-dividing cell these MTs continuously grow and shrink due to the constant addition and dissociation of tubulin molecules at both MT ends. This phenomenon is known as dynamic instability[10] and its microscopic mechanism is largely unexplained. It is utilized in cell division when MTs growing in random directions from two centro-

somes positioned at the opposite poles of the cell eventually attach to chromosomes in order to pull an equal number of them to each of the cell extremities. In a stable state MTs serve as tracks for the transport of organelles. This transport is mediated by motor proteins which attach to MTs.

Stable MTs form parallel networks in dendrites and axons of neurons. These networks have been compared to parallel information processors that may be basic for the functioning of the nervous system.[11] Nondynamic MTs also form the cores of cilia and flagella that extend from the cell surface and move in a coordinated way. It is conjectured that such motion is a result of the cooperative interactions between the ciliary motor proteins.

The physical pathways of the MT activities briefly outlined above have been a subject of growing theoretical investigation. Several researchers have suggested that the energy freed in the GTP hydrolysis which takes place soon after the addition of each tubulin molecule to a MT end propagates along a MT as a solitary wave.[1,12–14] This wave may locally alter the elastic state of tubulin which may consequently lead to a dissociation of a tubulin dimer from a MT end or may be involved in the coordinated behavior of the motor proteins.

The present paper is focused on the investigation of the dipolar order in MTs. This question has been studied by Tuszyński *et al.* who put forward the hypothesis that some aspects of the MT behavior may be due to the interactions between the permanent dipoles carried by the tubulin molecules.[2] So far Tuszyński and his coworkers have investigated the dipolar ordering only in MTs that are composed of 13 protofilaments and are represented by the A lattice (see the following section).[3] In this work, a similar type of analysis is extended to MTs with both A and B lattices and number of protofilaments 12, 13 and 14.

2. Microtubule Lattice

Neighboring MT protofilaments are longitudinally shifted with respect to each other. Consequently, the tubulin dimers bound in a MT are arranged in a hexagonal manner and a MT can be represented by a hexagonal lattice.

As mentioned earlier, the most common number of protofilaments in a MT *in vivo* is 13 and *in vitro* 13 and 14 where MTs consisting of different numbers of protofilament in the range $p = 12$–17 have been also observed.[15] In all MTs, independent of the number of protofilaments, the tubulin monomers are arranged along a 3-start helix, i.e. each MT consists of three helices of tubulin monomers.

Depending on the geometrical arrangement of the α and β monomers two types of the MT lattice can be defined. They have been termed the A lattice and the B lattice. In MTs that are represented by the A lattice the α and β monomers along a 3-start helix alternate. If the number of protofilaments is odd then the connection between two monomers which are positioned in the last and first protofilament along a 3-start helix is heterologous, i.e. it is an α-β or a β-α connection. Hence, MTs with these A lattices are helically symetric [Fig. 1(a)]. In MTs that possess an A

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

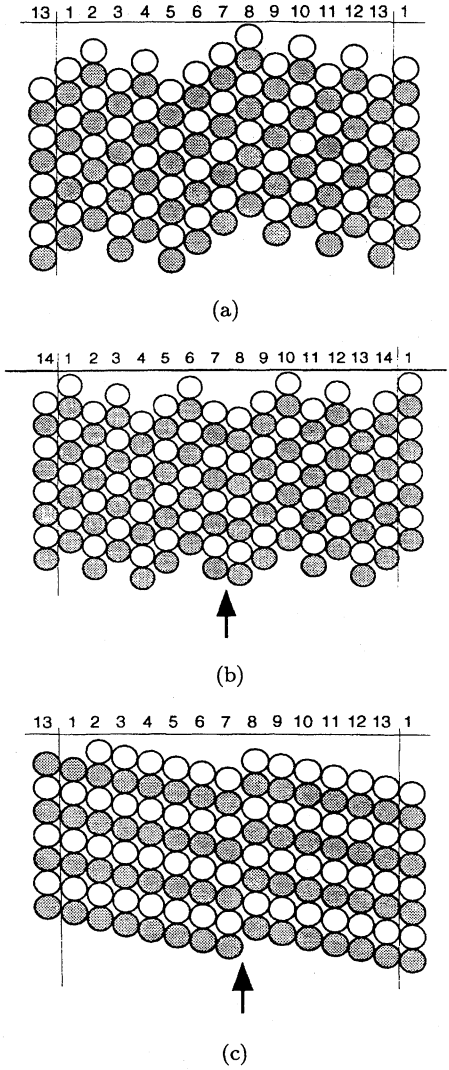

Fig. 1. A two-dimensional schematic view of a MT: (a) A lattice for $p = 13$, (b) A lattice for $p = 14$, (c) B lattice for $p = 13$. The α monomers are white, the β monomers are grey. The seam is indicated with an arrow. [Drawn according to (Martin *et al.*, 1993).]

lattice with an even number of protofilaments this connection is homologous, i.e. it is an α-α or a β-β connection. This means that in such MTs there is a discontinuity between the first and the last protofilament. This discontinuity is called a "seam" [Fig. 1(b)]. A seam is present in all MTs that possess a B lattice. In these MTs each of the three 3-start helices consists of sections that are composed of p monomers of one type. Along one 3-start helix each such section is connected at both ends to sections formed of p monomers of the opposite type. This results in heterologous monomer-monomer contacts along the seam in MTs with a B lattice [Fig. 1(c)].

To maintain the 3-start helix monomer symmetry of MTs that are composed of different numbers of protofilaments one can adjust the longitudinal shift between two neighboring protofilaments that is also referred to as stagger, as was done in Figs. 1(a) and 1(b). In this way the distances between the monomers and dimers are slightly changed so that the values of the stagger were calculated according to the expression $(4 + 12/p) \times 10^{-9}$ m for the A lattice and $(12/p) \times 10^{-9}$ m for the B lattice[a] (see Fig. 4).

From the consideration above it is obvious that if each monomer in the MT was represented by a site, the A and B type arrangements of tubulin dimers would be represented by the same lattice.[8] The fact that the A and B lattices are equivalent on the level of monomers may suggest that MTs possess only one of them. Recent experimental evidence indicates that the MT lattice is a B lattice.[6,16,17] This result was obtained indirectly by decorating tubulin with motor protein kinesin since due to the very similar structure of α- and β-tubulin current observational techniques cannot satisfactorily detect the difference between the two tubulin monomers.[6,8] However, at present no definite conclusions can be made about the type of the MT lattice.

3. A Model of Dipolar States of Tubulin and their Interactions in a Microtubule

Experimental investigations of Athenstaedt[18] have shown that a number of biological structures including MTs exhibit pyroelectric and piezoelectric behavior. Such properties originate as a result of the elementary dipoles carried by the constituent particles of the structure. This implies that a tubulin dimer carries a permanent dipole moment. However, the charge distribution within the tubulin molecule is not very well known. It seems, though, that at one end of the tubulin heterodimer the density of ions sitting on the amino acid residues of the protein chains is higher than in the rest of the molecule.[19] This attracts charges of the opposite polarity from the MT surroundings and can give rise to a dipole. What would be the charge and the length of the dipole is not precisely clear. Consequently, in the numerical calculations presented here these parameters were adjustable. As will be seen below the adopted value of the magnitude of the dipole moment was not unreasonable.

The model of dipolar interactions utilized in this paper was suggested by Tuszyński *et al.*[1–3] According to this model a MT is viewed as an assembly of dipoles that are placed at sites of a two-dimensional hexagonal MT lattice. In this hexagonal lattice each three nearest sites form identical triangles. Hence the MT lattice is also a triangular lattice. The directions along the sides of a triangular cell determine the three directions of the dipole–dipole interactions in the MT lattice (see Fig. 2).

[a]An A or a B lattice that represents a MT which consists of p protofilaments will be also termed p-A, p-B, where p can be 12, 13 or 14.

In the model each tubulin dipole interacts only with its six nearest neighbors and it can be in one of two orientational states that are characterized by the same magnitude of the dipole moment. These states were called the α and the β state. (The α and the β state of a tubulin dimer originally refer to two electrostatic states of tubulin that have been adopted in the cellular automata models.[11] These states were associated with a mobile electron that could be localized either more toward the α or more toward the β monomer of the dimer.) Since the longitudinal axis of the tubulin dimers assembled in a MT is parallel to the MT axis we have assumed that in the two dipolar states the projections of the dipole on the MT axis point in opposite directions. This direction was chosen to be positive in the α state and negative in the β state. Hence, the two dipolar states can be also termed the up and down state.

First we considered the simplest case in which the dipole on the tubulin is parallel to the MT axis in both α and β state. If an array of such dipoles is placed at sites of a triangular lattice and it is subjected to an external electric field $\mathbf{E}$ the total potential energy of the whole system is

$$H = -\sum_{j=1}^{N_C}\sum_{i=1}^{N_R}(J_1\sigma_{i,j}\sigma_{i+1,j} + J_2\sigma_{i,j}\sigma_{i-1,j+1} + J_3\sigma_{i,j}\sigma_{i,j+1})$$

$$-\mathbf{p}\cdot\mathbf{E}\sum_{j=1}^{N_C}\sum_{i=1}^{N_R}\sigma_{i,j}\,. \tag{1}$$

In the sum (1) N_R is the number of rows and N_C is the number of columns of the triangular lattice, $\sigma_{i,j}$ is a dipole variable that can have two values $+1$ or -1 which correspond to the two tubulin dipole states $\pm qs$ and J_1, J_2, J_3 are energy constants that characterize the interactions between the nearest dipoles along the three directions in the MT lattice (J_1, J_2, J_3 direction, Fig. 2). As can be seen Eq. (1) represents the Hamiltonian of a two-dimensional Ising model.[20]

The interaction constants J_n were found from the expression

$$W_n^{\uparrow\uparrow} - W_n^{\uparrow\downarrow} = -2J_n\,, \tag{2}$$

where $W_n^{\uparrow\uparrow}$ is the interaction energy between two neighboring dipoles in the nth direction when they both are in the up state and $W_n^{\uparrow\downarrow}$ is the interaction energy between two neighboring dipoles in the nth direction when one dipole is up and the other dipole is down. $W_n^{\uparrow\uparrow}$ and $W_n^{\uparrow\downarrow}$ were calculated using the classical formula for the interaction energy between two dipoles

$$W_n = \frac{1}{4\pi\epsilon_0\epsilon_r} \frac{(\mathbf{p}_1 \cdot \mathbf{p}_2)_n - 3(\mathbf{u} \cdot \mathbf{p}_1)_n(\mathbf{u} \cdot \mathbf{p}_2)_n}{|(\mathbf{x}_1 - \mathbf{x}_2)_n|^3} . \tag{3}$$

Here $\mathbf{p}_1$ and $\mathbf{p}_2$ are the dipole moments of the dipoles whose components with respect to the MT axis in our case have the magnitudes $\pm qs$, where q is the charge of the dipole and s is its length, $\mathbf{u}$ is a unit vector oriented along a line that connects the centers of the two dipoles, $\mathbf{x}_1$, $\mathbf{x}_2$ are the position vectors of the centers of the dipoles, ϵ_0 is the permittivity of vacuum and ϵ_r is the relative permittivity of the medium.

Since the magnitude and the orientation of the tubulin dipole are not very clear we have also considered a more general case in which the dipole in one of the states, for example, β is tilted with respect to the protofilament axis (Fig. 3). Because a MT is a cylinder the orientation of the dipole in the β state is given by two angles. One angle gives the orientation with respect to the MT axis and the other angle with respect to an axis that is perpendicular to the MT surface and passes through the center of the dipole. In the calculations presented here the curvature of the MT was not taken into account. The MT was treated as a sheet and the dipoles were assumed to lie in the plane of the sheet so that the tilting in the β state was given only by one angle θ. As will be seen in Sec. 9 varying θ results in various low temperature configurations of dipoles in the MT as the interaction constants J_n's change [see Eq. (3)]. Including the angle that characterizes the curvature would have the same effect. Hence to show the capabilities of the model it seemed to us sufficient to do calculations using the two-dimensional case at this moment.

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

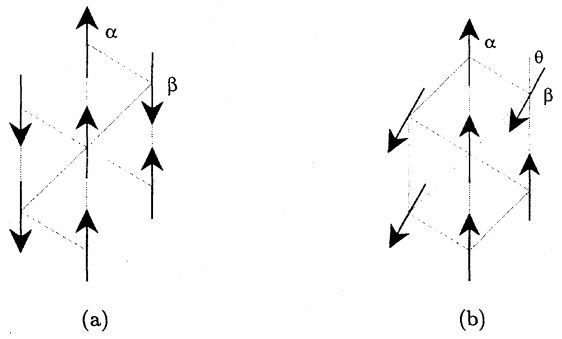

Fig. 3. A dipole and its nearest neighbors in a MT A lattice. (a) In both α and β state the dipole is parallel to the MT axis and oriented in opposite directions as is indicated by arrows. (b) In the β state the dipole is tilted by an angle θ with respect to the negative MT axis.

In the MT lattice in which the dipoles are tilted in the β state and lie in a two-dimensional plane the potential energy due to the interaction between the dipoles can be given by the following expression (Yeomans, 1992)

$$H_t = \frac{1}{4}\sum_{n=1}^{3}\sum_{\langle \mathrm{NN}\rangle} J_{n1}(1+s_k)(1+s_l) + J_{n2}(1-s_k)(1-s_l) + J_{n3}[(1+s_k)(1-s_l)+(1-s_k)(1+s_l)]\,. \tag{4}$$

In the equation above, the sum over n runs over the three sides of each triangular cell and $\langle \mathrm{NN}\rangle$ denotes the sum over the nearest neighbors. The variable s_k can have two values $+1$ or -1 which correspond to the α and β state, respectively. Each direction n of the triangular cell is characterized by three interaction energies: J_{n1} is the interaction energy between two dipoles that are in the nontilted state, J_{n2} is the interaction energy between two dipoles that are both tilted and J_{n3} is the interaction energy between a dipole in the tilted and a dipole in the nontilted state.

The terms in Eq. (4) can be rearranged so that one can be write it in the form

$$H_t = H_{\mathrm{int}} + V_{\mathrm{eff}}\sum_{j=1}^{N_\mathrm{C}}\sum_{i=1}^{N_\mathrm{R}}\sigma_{i,j} + C\,, \tag{5}$$

where H_{int} is the same as the interaction part of (1) but with a plus sign, V_{eff} is an effective potential energy, and C is a constant. The three interaction constants J_n in H_{int} are given by the equations

$$\begin{aligned} J_1 &= \frac{1}{4}(J_{11}+J_{12}-2J_{13})\,,\\ J_2 &= \frac{1}{4}(J_{21}+J_{22}-2J_{23})\,,\\ J_3 &= \frac{1}{4}(J_{31}+J_{32}-2J_{33})\,, \end{aligned} \tag{6}$$

where the interaction energies J_{nm} were calculated from the formula (3). The effective potential energy V_{eff} and the constant term C have the following form

$$V_{\mathrm{eff}} = \frac{1}{2}(J_{11}-J_{12}+J_{21}-J_{22}+J_{31}-J_{32}) \tag{7}$$

and

$$C = \frac{N}{4}\times(J_{11}+J_{12}+2J_{13}+J_{21}+J_{22}+2J_{23}+J_{31}+J_{32}+2J_{33})\,. \tag{8}$$

In the latter equation $N = N_\mathrm{C}\times N_\mathrm{R}$ is the total number of lattice sites.

In Eqs. (1) and (5) toroidal boundary conditions have been used. Due to the helical arrangement of the tubulin dimers a dipole in the last protofilament, σ_{i,N_C},

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

is neighboring to the dipole $\sigma_{i+a,1}$, where a depends on the stagger. The formulas (6)–(8) are the same both inside and at the boundaries of the A lattice with an odd number of protofilaments. All other lattices contain a seam at which the distances between the tubulin dimers are different and, consequently, the values of the interaction constants are different from those inside the lattice. This has to be taken into consideration in the three equations above.

It is not difficult to show from Eq. (3) that the values of the interaction constants J_n and the interaction energies J_{nm} depend on the type of the MT lattice, i.e. on the stagger which determines the distances $|(\mathbf{x}_1 - \mathbf{x}_2)_n| = r_n$ (Table 1) and therefore the angles θ_n (Fig. 4), on the orientation of the tubulin dipole when it is tilted and on the parameters q, s and ϵ_r. The dependence on the latter three parameters can be reduced to a dependence on the single parameter $\bar{Q} = q^2 s^2 / \epsilon_r$. In a realistic model, q should have a value of the order of one electronic charge 1.602×10^{-19} C and s should be of the order of several nanometers. As a relative permittivity one can use the value measured for proteins. This value is between 20 and 30 and it is

Table 1. Staggers and distances r_2 and r_3 inside the A and B lattices. The parameter $r_1 = 8 \times 10^{-9}$ m (length of the tubulin dimer).

the effective relative permitivitty, i.e. such which reflects the response of both the protein and its solvent.[21] We can point out that this value is not so much different from the value used in the previous papers by Tuszyński *et al.* This was $\epsilon_r = 70$ which is the value for free water in the static case (for nonoscillating dipoles) at body temperature.[22]

4. Numerical Procedure: Monte Carlo Method

The numerical calculations presented in this work have been performed on the basis of the classical Monte Carlo method that was realized by means of the Metropolis algorithm.[23] The procedure was used to find the configurations of the interacting system of dipoles in a MT at different temperatures. The configuration is a result of the competition between the potential energy of the dipoles and thermal energy. The interactions with neighboring dipoles and an electric field force a dipole to assume a state with the lowest potential energy (ground state). If the thermal energy is small compared to the potential energy the probability that the dipole will change its state due to a random thermal fluctuation is very small. With increasing thermal energy this probability also increases as the charges of the dipoles become more free to move.

In the algorithm the change of state of a dipole (a flip) happens when the number

$$\exp\left[-\frac{(E_{\text{new}} - E_{\text{old}})}{k_{\text{B}}T}\right], \tag{9}$$

is greater than a random number with a value between 0 and 1. In (9) E_{old} is the energy of a dipole in its old state, E_{new} is the energy of the dipole in its possible new state and k_{B} is Boltzmann's constant. Since in our model each dipole interacts only with its nearest neighbors the two energies depend only on the configuration of these dipoles.

It is obvious that a dipole always flips if $E_{\text{new}} < E_{\text{old}}$ because in that case the argument of the exponential in (9) is a positive number. In the opposite situation the argument is negative and the dipole flips only if (9) is larger than a randomly generated number whose value is between 0 and 1. This means that the probability of flipping a dipole is larger at higher temperatures. Such a procedure ensures that locally configurations of dipoles can form that are not in a ground state. With the increasing temperature the number of these regions increases and eventually at high temperatures the whole array of dipoles in a MT is completely randomized.

In the program used for the calculations shown below the number (9) was calculated and compared to the random number at each lattice site. The lattice was examined column by column. One such examination of the lattice is one Monte Carlo step. The dipolar ordering was calculated at different temperatures in the range 1–2000 K. The temperature step varied from $\Delta T = 1$ K to $\Delta T = 5$ K. In order for the array of dipoles to become uncorrelated with its initial state, at each investigated temperature 1000 Monte Carlo steps were performed and the last 200

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

were used to calculate polarization per site (relative polarization). If the simulation was started from the low temperature end we chose as the starting configuration one of the ground states of the system. In the simulations started from the high temperature end the configuration at the beginning of the simulation was a random configuration. The final configuration from the previous Monte Carlo step was used as the initial configuration for the next Monte Carlo step.

Polarization per site was calculated after each Monte Carlo step (starting from the step 801) by dividing the sum of the values of the dipole variables $\sigma_{i,j}$ at all lattice sites by the total number of lattice sites. A dipole tilted in the β state contributed to the sum by $(-\cos\theta)$. The values of relative polarization plotted in figures below are the average of the values calculated in the Monte Carlo steps 801 to 1000. All Monte Carlo simulation shown here were performed for a 100 rows long MT (with the exception of simulations that involved MAPs, see Sec. 8) and $\bar{Q} = 12 \times 10^{-56}$ C^{2}m^2. The polarization curves and data in tables in Secs. 5–8 were obtained assuming that the dipole in the β state is nontilted. The calculations for the case when the dipole in the β state is tilted are discussed in Sec. 9.

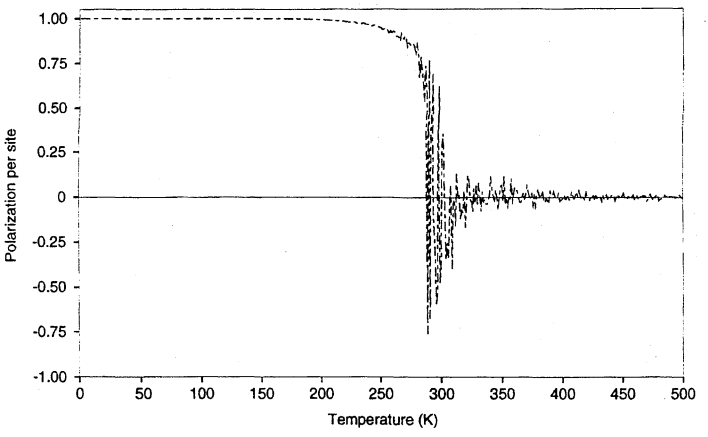
5. Microtubule Represented by the A Lattice

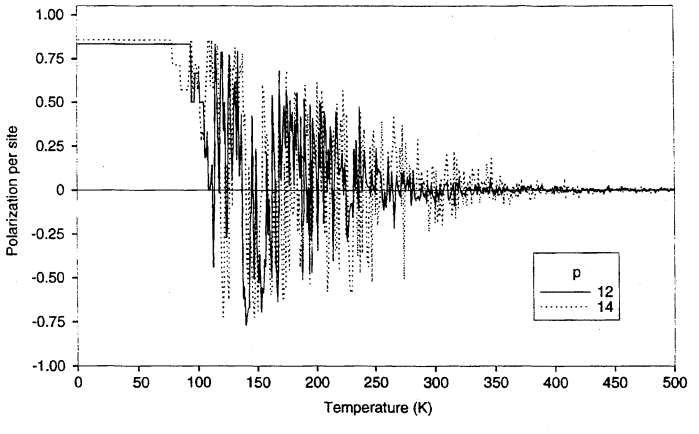
Figure 5(a) is a plot of polarization per site as a function of temperature calculated for a MT represented by the 13-A lattice. As can be seen at low temperatures the MT is in a completely ordered state with all dipoles pointing in the positive direction along the MT axis as was chosen at the beginning of the simulation. At temperatures close to the room temperature (300 K) the system undergoes a transition into a disordered state when the dipoles are oriented randomly and the total polarization is zero. The small fluctuations around zero are due to the thermal fluctuations. In analogy with ferroelectric crystals the two states of the array of dipoles in a MT will be further termed a ferroelectric and a paraelectric phase, respectively.[24]

It is not difficult to explain the character of the curve shown in Fig. 5(a). By examining the values of the corresponding interaction constants that are listed in Table 2 it becomes obvious that all J_n's are of the order of magnitude 10^{-21} J. The transition from the low temperature phase to the high temperature phase takes place when the energy of the thermal fluctiations $k_{\mathrm{B}}T$ is sufficiently large to allow the dipoles to exist in configurations that do not correspond to one of the ground states. This happens when $k_{\mathrm{B}}T$ is comparable to the interaction energy between the dipoles.[25] Since the value of the Boltzmann's constant is 1.38×10^{-23} JK^{-1} the transition occurs at temperatures $T \sim 100$ K.

The considerations above imply that increasing the interaction energies between the dipoles in the MT increases the transition temperature and *vice versa* which we also verified by the Monte Carlo simulations. As was noted in Sec. 3, the magnitudes of the interaction constants J_n depend on the value of the parameter $\bar{Q} = q^2 s^2/\epsilon_{\mathrm{r}}$ and the geometrical configuration of the tubulin dimers in the MT which is given



(a)



(b)

Fig. 5. Polarization per site: (a) 13-A MT, (b) 12-A and 14-A MT.

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

by the type of the MT lattice A or B and the number of protofilaments. Changing these parameters changes the transition temperature and, consequently, determines the character of the dipolar order in a MT at body temperature (310 K).

Curves plotted in Fig. 5(b) represent polarization per site calculated for a 14-A and 12-A MT. The figure shows that at low temperatures in the 12- and 14-protofilament MTs not all dipoles point in the same direction — the value of the total relative polarization is less than one. This is due to the presence of the seam. As can be found in Table 2 in the 12-A and 14-A lattices the constant J_{3s} is negative and has a larger magnitude than any other interaction constant. The second most dominant interaction constant is J_1 which is positive and characterizes the dipole–dipole interaction along the longitudinal direction in the MT lattice.

Table 2. The interaction constants in the MT A lattice for $p = 12, 13, 14$. J_1, J_2, J_3 characterize the interaction inside the lattice, J_{2s} and J_{3s} refer to the seam.

p	12	13	14
J_1 (10^{-21} J)	+4.21	+4.21	+4.21
J_2 (10^{-21} J)	−1.12	−0.94	−0.79
J_3 (10^{-21} J)	+1.53	+1.49	+1.45
J_{2s} (10^{-21} J)	+1.67	−0.94	+1.65
J_{3s} (10^{-21} J)	−7.20	+1.49	−7.56

The form of the Hamiltonian (1) is such that when the interaction between two nearest dipoles is characterized by a negative interaction constant, this bond is in the state with the lowest energy if the dipoles point in the opposite directions. On the contrary, interaction between two nearest dipoles characterized by a positive interaction constant requires the dipoles to be aligned. Thus, the dipoles in the two protofilaments along the seam are at low temperatures aligned but in a different direction in each protofilament giving the total relative polarizations $10/12 = 0.833$ and $12/14 = 0.857$ for 12-A and 14-A lattices, respectively.

In a MT that is assembled from 13 protofilaments such a situation does not occur. This MT does not have a seam and the two dominant interaction constants J_1 and J_3 are positive. Consequently, even though the energetically more favorable state along the J_2 direction is when each two nearest dipoles point in the opposite directions, the effect of J_1 and J_3 overcomes the effect of J_2 and all dipoles at low temperatures are in the same state.

It can also be noticed that the interval of temperatures over which the transition from the ordered to the disordered state in the 12-A and 14-A lattices takes place is much larger than in the 13-A lattice. This effect is also caused by the presence of the seam. Since the magnitude of the interaction constant J_{3s} is larger than the magnitudes of the remaining four J_n's, the energy of the thermal fluctuations must be sufficiently large to eventually overcome also the interaction through J_{3s} that forces the dipoles to be ordered along the seam in opposite directions which affects the dipolar ordering in the whole lattice.

Another feature of the array of dipoles with the potential energy (1) is that the state in which all dipoles are oriented in one or the other direction along the MT axis has the same energy. Due to this the ground state of the 13-A lattice is doubly degenerate and the 12-A and 14-A lattices possess a multitude of ground states. For example, all states in which the assembly of dipoles in the MT forms two subclusters, one consisting of protofilaments 1 to $N_T < N_C$ and all dipoles in it are up/down and the other of protofilaments $(N_T + 1)$ to N_C with all dipoles pointing down/up, have the same energy. For instance, the simulation for the 14-A lattice in Fig. 5(b) was started from the configuration in which $N_T = 1$ that is shown in Fig. 6(a).[b]

[b]In all figures below that depict configurations of dipoles are included columns 0 and $(N_C + 1)$.

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

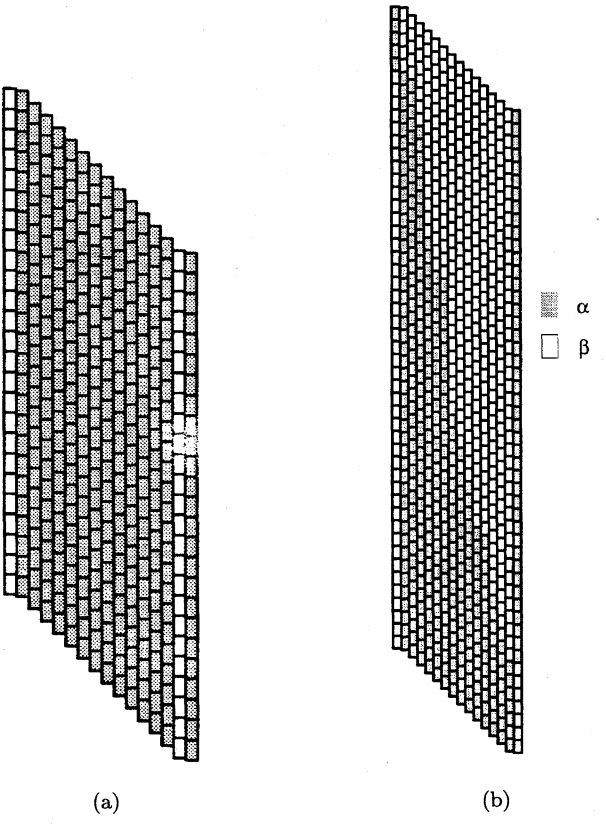

Fig. 6. (a) One of the ground states of a 14-A MT in which in the protofilaments 1 and 14 along the seam the dipoles are aligned in different directions and in the rest of the MT they point up. (b) A configuration of dipoles in a 50 row long section of the 14-A MT at $T = 5$ K. In the whole lattice (100 rows) the two subclusters in which the directions polarization are opposite have almost the same size so that the total relative polarization is almost zero.

The two clusters with different directions of polarization can also have a different form, for example, such as in Fig. 6(b). The figure shows a configuration of dipoles in a section of the 14-A lattice at temperature $T = 5$ K at which the system of dipoles arrived when it was initially completely randomized at $T = 1000$ K. This configuration is not a groundstate because in the 14-A lattice in a groundstate all dipoles in one protofilament have to point in the same direction. However, the total interaction energy is only slightly higher than the energy in a groundstate.

The polarization curve corresponding to the configuration shown in Fig. 6(b) is the solid line in Fig. 7. The dotted line in Fig. 7 represents a simulation that was also started from a random configuration of dipoles but the generated sequence of random numbers used by the Monte Carlo algorithm in this calculation was different. In this case in the ground state all dipoles in protofilaments 1 to 8 pointed up and 9 to 14 down so that the corresponding polarization was $2/14 = 0.143$.

We can conclude that the presence of a seam in a MT with the A-lattice introduces a multitude of states that are characterized by different configurations of dipoles but the same energy. The ground state that the regular array of dipoles in a MT reaches in a Monte Carlo simulation depends on the initial configuration of the dipoles and the chosen sequence of random numbers. If the configuration of dipoles in a MT is changed by some external factor (for example, an external electric field) a MT can switch into a different ground state. At low temperatures the MT remains in the ground state for a long time. At high temperatures it is easier for a MT to switch between various states due to the increase in thermal energy. [According to Figs. 5(b) and 7 at temperatures from the range of about 0–100 K the polarization in the 12-A and 14-A lattice has the same value. Thus, a thermal fluctuation by several degrees does not alter the value of polarization. However, at higher temperatures the polarization can fluctuate within 1 K.]

6. Microtubule Represented by the B Lattice

As was explained earlier for any number of protofilaments a MT represented by the B lattice contains a seam along which the values of the interaction constants are different from those inside the MT (Table 3). Because the largest interaction constant in the B lattices is J_3 and the second largest J_1 the ground state of a MT that exhibits a B lattice is antiferroelectric: all dipoles in one protofilament point in the same direction and in each two neighboring protofilaments these directions are opposite. Since J_{2s} and J_{3s} are several times smaller than J_1 and J_3 the dipolar order along the seam will also be determined by the latter interaction constants.

Table 3. The interaction constants in the MT B lattice.

p	12	13	14
J_1 (10^{-21} J)	+4.21	+4.21	+4.21
J_2 (10^{-21} J)	+1.67	+1.66	+1.65
J_3 (10^{-21} J)	−7.20	−7.40	−7.56
J_{2s} (10^{-21} J)	−1.12	−0.94	−0.79
J_{3s} (10^{-21} J)	+1.53	+1.49	+1.45

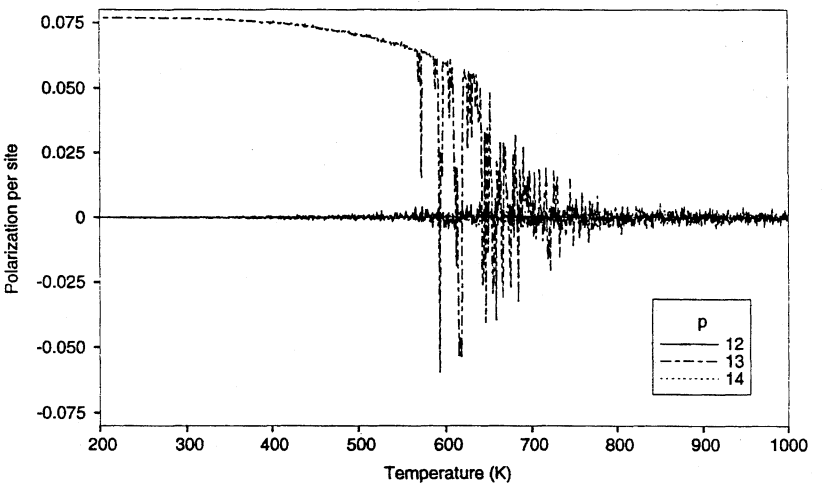

Fig. 8. Polarization per site in 12-B, 13-B and 14-B lattices.

Polarization curves for the B type lattices are shown in Fig. 8. All simulations were started from the low temperature end. The initial configuration was antiferroelectric (Fig. 9) which corresponds to the total relative polarization zero in the 12-B and 14-B and $N_R/(13 \times N_R) = 1/13 = 7.69 \times 10^{-2}$ in the 13-B lattice. As can be seen in Fig. 8 the lattices undergo a transition from the ordered antiferroelectric phase to the disordered paraelectric phase. Because the interaction constants in the B lattice are larger than in the A lattice the transition happens at higher temperatures. Since the two directions of polarization along the MT axis are energetically equivalent the antiferroelectric ground states are doubly degenerate.

7. Effects of an External Electric Field

According to the Ising Hamiltonian (1) the array of dipoles in a MT subjected to an external electric field has the tendency to point in the same direction as the field (to minimize the potential energy due to the interaction with the electric field). Figure 10 shows the effect of an external electric field that points in the positive

direction along the MT axis on a 13-A MT. To calculate the polarization curves plotted in this figure and also in Figs. 11 and 12 we chose the dipole strength $p = qs = 10^{-27}$ Cm. As can be seen in Fig. 10 the stronger is the electric field the larger is the number of dipoles that at a temperature T point in the positive direction. This is a consequence of adding the electric potential energy to the dipole–dipole interaction energy. Therefore a larger thermal energy is required to overcome the total potential energy.

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

The character of the plots in Fig. 10 implies that the electric field starts to be effective at about 10^4–10^5 Vm^{-1}. This is because for these fields the potential energy $-pE$ becomes of the order of magnitude of the dipole–dipole interaction energies (see Sec. 3). For $E = 10^7$ Vm^{-1} up to very high temperatures all dipoles point in the direction of the electric field. It can be noted that Vassilev *et al.*[26] applied electric pulses with amplitudes of the order of magnitude 10^0 to 10^1 Vm^{-1} to assemblies of MTs with the result that the MTs aligned along the electric field lines. According to our model this would mean that the assembly of dipoles in the tested MTs was in an ordered state so that even small electric fields align the MTs along their field lines. The electric fields that exist inside the cell have been reported to be of similar magnitudes than those used by Vassilev *et al.*[27] Hence in our model the electric fields inside the cell wouldn't have an effect on the dipolar ordering in MTs. However, for example, in membranes the electric fields are of the order of 10^6–10^7 Vm^{-1}.

In the 12- and 14-protofilament A lattices the effect of an external electric field is more complex than in the 13-protofilament A lattice due to the presence of the seam. As was already shown in these lattices the diagonal interaction along the seam that is the strongest causes the two protofilaments along the discontinuity to be polarized in opposite directions. Consequently, at lower fields it is still more energetically favorable for the dipoles to be aligned in opposite directions in the two protofilaments along the seam. At the same time even though the electric field is not sufficiently strong to flip the dipoles along the seam it is strong enough to flip the dipoles inside the lattice. Hence, for such electric fields at low temperatures all protofilaments are polarized in the direction of the electric field except for one of the two protofilaments that form the seam. When the electric field is sufficiently large so that also the dipoles along the seam are in the state with the lowest potential energy if they point in the same direction as the external electric field, the whole lattice becomes completely ordered at low temperatures.

The effect of an external electric field on a 14-A MT is shown in Fig. 11. For $0 \leq E \leq 3 \times 10^6$ Vm^{-1} at low temperatures all dipoles point in the same direction (positive) as the electric field with the exception of one of the protofilaments along the seam in which all dipoles point in the opposite direction. At some transition temperature the polarization starts to decrease with the increasing temperature. When $E = 5 \times 10^6$ Vm^{-1} at low temperatures the configuartion of dipoles is the same as for the lower fields. However, as the thermal energy increases with the increasing temperature, in the protofilament along the seam in which the dipoles are oriented in the negative direction some of them can flip up due to random thermal fluctuations while the dipoles in the rest of the MT point in the positive direction. Consequently, the relative polarization is larger than 12/14. After reaching its maximum the polarization decreases as the temperature increases. The electric fields with the magnitude 6×10^6 Vm^{-1} and higher are sufficiently strong so that at low temperatures all dipoles in the MT point in the same direction as the fields.

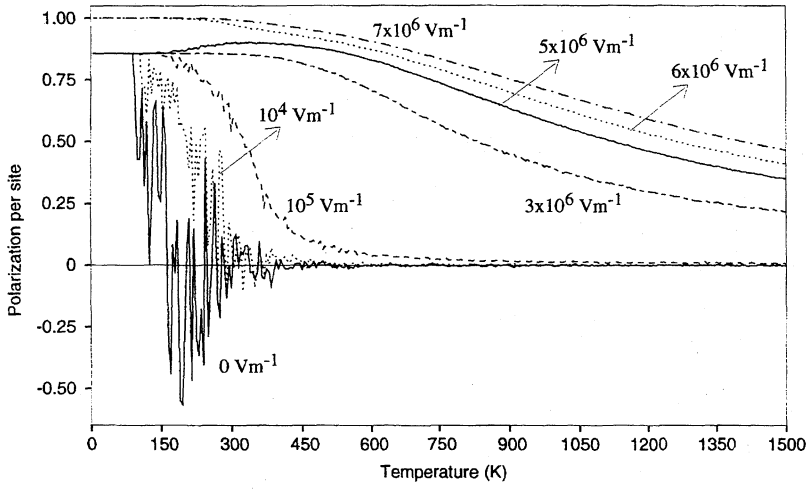

Fig. 11. Polarization per site in a 14-A MT that is subjected to external electric fields. The curves for $E = 3 \times 10^6$ Vm^{-1} and larger fields were calculated starting from random configurations at $T = 2000$ K.

The picture would be very similar in the 12-A lattice since its interaction constants do not substantially differ from those in the 14-A lattice (see Table 2).

The behavior of the array of dipoles in the B lattices under the influence of changing external electric field has a similar character as in the 12-A and 14-A lattices and it is shown for a 13-B lattice in Fig. 12. As was discussed in Sec. 6 the ground state of a MT represented by the B lattice is antiferroelectric because the largest interaction constant is J_3. As can be seen in Fig. 12 when the MT is subjected to lower electric fields, the ground state of the array of dipoles at low temperatures is antiferroelectric. However, as the thermal energy increases with the increasing temperature the random thermal fluctuations allow also the dipoles in the protofilaments with negative polarization to point in the same direction as the electric field. As a result, at fields 5×10^6 Vm^{-1} to 1.1×10^7 Vm^{-1} at higher temperatures the polarization per site increases above 1/13. Once the polarization reaches its maximum given by the combination of the three factors — thermal energy, dipole–dipole interaction energy and the potential energy that is due to the interaction with the electric field — it slowly decreases with the increasing temperature. When the external electric field is larger than a certain value, at low temperatures all dipoles in the lattice point in the direction of the field and at some critical temperature the total polarization starts to decrease. For even larger electric fields the whole lattice would be ordered also at high temperatures.

It can be pointed out that in the 13-B MT due to the odd number of protofilaments the dipoles in the two protofilaments along the seam point in the same direction in the antiferroelectric phase. However, since the values of the interaction constants along the seam are several times smaller than J_3 and J_1 this feature would

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

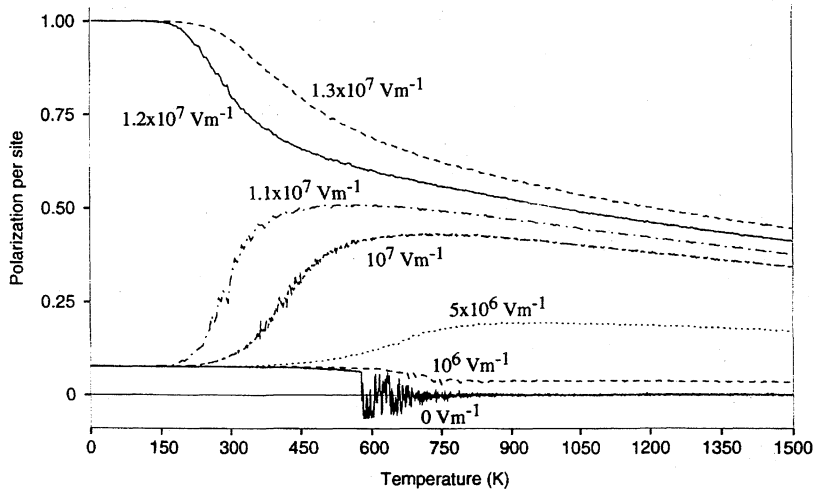

Fig. 12. Polarization per site calculated for a 13-B MT in the presence of external electric fields. The curves for $E = 1.1 \times 10^7$ Vm^{-1} and larger fields were calculated starting from random configurations at $T = 2000$ K.

not introduce a substantial difference in the character of the dipolar order in this lattice. Since the values of the interaction constants in the 12-B and 14-B lattices are not very different from those in the 13-B lattice the array of dipoles in MTs with these lattices when they are subjected to external electric fields with various magnitudes will behave in a similar manner. The difference in the magnitudes of the interaction constants will cause different critical temperatures and at low fieds and low temperatures the polarization in the B-lattices with even number of protofilaments will be zero.

8. Effects of MAPs

Experimental evidence indicates that MAPs can bind to MTs in both regular and irregular way.[8] Since a MT is a helical structure it has been suggested that the regular MAP patterns form superhelices.[8,11] Based on this the influence of MAPs on the dipolar order in the MT lattice was studied here for three different superhelical MAP arrangements. The superhelices were constructed according to[11] and they are shown for a 13-A MT in Fig. 13. In the other types of lattices these patterns do not form superhelices due to the presence of the seam (see Figs. 16, 17 and 19). The ratio of the number of MAPs (MAP ratio) to the total number of lattice sites in the three MAP arrangements is 1/11, 1/22 and 1/48. In the simulations these patterns were imposed on MTs 99, 110 and 96 rows long, respectively. Some simulations for MAP ratio 1/11 were performed for a shorter 44 row long MT.

As can be noticed, in forming the patterns we have assumed that each MAP is attached to one tubulin dimer. However, since most MAPs are several times heavier than tubulin they most likely bind to more than one tubulin heterodimer.[4,28]

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

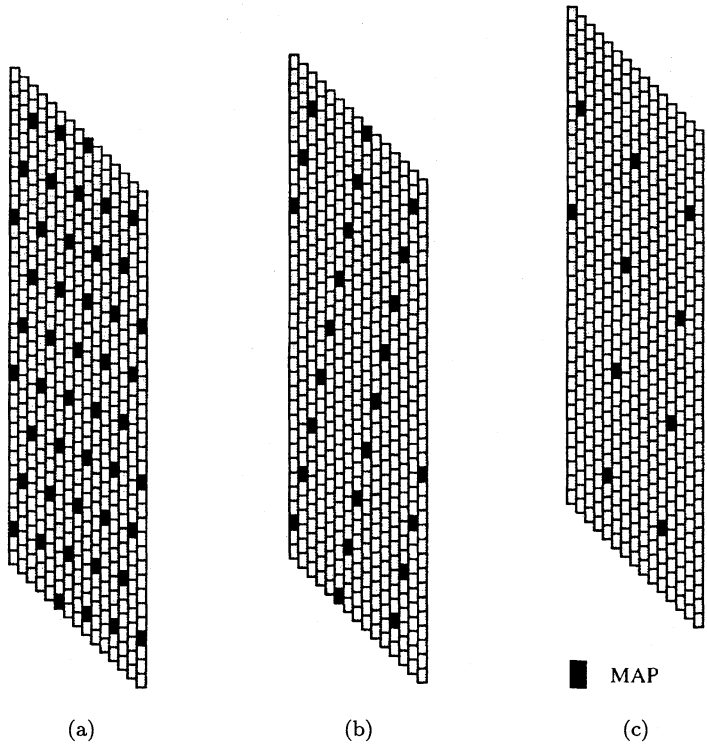

Fig. 13. Three superhelical patterns of MAPs for which the ratios of the number of MAPs to the total number of lattice sites are (a) 1/11, (b) 1/22, (c) 1/48. The patterns are imposed on a 13-protofilament A lattice.

We further assumed that a MAP attached to a tubulin subunit in the MT either prevents the dipole on the tubulin to flip or that it neutralizes the tubulin molecule. Hence, the dipole variable $\sigma_{i,j}$ at the sites of the MT lattice at which MAPs were bound (MAP sites) was set either to one or to zero, respectively.

The polarization curves that represent the dipolar order in a 13-A MT to which MAPs attach according to the three patterns depicted in Fig. 13 are shown in Fig. 14. Figure 14(a) represents a set of calculations in which at the MAP sites $\sigma_{i,j} = 1$. The polarization curves show that the number of tubulin dipoles that point in the same direction, in this case up, is larger in the lattices in which MAPs are present compared to the lattice without MAPs. This behavior is due to the fact that in the 13-A lattice in the state with the lowest energy all dipoles point either up or down (see Sec. 5). If some of the dipoles permanently point up they will force their neighbors also to point up. The more MAPs bind to a MT the greater is at a temperature T the number of dipoles which point in the same direction as the permanent dipoles carried by the tubulins to which the MAPs are attached.

The numerical data obtained for the case when MAPs are represented by $\sigma_{i,j} = 0$ are plotted in Fig. 14(b). The data were normalized with respect to the total number of lattice sites excluding the MAP sites. As can be seen the bound MAPs do not

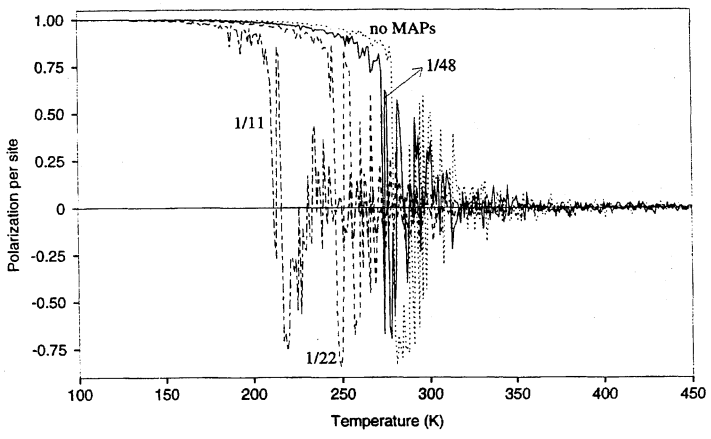
(a)



(b)

Fig. 14. Polarization curves calculated for a 13-A MT in which MAPs bound to the molecules of tubulin form the three patterns shown in Fig. 13. At the MAP sites $\sigma_{i,j}$ is (a) 1, (b) 0.

change the character of the dipolar order that exists in the lattice in which MAPs are not present — the array of dipoles undergoes a transition from the low temperature ferroelectric phase to the high temperature paraelectric phase. However, the MAPs affect the transition temperature. The larger is the MAP ratio, the lower is the temperature of the transition from the ferroelectric to the paraelectric phase. The reason for this behavior is quite obvious. As was discussed in Sec. 5, in the 13-A lattice the dipolar order is determined by the positive interaction constants J_1 and J_3. Along the two directions in the MT lattice characterized by these interaction constants in the configuration x, 1 it requires less energy for the dipole that is up to flip down if $x = 0$ compared to the case when $x = 1$. In the configuration x, -1

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

the dipole that is down flips up at less energy cost for $x = 0$ than for $x = -1$. Thus, if in the starting configuration at low temperatures all dipoles in the MT point in the same direction, it requires less energy and, consequently, lower thermal energy k_BT to undergo a transition to the paraelectric phase if some tubulin molecules in the MT are neutral.

The type of the dipolar ordering in the presence of MAPs in a MT A lattice that has an even number of protofilaments is represented in Fig. 15 that shows a simulation for the 14-A lattice in which at the MAP sites $\sigma_{i,j} = 1$. As in the 13-A lattice the number of dipoles that point up increases with the increasing MAP ratio except for at the seam where the dipoles that interact through the large and negative interaction constant J_{3s} are oriented in opposite directions. Because of the chosen MAP patterns and the type of the boundary conditions the MAPs that are placed in protofilaments 1 and 14 happen to be nearest neighbors along the J_{3s} direction (Fig. 16). Hence, the total relative polarization in the low temperature state is slightly higher than in the case when no MAPs are present in the lattice. Another consequence of this arrangement of MAPs along the seam in the 14-A lattice is that in each of the protofilaments 1 and 14 the direction of polarization can be different in the sections between two nearest MAPs. Consequently, this lattice possesses a multitude of groundstates that are characterized by different configurations of dipoles along the seam.

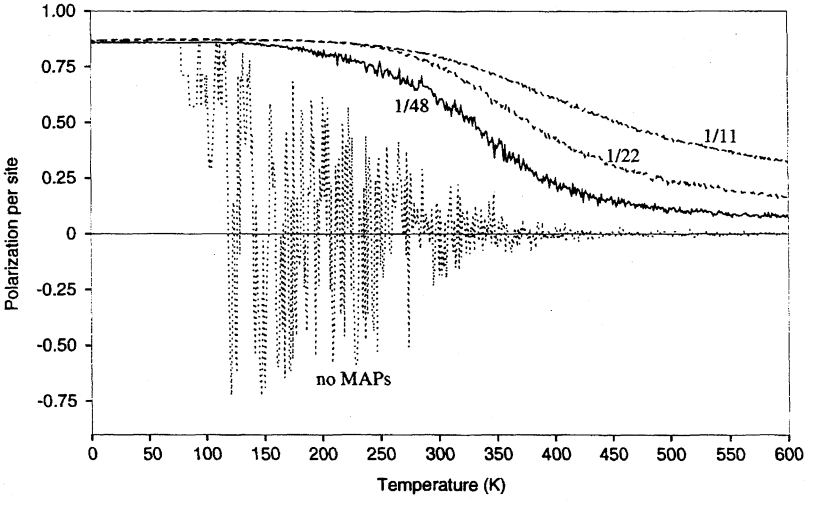

Fig. 15. Polarizations per site in a 14-A MT to which MAPs are bound according to the three patterns shown in Fig. 13. At the MAP sites $\sigma_{i,j} = 1$.

As in the 13-A lattice representing MAPs by $\sigma_{i,j} = 0$ in the 12-A and 14-A lattices does not favor any of their ground states. The dipolar configurations are of a similar type as those found in MTs that do not bind MAPs, however, the

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

presence of MAPs introduces also groundstates of different types. We performed numerical calculations for a 14-A MT for all three MAP ratios starting from random configurations at high temperatures. The configuration at which the array of dipoles arrived at low temperatures most often was of the type shown in Fig. 17(a) for the MAP ratio 1/11. It can be seen that along the seam each two dipoles that interact through J_{3s} point in opposite directions. The assembly of dipoles forms two subclusters in each of which the directions of polarization is different [compare to Fig. 6(b)]. The boundary between the two subclusters forms along one of the diagonal lines that connect MAPs since it consumes less energy to flip a dipole in the neighborhood of a tubulin dimer that does not carry any dipole moment.

As was discussed in Sec. 5 the configuration in Fig. 17(a) is not a ground state of the array of dipoles, but it is close to it. Another low temperature state that is close to the state with the lowest energy was obtained for a MT that bound MAPs in the ratio 1/22. In this state all dipoles inside the MT pointed down and all dipoles neighboring along J_{3s} were oriented in opposite directions, but the polarization of dipoles varied between two neighboring MAPs along the protofilaments 1 and 14. In many simulations performed for lower MAP ratios or shorter MTs the MT lattice reached one of the groundstates. Two such groundstates are shown in Figs. 17(b) and (c). Figure 17(b) depicts a section of a 110 rows long MT that is in a groundstate

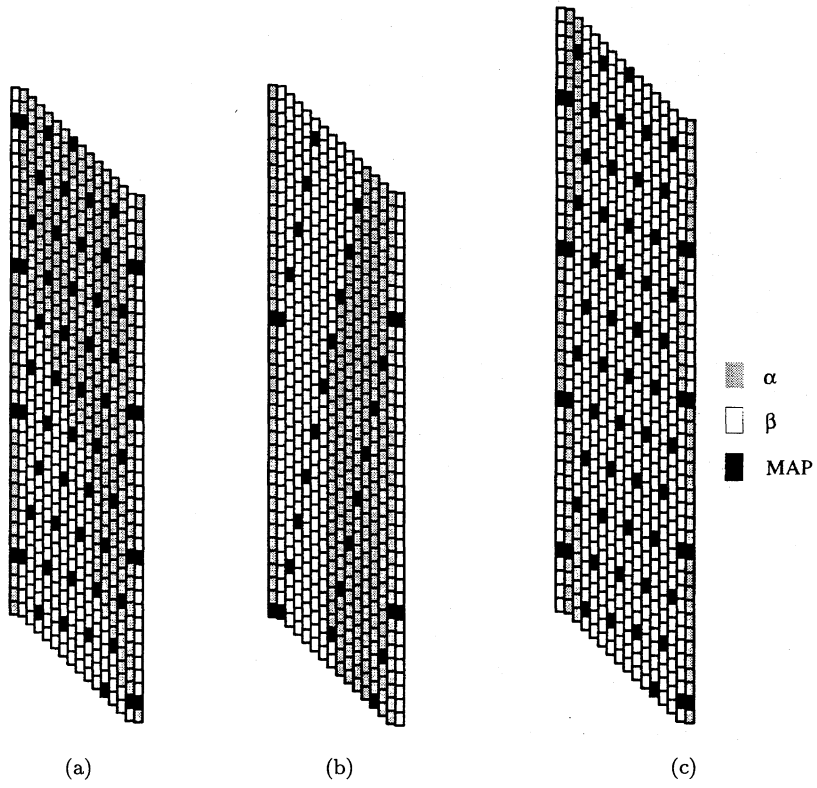

Fig. 17. Three different low temperature dipolar configurations in MTs in the presence of MAPs that are represented by $\sigma_{i,j} = 0$. (a) A section of a MT that is 99 rows long, MAP ratio is 1/11. (b) A section of a 110 row long MT, MAP ratio is 1/22. (c) A 44 row long MT, MAP ratio is 1/11.

for MAP ratio 1/22. Figure 17(c) shows a groundstate in a 44 row long MT to which bind MAPs in the ratio 1/11. The figures imply that there exists a large multitude of groundstates of the types shown. We also found the groundstate configurations that consist of two subclusters, one polarized up and the other down each consisting of 1 up to 13 neighboring protofilaments [see Fig. 6(a)].

Figure 18 shows a set of calculations performed for the 12-B lattice for all three MAP ratios when $\sigma_{i,j} = 1$ at the MAP sites. The simulations were started from the low temperature end. All three lattices are in a ground state or close to a ground state at low temperatures. At $T \sim 200$ K the polarization in the lattice exhibits a maximum, then decreases until it reaches a minimum and eventually increases and at very high temperatures oscillates around the value equal to the MAP ratio. The latter effect cannot be seen because it occurs at temperatures of the order of 10^4 K.

A character of dipolar ordering such as the one represented by Fig. 18 is given by the combination of antiferroelectric interactions, the MAP configuration and thermal energy. At low temperatures at least one of the ground states is such as shown in Fig. 19 for the MAP ratio 1/48. In the background of the antiferroelectric

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

arrangement of dipoles are inserted MAPs which at low temperatures do not have an effect on their surrounding dipoles inside the lattice. Along the seam, however, for the dipoles in the 12th row which are neighboring to MAPs in the 11th row it is more energetically favorable to be down. The energy of each of these dipoles is -0.86×10^{-21} J. The relative polarization that corresponds to this state in the lattice is then $20/(12 \times N_{\mathrm{R}}) = 0.0174$. As the temperature increases the thermal fluctuations allow the dipoles along the seam which are neighboring to MAPs to flip into the energetically unfavorable up state ($+0.86 \times 10^{-21}$ J) since the flip does not require much energy. To flip any other dipoles would require several times more energy. Thus, the polarization increases. It should be realized, though, that this increase is due to flipping of only a few dipoles. After the polarization reaches its maximum it decreases because the thermal energy increases and as a consequence some of the dipoles inside the lattice can flip. From its minimum the polarization slowly increases and eventually reaches a state in which all dipoles in the lattice except for at the MAP sites are oriented at random so that the total polarization is equal to the MAP ratio. This happens at temperatures of about 5×10^4 K at which the thermal energy is very large so that it completely overcomes the influence of the dipole–dipole interactions.

For the MAP ratio 1/48 the ground state shown in Fig. 19 was reached at low temperatures in the simulation shown in Fig. 18. When the MAP ratios were 1/22 and 1/11 the states at low temperatures were close to this groundstate. But even for the highest MAP ratio 1/11 the groundstate above existed in shorter MTs (44 rows). We also found that at low temperatures in lattices that contain a smaller

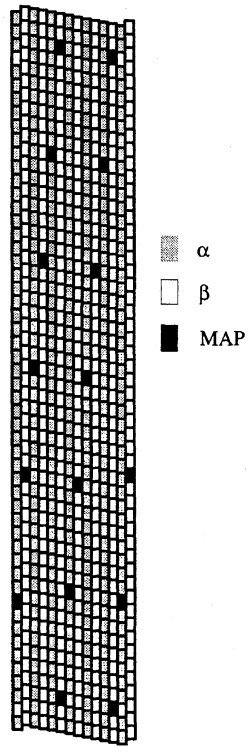

Fig. 19. A ground state in the 12-B lattice that corresponds to $T = 4$ K on the curve for the MAP ratio 1/48 in Fig. 18.

number of MAPs, so that the spaces between two neighboring MAPs along one protofilament are larger, and for $\sigma_{i,j} = 1$ at the MAP sites, along one protofilament can form subsections in which the dipoles are oriented in opposite directions. Most MAPs in the lattice occur in the subsections in which the dipoles are up to minimize the energy of the interaction along the J_1 direction.

In the 13-B and 14-B lattices the effect of MAPs represented by $\sigma_{i,j} = 1$ is similar as in the 12-B lattice. The dipolar order in the MT is a result of the competition between the thermal energy, dipole–dipole interactions and a MAP configuration. Unlike the lattices that consist of an even number of protofilaments in the 13-B lattice to the antiferroelectric ground state can correspond two different values of polarization: $-1/13$ when all dipoles in six rows point up and all dipoles in seven rows point down, or $+1/13$ in the alternative case. The positive branch of polarization is most likely to appear in lattices that contain higher ratios of MAPs which are represented by $\sigma_{i,j} = 1$. When $\sigma_{i,j} = 0$ at the MAP sites, the lattice is equally likely to choose one of the two branches of polarization. This feature of the 13-protofilament B lattice is an additional factor to those listed above that determine the complex dipolar behavior in the lattices that contain MAPs.

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

As in the A lattice, if the dipole variable at each MAP site is zero the MAPs do not affect the type of the dipolar ordering in the B lattice, but their presence lowers the transition temperature. In the antiferroelectric phase in the two directions characterized by the large interaction constants J_3 and J_1 it costs less enegy to flip a dipole one of whose nearest neighbors is a MAP. Hence, the transition between the antiferroelectric phase and the paraelectric phase takes place at lower temperatures compared to the lattices in which MAPs are not present. To see this, in Fig. 20 is plotted polarization per site calculated for a 13-protofilament MT which contains MAPs in the ratio 1/11 represented by $\sigma_{i,j} = 0$. The simulation started from the high temperature end and the lattice which contains MAPs chose the negative branch of polarization.

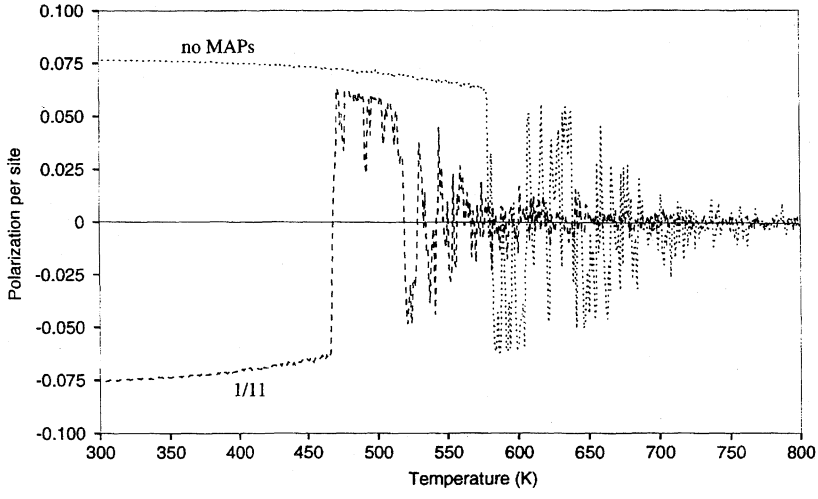

Fig. 20. Relative polarization in the 13-B lattice that contains MAPs represented by $\sigma_{i,j} = 0$ in the ratio 1/11. The calculations were started from a random configuration at $T = 1500$ K.

9. Dipoles Tilted in the β State

To study the dipolar order in lattices in which the dipoles in the β state are tilted by an angle θ with respect to the MT axis we performed calculations for the values of θ in the range $+90°$ to $-90°$ with a step $\pm 10°$ except for the largest angles that were taken to be $\pm 89°$. The sign "+" refers to tilting to the left and "−" refers to tilting to the right with respect to the MT axis. It should be pointed out that tilting to the right and tilting to the left by the same angle are not equivalent in the 12-, 13- and 14-protofilament MT lattices because the distances between two nearest tubulin dimers in the two diagonal directions are not the same (see Table 1, Figs. 3 and 4).

In Fig. 22(a) are plotted curves that represent relative polarization in the 13-A lattice for some "+" values of θ. When $\theta = +10°$ to $+70°$, at low temperatures

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

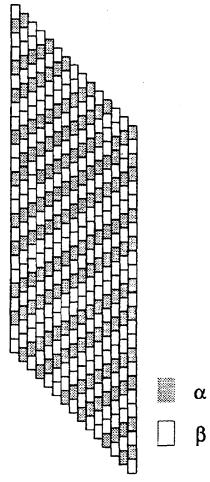

Fig. 21. A section of a MT that corresponds to the curve for $\theta = +89°$ in Fig. 22(a) at $T = 4$ K.

all dipoles are in the tilted state and the value of relative polarization is equal to $(-\cos\theta)$, i.e. it increases with increasing θ. Since $|\cos\theta| < 1$ for $0° < \theta < 90°$, at high temperatures, when due to the thermal energy the dipoles flip into the nontilted state, the polarization per site becomes positive.

The configuration of dipoles for $\theta = +80°$ and $+89°$ at low temperatures is shown in Fig. 21. The dipoles that are in the same state have the tendency to order themselves along the diagonal direction characterized by the constant J_2 and along the J_3 direction the dipole states tend to alternate.

Table 4. The interaction constants in the 13-A lattice for $\theta = -10°$, $-30°$, $\pm 40°$, $+60°$, $+70°$, $\pm 80°$.

θ (°)	+40	+60	+70	+80	−10	−30	−40	−80
J_1 (10^{-21} J)	−3.07	−1.98	−1.43	−0.94	−4.14	−3.54	−3.07	−0.94
J_2 (10^{-21} J)	−3.97	−5.29	−5.46	−5.32	+2.11	+3.76	+4.14	+2.93
J_3 (10^{-21} J)	+1.33	+1.90	+1.92	+1.80	−2.29	−3.58	−3.99	−3.62

Table 4 which contains the values of the interaction constants J_1, J_2 and J_3 for certain angles θ shows why the above types of dipolar order arise. For angles less than $+70°$ the constants J_1 and J_2 are negative and larger in magnitude than the positive constant J_3. Consequently, in the state with the lowest energy all dipoles have the same orientation. Whether they are tilted or nontilted is determined by the second term in the Hamiltonian (5) [the dipolar ordering depends on the difference of energies, see (9)].[c] For $\theta = +70°$ the magnitude of the negative J_1 is smaller

[c]The energy of a dipole due to the interaction with its nearest neighbors can be calculated directly from (4) by summing up the appropriate constants J_{nm}.

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

than the positive J_3 but in the ground state all dipoles are nontilted as a result of the combination of J_n's, V_{eff} and thermal energy. For $\theta = +80°$, J_3 is sufficiently large compared to the magnitude of J_1. As a consequence the dipoles mostly are in the same state along the J_2 direction and their states mostly alternate along the J_3 direction. Hence, when θ is large enough and positive the low temperature configuration of dipoles in the 13-A lattice is close to antiferroelectric with respect to the diagonal J_2 direction.

by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

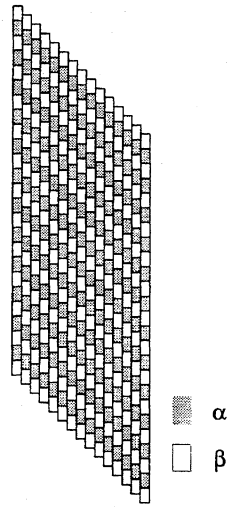

Fig. 23. A section of a MT that corresponds to $T = 4$ K on the curve for $\theta = -40°$ in Fig. 22(b).

The dipoles in the same state form rows along the J_3 direction and the sign of polarization along the J_2 direction alternates. This is a similar kind of order as in the case of $\theta = +80°$ and $+89°$ except for that the types of polarization along the two diagonal directions characterized by the constants J_2 and J_3 are interchanged and this lattice is antiferroelectric with respect to the the J_3 direction (see Table 4).

The dipolar ordering in MTs represented by the A lattices with an even number of protofilaments can be expected to be similar to that in the 13-A lattice. Due to the different number of protofilaments the stagger and therefore the interaction energies in these lattices are slightly different. The configuration of dipoles is also influenced by the presence of the seam. Relative polarization in the 14-A lattice for selected positive θ's is shown in Fig. 24(a). In the low temperature state for $\theta < +40°$ in one of the protofilaments along the seam all dipoles are nontilted and in the rest of the lattice the dipoles are in the tilted state. When θ ranges from $+40°$ to $+70°$ dipoles in the whole lattice are tilted at low temperatures. For angles $+80°$ and $+89°$ in the ground state the configuration of dipoles is antiferroelectric with respect to the direction characterized by J_2 and it is shown in Fig. 25.

In Fig. 24(b) are plotted polarization curves obtained for the 14-A lattice for some negative angles θ. When $-40° < \theta$ the dipoles in the ground state are nontilted except for one of the protofilaments along the seam in which all dipoles are tilted. For $\theta < -40°$ the configuration of dipoles in the ground state is antiferroelectric with respect to the J_3 direction.

To illustrate the influence of tilting of the dipole in the β state on the dipolar ordering in a MT that possesses a B lattice, in Fig. 26 are shown polarizations per site calculated for the 13-B lattice for different angles θ. In agreement with expectations as the tilting of the dipole and therefore the values of the interaction

constants in the lattice change (Table 5), the type of the low temperature configuration of the dipoles is altered. For angles $0 < \theta \leq +50°$ the configuration in the ground state of the 13-B lattice is antiferroelectric. The dipoles are tilted in odd and nontilted in even protofilaments. When θ is in the range 0 to $-30°$, the low temperature configuration is also antiferroelectric but the dipolar states in the odd and even protofilaments are interchanged compared to the previous case. In the ground states that correspond to $+60° \leq \theta \leq +90°$ and $-90° < \theta < -40°$ all dipoles in the lattice are tilted.

The effect of external electric fields and MAPs in a MT lattice in which the dipoles are tilted with respect to the longitudinal axis at least in one of their states can be investigated in a similar way as in the case when the dipole in both of its

states is nontilted. However, since the tilted and nontilted dipolar states are not energetically equivalent the effect is more complex — it matters in which direction point the external electric fields and whether the dipole states on the tubulin dimers to which bind MAPs are tilted or nontilted.

10. Discussion

In this paper the classical two-dimensional Ising model has been used to investigate the properties of an array of dipoles placed at sites of the hexagonal MT lattice at different temperatures. The lattices of both A and B type for the numbers of MT protofilaments 12, 13 and 14 have been studied. The analysis was supported by numerical simulations using the Monte Carlo method. Each dipole, which represented the charge distribution within one tubulin dimer, was assumed to possess two distinct states whose projections on the MT axis were oriented in opposite directions. The two dipolar states were assumed to be (i) both parallel to the MT axis, (ii) the dipole in one of the states was assumed to be tilted with respect to the MT axis in the two-dimensional space.

The investigation has shown that a MT may exist in different dielectric phases at different temperatures. At low temperatures the array of dipoles can form regular patterns. The kind of the pattern depends on the type of the lattice, the number of protofilaments and the angle by which the dipole on the tubulin is tilted. With increasing temperature the regular ordering decays due to increasing thermal energy and at sufficiently high temperatures the dipoles are oriented at random. The range of temperatures over which the transition from the ordered phase to the disordered phase takes place depends on the magnitude and orientation of the dipole moment, relative permittivity of the MT and the geometrical dimensions of the MT lattice.

The dipolar ordering is also affected by the presence of external electric fields and binding of MAPs. According to the model the electric field forces the dipoles

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

to point in its direction. This means that when a MT is subjected to an electric field it is more likely to be in a ferroelectric phase. The influence of MAPs was studied for three different superhelical patterns that the attached MAPs formed on a MT. We assumed that each MAP binds only to one tubulin dimer and that the associated protein either prevents the dipole on this dimer from flipping or that it neutralizes it. In the first case, naturally, the MAPs enhance the number of dipoles that point in the same direction as the dipole on the MAP tubulin. In the second case the character of the dipolar ordering is the same as in MTs that do not bind any MAPs, however, the presence of neutral tubulin dimers shifts the transition from the ordered to the disordered phase to lower temperatures. If each MAP binds to more than one tubulin molecule these effects can be expected to be greater. In both cases the numerical simulations have shown that the presence of MAPs gives rise to a number of groundstate dipolar configurations that have a more complex character than those found in MTs without MAPs.

The model can be improved by taking into account the curvature of the MT which is a more precise description than the two-dimensional view employed here (see Sec. 3). Then the orientation of the dipole would be determined by two angles in the three-dimensional space. One could also consider the dipole on the tubulin dimer to be tilted in both states by different angles. Introducing these additional parameters would provide more variability to the model. It can be noted that we have made the simplest assumption and took into account only the nearest neighbor interactions between the tubulin dimers. The interactions with the more distant dipoles could be also included but their importance decreases nearly as r^{-3}.

In this work a variety of dipolar configurations has been discussed that can exist in a two-dimensional hexagonal lattice at different temperatures for different parameters of the lattice and different orientation of one of the two dipolar states. The combination of the latter parameters, the dipole length, the charge on the dipole and the permittivity of the MT determines which of these dielectric states might exist in a MT at body temperature. The arrangement of the tubulin heterodimers in a MT is quite well known from experimental measurements. As was discussed in Sec. 3 the charge distribution within a tubulin dimer is not exactly known but it may have dipolar character due to the larger density of charges at one tubulin heterodimer end. Taking the value of the relative permitivity 20 and $q^2s^2/\epsilon_r = 12 \times 10^{-56}$ C ^{2}m^2 gives the dipole strength $qs = 15.5 \times 10^{-28}$ Cm. Then for $s = 10^{-9}$ m the charge on the dipole is about 10 electronic charges and for $s = 2 \times 10^{-9}$ m the q is about 5 electronic charges. This means that when the dipole switches its state quite a few charges have to be moving. These assumptions must hold if the states characterized by the regular patterns of dipoles should exist in MTs (see Sec. 5). It should also be pointed out that *in vivo* only a few MTs do not consist of 13 protofilaments (L. A. Amos and W. B. Amos, 1991).

As has been discussed here[18,19] the tubulin dimers carry permanent dipoles. As was mentioned above the experiments of Vassilev *et al.*[26] suggest that MTs are both electric and magnetic structures. Electromagnetic properties of MTs can be the

Int. J. Mod. Phys. B 1998.12:543-578. Downloaded from www.worldscientific.com
by UNIVERSITY OF CALIFORNIA @ DAVIS on 02/06/15. For personal use only.

basis of some of the MT functions. For example, an attractive/repulsive electrostatic interaction between the dipole on free tubulin and the electric field produced by the charges on the tubulin dimers assembled in the MT could play a role in the MT assembly/disassembly. Electromagnetic interaction could be responsible for regular patterns formed by MTs such as the mitotic spindle during cell division.[26] The dipolar states existing on the tubulin dimers coupled to tubulin elastic states may give rise to the solitary waves mentioned above. The solitary waves propagate when the dipoles in a MT form regular low temperature arrangements — ferroelectric, antiferroelectric or ferrielectric.[14] Thus according to the investigation presented in this paper the existence of such waves and the possible effects they could have on the MT behavior would depend on the parameters of the MT lattice and the tubulin dipoles. It should be pointed out that the electrostatic properties of the tubulin heterodimer provide means for the MTs to interact with cellular electric fields (including electric fields from other MTs) which may play an important role in controlling the above mentioned biological processes.

In the future using a more precise model of the charge distribution in the tubulin dimer the interactions directly between the charges could be calculated. If the charges can change positions, as we and some other authors[1–3,11,29] assume, then different electrostatic fields arise. By moving while switching their positions the charges create electric currents and consequently magnetic fields. Hence the investigation of MTs in the direction suggested in this paper could provide very useful insights into the electromagnetic nature of these cytoskeletal structures.

PRODUCTION OF COHERENT STATES IN BIOLOGICAL SYSTEMS

R. PAUL
Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received 23 February 1983
Revised manuscript received 20 April 1983

It is shown that Glauber-type coherent states exist in biological systems as a result of the broken symmetry of the free phonons. The symmetry of the system is reduced by the presence of the interaction terms in the hamiltonian. The coherent states so produced allow for the existence of giant dipoles capable of long-range interactions.

During recent years Fröhlich [1,2] has shown that under certain conditions a phenomenon resembling the well-known Bose–Einstein condensation can occur and produces important biological consequences. One of these consequences is the fact that if the quasiparticles, that have undergone condensation, are characterized by the presence of dipoles then the entire condensate behaves as a giant dipole. If this giant dipole possesses oscillatory character then Fröhlich [3] has shown that long-range (r^{-3}) potentials between two dipoles can occur. Experimentally, Rowlands and co-workers [4] have shown that human red blood cells, in the presence of metabolism and under conditions where transmembrane potentials exist, are capable of exerting long-range forces on each other that result in the production of aggregates commonly referred to as rouleaux. In order to develop a theoretical model for this phenomenon the author of this paper has utilized the idea of a giant dipole on each cell with the concomitant production of a long-range interaction [5,6]. This theory has successfully accounted for Rowlands observation. The theoretical structure is based upon the primary premise regarding the possibility of a dipolar coherent state on each cell. In his original work Fröhlich used a phenomenological rate equation for which a steady-state solution was obtained and recast into a standard Bose–Einstein-type distribution (displaying condensation and coherence) after certain assumptions have been introduced. Such an approach, immediately, became the subject of serious attack by Lifshits [7] and the occurrence of condensation was questioned. Wu and Austin [8] considered the problem from a microscopic point of view and refuted Lifshits contention. The approach adopted by Wu and Austin is in many ways similar to that of Fröhlich since a rate equation is first obtained from the microscopic hamiltonian and then a steady-state solution resembling that of Fröhlich is derived. This derivation has not, however, settled the matter since Yushina [9] repeated the calculations using essentially the Wu–Austin hamiltonian and showed that the specific and desired form of the steady-state solution, leading to Bose–Einstein condensation, does not result. The work of Yushina has been recently attacked by Mills [10–12] who has proved the existence of non-thermal excitations even under conditions where Bose condensation fails. The work presented by Mills provides a firm theoretical foundation for phenomena requiring the existence of polarization waves.

In this paper we adopt the Wu–Austin hamiltonian and proceed via an alternative route that does not depend upon a rate equation. Our approach is a group-theoretic one and is based upon the fact that the interaction terms of the hamiltonian break the phase symmetry of the free hamiltonian. This condition of broken symmetry leads to a translation of the phonon-field operators by a c-number and the production of a coherent state. Since the operators of the phonons of interest are dipolar in nature it follows that the system may be associated with a giant dipole. This resultant dipole is the outcome of the coherent state because a chaotic state would produce a vanishing average value for the dipole moment.

0 031-9163/83/0000–0000/$ 03.00 © 1983 North-Holland

The Wu–Austin hamiltonian is given by

$$H = H_0 + H_1 \,, \tag{1}$$

where

$$H_0 = \sum_1 \epsilon_1^{\mathrm{a}} a_1^{+} a_1 + \sum_1 \epsilon_1^{\mathrm{b}} b_1^{+} b_1 + \sum_1 \epsilon_1^{\mathrm{P}} P_1^{+} P_1 \,, \tag{2}$$

$$H_1 = \sum_{1,2} (\lambda b_1^{+} a_2 + \lambda^{*} b_1 a_2^{+}) + \sum_{1,2,3} (\chi a_1^{+} a_2 b_3^{+} + \chi^{*} a_1 a_2^{+} b_3) + \sum_{1,2} (\xi P_1 a_2^{+} + \xi^{*} P_1^{+} a_2) \,. \tag{3}$$

Here, the definitions are the same as those used in ref. [8] except the indices are enumerated as numbers and the energies of the phonons are given the symbol ϵ.

If we now make the transformation

$$a_i = \mathrm{e}^{\mathrm{i}\theta} a_i \tag{4}$$

(where θ is some phase) we find that H_0 is invariant to this transformation but H_1 possesses a lower symmetry. Thus the total hamiltonian H is of lower symmetry than H_0 and we do not expect the quantum statistical average $\langle\langle a_l \rangle\rangle$ to vanish with the exact density operator ρ

$$\rho = \mathrm{e}^{-\beta H}/Q \,, \tag{5}$$

where Q is the exact partition function. In the subsequent analysis we adopt the following definitions

$$\langle \text{operator} \rangle \equiv \mathrm{tr}(\mathrm{e}^{-\beta H_0}/Q_0)\,(\text{operator}), \quad \langle\langle \text{operator} \rangle\rangle \equiv \mathrm{tr}(\mathrm{e}^{-\beta H}/Q)\,(\text{operator}) \,. \tag{6,7}$$

Physically, we may view a non-vanishing $\langle\langle a_l \rangle\rangle$ as follows:

(1) We start with a collection of three types of non-interacting phonons: the system phonons, the bath phonons and the pump phonons.

(2) This collection is in complete thermal equilibrium and yields

$$\langle a_l \rangle = 0 \tag{8}$$

(3) When the interactions are switched on, via H_1, a translation of the operators occurs. This translation is given by

$$a_l = a_l + c_l \,, \tag{9}$$

with

$$c_l \equiv \langle\langle a_l \rangle\rangle. \tag{10}$$

The term translation or displacement was used by Glauber [13] because eq. (9) can be induced by a unitary operator

$$D(c_l) \equiv \exp(c_l a_l^{+} - c_l^{*} a_l) \,. \tag{11}$$

In this terminology the vacuum state is converted to an eigenstate of the operator a_l:

$$|c_l\rangle = D(c_l)|0\rangle \,, \tag{12}$$

where

$$a_l |c_l\rangle = c_l |c_l\rangle \,. \tag{13}$$

States such as $|c_l\rangle$ are called *coherent states.* If we assume that the dipole moment μ_l of the phonons are related to the coordinate q_l

$$\mu_l \propto q_l \propto (a_l^+ + a_l) \tag{14}$$

then in the coherent state

$$\langle \mu_l \rangle \neq 0 \,. \tag{15}$$

In this description the macroscopic dipole moments $\langle \mu_l \rangle$ arise quite naturally and the rest of the theoretical arguments, requiring the existence of these dipole moments, can be carried out. The translation phenomenon indicated by eq. (9) has been recognized as a generalized criterion for Bose–Einstein condensation by other workers (see for example Umezawa [14]). The remainder of this paper will be devoted to the explicit computation of c_l.

From eqs. (7) and (6) along with the definition of H we have

$$c_l = Q^{-1} \operatorname{tr}\{\exp[-\beta(H_0 + H_1)]\, a_l\} = \langle \mathcal{S}(\beta) a_l \rangle_{\text{connected}} \,, \tag{16}$$

where the finite temperature expansion of the density operator is utilized and by the retention of only the connected Feynman diagrams the necessity of computing the exact partition function Q is eliminated. This simplification is the result of the well-knonw Wick theorem (see for example Paul [15]). The operator $\mathcal{S}(\beta)$, appearing in eq. (6), is defined by

$$\mathcal{S}(\beta) = \sum_{n=0}^{\infty} \left(\frac{-1}{\hbar}\right)^n \frac{1}{n!} \int_0^{\beta\hbar} \mathrm{d}u_1 \mathrm{d}u_2 \ldots \mathrm{d}u_n \, \mathrm{T} H_1(u_1) H_1(u_2) \ldots H_1(u_n) \,. \tag{17}$$

Here T is the well-known Wick time ordering operator and u_i are imaginary time variables that are defined within the limits $0 \leqslant u_i \leqslant \beta\hbar$. In order to facilitate a diagramatic development it is convenient to introduce an imaginary time variable u in the operator in a_l in eq. (16). This allows us to calculate $c_l(u)$ from which c_l can be obtained by setting $u = 0$ at the end of the computation.

If we examine the interaction hamiltonian given in eq. (3) we notice the presence of six vertices which are displayed in fig. 1 and the meaning of arrows are given in the following rules:

(1) Phonons with operators a_i, a_i^+ are denoted by a single arrow and since these phonons are dipolar in nature they will be called "active" phonons.

(2) Bath phonons (b_i, b_i^+) are given two arrows.

(3) Pump phonons (P_i, P_i^+) are given three arrows.

(4) All diagrams will contain an external condensate point which carries the label l. This point will be designated by a square $\square_l$.

(5) All zero-order Green's (G_{ij}^{a}, G_{ij}^{b} and G_{ij}^{P}) functions will be indicated by thin lines carrying the appropriate numbers of arrows as indicated by rules (1), (2) and (3).

(6) All renormalized Green's functions ($\bar{G}_{ij}^{\mathrm{a}}$, $\bar{G}_{ij}^{\mathrm{b}}$ and $\bar{G}_{ij}^{\mathrm{P}}$)will be indicated by heavy lines with the appropriate numbers of arrows as indicated by rules (1), (2) and (3).

The simplest renormalized diagrams that appear in the present theory are shown in fig. 2. It is our main objective, in this paper, to demonstrate the existence of a nonvanishing field translation given by the topologically dis-

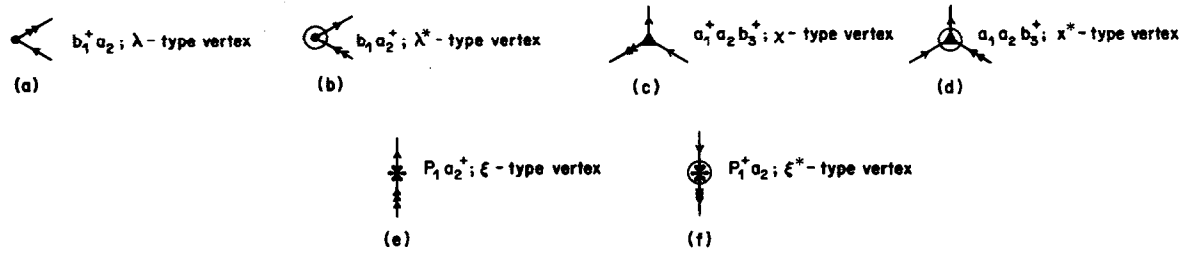

Fig. 1.

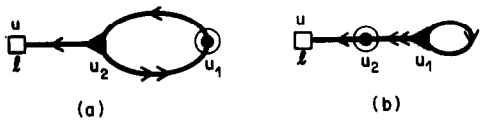

Fig. 2.

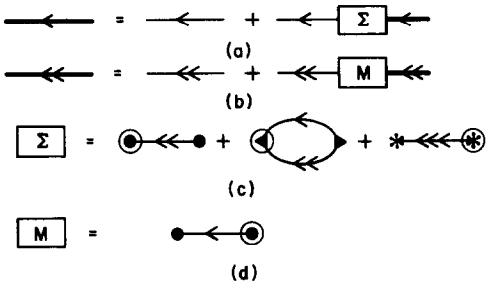

Fig. 3.

tinct diagrams (2a) and (2b). It is sufficient to show a non-vanishing result from either of these diagrams since possible cancellation amongst such topologically distinct diagrams is very unlikely.

For the renormalization procedure we adopt the diagrams displayed in fig. 3, where we use the symbol Σ to designate the self-energies of the active phonons and the symbol M for the self-energies of the bath phonons. The actual computations are done, most conveniently, in a frequency space which is related to the imaginary time space by the following equation:

$$f(u) = \frac{1}{\beta\hbar} \sum_{n=-\infty}^{\infty} f(\omega_n) \exp(-i\omega_n u) , \tag{18}$$

where the discrete frequencies ω_n are given for the Bose operators by

$$\omega_n = 2\pi n/\beta\hbar . \tag{19}$$

The zero-order Green's function (quantities corresponding to the thin lines) for the three kinds of phonons are given by

$$G^s_{ij}(\omega_n) = (i\omega_n - \hbar^{-1}\epsilon^s_i)^{-1}\,\delta_{ij} \quad (s = \text{a, b or P}) . \tag{20}$$

With this definition of the zero-order Green's functions and employing the diagrams of fig. 3 we obtain

$$\bar{G}^a_{i,j}(\omega_m) = \delta_{ij}/[i\omega_m - \hbar^{-1}\epsilon^a_i - \Sigma(\omega_m)] , \quad \bar{G}^b_{i,j}(\omega_m) = \delta_{ij}/[i\omega_m - \hbar^{-1}\epsilon^b_i - M(\omega_m)] . \tag{21,22}$$

The self-energies are given by

$$\Sigma(\omega_m) = \frac{|\lambda|^2}{2\hbar^2} \sum_2 \frac{1}{i\omega_m - \hbar^{-1}\epsilon^b_2} - |\chi|^2 \sum_{2,3} \frac{f(\epsilon^a_2) - f(-\epsilon^b_3)}{i\omega_m + \hbar^{-1}(\epsilon^a_2 + \epsilon^b_3)} + |\xi|^2 \sum_2 \frac{1}{i\omega_m - \hbar^{-1}\epsilon^P_2} , \tag{23}$$

$$M(\omega_m) = \frac{|\lambda|^2}{2\hbar^2} \sum_2 \frac{1}{i\omega_m - \hbar^{-1}\epsilon^a_2} , \quad f(\epsilon^s_d) \equiv [\exp(\beta\epsilon^s_j) - 1]^{-1} . \tag{24,25}$$

If eqs. (21) and (22) are substituted for the renormalized Green's functions in fig. 2b then the field displacement in frequency space becomes

$$c_l(\omega_m) = \frac{\chi\lambda^*}{2\hbar^2[\hbar^{-1}\epsilon^a_l + \Sigma(0)]} \sum_{2,4} \frac{1}{i\omega_m - \hbar^{-1}\epsilon^a_2 - \Sigma(\omega_m)} \frac{1}{i\omega_m - \hbar^{-1}\epsilon^b_4 - M(\omega_m)} . \tag{26}$$

From this equation the static-field displacement can be obtained by first transforming into an imaginary time space v and then allowing $u \to 0$:

$$c_l = \lim_{u\to 0} \frac{1}{\beta\hbar} \sum_m c_l(\omega_m) \exp(-i\omega_m u)$$

$$= \frac{\chi\lambda^*}{2\beta\hbar^3(\hbar^{-1}\epsilon_l^a + \Sigma)} \sum_{2,4,m} \frac{1}{i\omega_m - \hbar^{-1}\epsilon_2^a - \Sigma(\omega_m)} \frac{1}{i\omega_m - \hbar^{-1}\epsilon_4^b - M(\omega_m)} . \tag{27}$$

Here $\Sigma \equiv \Sigma(0)$. The frequency summation over m can be carried out by integrating in the complex plane if the frequency dependence of the self-energies $\Sigma(\omega_m)$ and $M(\omega_m)$ can be neglected. To carry out this process we define the spectral functions for the two self-energies appearing in eq. (27) as follows:

$$\Sigma(z) = \frac{1}{\pi} \int_{-\infty}^{\infty} d\omega' \frac{\Gamma_a(\omega')}{\omega' - z} , \quad M(z) = \frac{1}{\pi} \int_{-\infty}^{\infty} d\omega' \frac{\Gamma_b(\omega')}{\omega' - z} . \tag{28,29}$$

Here, Γ_a and Γ_b are the spectral functions for the two self-energies and in ordinary spectroscopy these quantities play the role of spectroscopic line broadening. The variable z is a complex frequency that represents an analytic continuation of the discrete frequencies ω_m over the entire complex plane. Just above and below the real frequency axes we obtain

$$\Sigma(\omega \pm i\eta) = \frac{1}{\pi} \int_{-\infty}^{\infty} d\omega' \frac{\Gamma_a(\omega')}{\omega' - \omega \mp i\eta} = P\frac{1}{\pi} \int_{-\infty}^{\infty} d\omega' \frac{\Gamma_a(\omega')}{\omega' - \omega} \pm i\Gamma_a(\omega) \equiv S_a(\omega) \pm i\Gamma_a(\omega) . \tag{30}$$

Similarly

$$M(\omega \pm i\eta) \equiv S_b(\omega) \pm i\Gamma_b(\omega) . \tag{31}$$

Here ω is a real frequency and will be treated as a constant in the frequency summation involved in eq. (27). The actual computation of the function $S_s(\omega)$ and $\Gamma_s(\omega)$ (with s = a, b) involves summations shown in eqs. (24) and (25). These summations over the phonon states cannot be carried out exactly and require numerical work. In this paper we do not propose to give actual numerical values for the field translations. It is our purpose to show that such a translation does occur and to display its mathematical form, therefore the actual computation of the frequency shift (S_s) and broadening will not be carried out. If we define the complex frequencies of the dressed phonons by ν_i^a and ν_j^b where

$$\nu_i^a \equiv \hbar^{-1}\epsilon_i^a + S_a \pm i\Gamma_a , \quad \nu_j^b \equiv \hbar^{-1}\epsilon_j^b + S_b \pm i\Gamma_b , \tag{32,33}$$

then the explicit summation over m in eq. (27) yields

$$c_l = \frac{\chi\lambda^*}{2\hbar^2\nu_1^a} \sum_{2,4} \frac{f(\hbar\nu_2^a) - f(\hbar\nu_4^b)}{\nu_4^b - \nu_2^a} . \tag{34}$$

This equation shows that as long as the coupling constants χ and λ^* are present there will always be a finite field translation. The magnitude of this translation is inversely proportional to the frequency of the dressed mode l ($c_l \propto 1/\upsilon_l^a$), this implies that the low-energy modes undergo a relatively more severe distortion or the main contribution to the condensate density arises from small values of l. If we compare our result given by eq. (34) with the result of Mills then at a superficial level they appear contradictory. This is not, however, the case. The main difference arises from the fact that eq. (34) does not explicitly contain the coupling constant ξ (or ξ^*) corresponding to the pump and in Mills work it is precisely the energy pump that produces the non-thermal excitations. Moreover the importance of the pump has been well established by various experimental measurements. The apparent contradic-

tion disappears when it is realized that the present result is a group-theoretical one and is a direct consequence of the symmetry properties of the hamiltonian given by eq. (2). It is easy to see that part of the symmetry breaking is induced in the hamiltonian by the linear coupling with the bath through the $\lambda(\lambda^*)$ dependent terms and the form of these terms is the same as that given by the pump-dependent terms. From a purely mathematical standpoint the inclusions of the symmetry-breaking terms in the hamiltonian have already biased the problems towards coherence. In the treatment based upon the rate equation further physical assumptions (not contained in the hamiltonian or the Heisenberg's equations of motion) are introduced and these give the pump the special significance it finally achieves. These additional physical assumptions are perfectly reasonable and the results obtained are correct, however, the work of this paper is meant to augment the phenomenon of coherence given by Mills and not to negate it.

If the index l is taken to be the phonon propagation vector ($\boldsymbol{k}$) then, in our theory, $\boldsymbol{k}$ is the propagation vector of the dressed phonons and the condensate will be composed, predominantly, of modes with $|\boldsymbol{k}| \to 0$. With this description of the index l we may define the field operators:

$$\psi(r) = \sum_{k} a_k \exp(\mathrm{i}\boldsymbol{k}\cdot r) + \sum_{k} c_k \exp(\mathrm{i}\boldsymbol{k}\cdot r) . \tag{35}$$

The density matrix becomes

$$\rho(r, r) = \langle \psi^+(r)\phi(r') \rangle = \sum_{kk'} \langle a_k^+ a_{k'} \rangle \exp(-\mathrm{i}\boldsymbol{k}\cdot r + \mathrm{i}\boldsymbol{k}'\cdot r') + \sum_{kk'} c_k^* c_{k'} \exp(-\mathrm{i}\boldsymbol{k}\cdot r + \boldsymbol{k}'\cdot r')$$

$$= \sum_{k} n_k \exp[\mathrm{i}\boldsymbol{k}\cdot(r-r')] + \sum_{kk'} c_k^* c_{k'} \exp(-\mathrm{i}\boldsymbol{k}\cdot r + \mathrm{i}\boldsymbol{k}'\cdot r') . \tag{36}$$

The first term of this expression describes the normal (uncondensed) phonons in the system and vanishes when $|r - r'| \to \infty$ due to the oscillatory nature of the exponential and produces no long-range order. The second term clearly does not display this feature and corresponds to the well-known phenomenon of off-diagonal long-range order (ODLRO) that has been observed in other branches of physics [16].

The author wishes to thank Dr. R. Chatterjee and Mr. J. Tuszyński of the Department of Physics of the University of Calgary for several useful discussions.

Received 2 May 2002

We refine a QED-cavity model of microtubules (MTs), proposed earlier by two of the authors (N.E.M. and D.V.N.), and suggest mechanisms for the formation of biomolecular mesoscopic coherent and/or entangled quantum states, which may avoid decoherence for times comparable to biological characteristic times. This refined model predicts dissipationless energy transfer along such "shielded" macromolecules near room temperatures as well as quantum teleportation of states across MTs and perhaps neurons.

Keywords: Microtubules; cavities; QED; quantum coherence; entanglement; biological quantum computation.

1. Introduction

Observable quantum effects in biological matter such as proteins are naively expected to be strongly suppressed, mainly due to the macroscopic nature of most biological entities as well as the fact that such systems live near room temperature. These conditions normally result in a very fast *collapse* of the pertinent wave-functions to one of the allowed classical states. However, we suggest that under certain circumstances it is in principle possible to obtain the necessary

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

isolation against thermal losses and other environmental interactions, so that *meso- and macroscopic* quantum-mechanical coherence, and conceivably entanglement extending over scales that are considerably larger than the atomic scale, may be achieved and maintained for times comparable to the characteristic times for biomolecular and cellular processes.

In particular, we have shown[1] how microtubules (MTs)[2] can be treated as quantum-mechanically isolated (QED) cavities, exhibiting properties analogous to those of electromagnetic cavities routinely used in quantum optics.[3–6] Recently, our speculative model has been supported by some indirect experimental evidence. It has been experimentally shown,[7] that it is possible to maintain partial entanglement of the bulk spin of a macroscopic quantity of Caesium (Cs) atoms ($N = 10^{12}$), *at room temperature*, for a relatively long time (0.5 ms). Note that in this experiment, the large quantity of atoms was of paramount importance in creating and maintaining the entanglement, and even though the gas samples were in constant contact with the environmental heat bath, by using a careful experimental arrangement, Julsgaard *et al.* managed to detect the existence of entanglement for a much longer time than one would intuitively expect. Here, we outline the main features of our model of the quantum mechanical properties of MTs (described in detail in Ref. 1), and we exhibit the relevance of the Julsgaard *et al.* experiment to our model. A direct consequence of our model for MTs as QED cavities is that virtually every experimentally known QED-cavity-based observation may have an analogue in living MTs and we show this analytically with the specific case of intra- and inter-cellular dissipationless energy transfer and quantum *teleportation* of coherent quantum states.

Dissipationless energy would account for minimal energy in cancer

Energy transfer across cells, without dissipation, had been first speculated to occur in biological matter by Fröhlich.[8] The phenomenon conjectured by Fröhlich was based on a one-dimensional superconductivity model: a one-dimensional electron system with holes, where the formation of solitonic structures due to electron-hole pairing results in the transfer of electric current without dissipation. Fröhlich suggested that, if appropriate solitonic configurations are formed inside cells, energy in biological matter could also be transferred without any dissipation (supereefficiently). This idea has lead theorists to construct various models for cellular energy transfer, based on the formation of kink classical solutions.[9]

In these early works no specific microscopic models had been considered.[9] In 1993 Sataric *et al.* constructed a *classical* physics model for microtubule dynamics,[10] in which solitons transfer energy across MTs without dissipation. In the past, we have considered the *quantum aspects* of this one-dimensional model, and developed a framework for consistent quantization of the solitonic solutions.[1] Our work suggested that such semiclassical solutions may emerge as a result of "decoherence" due to environmental interactions, in agreement with ideas in Ref. 11.

The basic assumption used in creating the model of Ref. 1 was that the building blocks of MTs, the tubulin molecule dimers, can be treated as elements of Ising spin chains (one-space-dimensional structures). The interaction of each tubulin chain

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

(protofilament) with neighboring chains and the surrounding water environment has been accounted for by suitable potential terms in the one-dimensional Hamiltonian. The model describing the dynamics of such one-dimensional sub-structures was the ferroelectric distortive spin chain model of Ref. 10.

Ferroelecricity is an essential ingredient of the quantum-mechanical mechanism of energy transfer that we propose. We have speculated[12] that the ferroelectric nature of MTs will be that of *hydrated* ferroelectrics, i.e. the ordering of the electric dipole moment of the tubulin molecules will be due to the interaction of the tubulin dimers' electric dipoles with the *ordered water* molecules in the interior and possibly exterior of the microtubular cavities. Ferroelectricity induces a dynamical dielectric "constant" $\varepsilon(\omega)$ which is dependent on the frequency ω of the excitations in the medium. Below a certain frequency, such materials are characterized by almost vanishing dynamical dielectric "constants", which in turn implies that electrostatic interactions inversely proportional to ε will be enhanced, and thus become dominant against thermal losses. In the case of microtubules, the pertinent interactions are of the electric dipole type, scaling as $1/(\varepsilon r^3)$ with the distance r. For ordinary water media, the dielectric constant is of order 80. In the ferroelectric regime however, this ε is diminished significantly. As a result, the electric dipole-dipole interactions may overcome the thermal losses proportional to $k_{\mathrm{B}}T$ at room temperature inside the interior cylindrical region of MT bounded by the dimer walls of thickness of order of a few Angstroms.[1] The situation is depicted in Fig. 1.

It is known experimentally,[13] that in a thin exterior neighborhood of MTs there are areas of atomic thickness, consisting of charged ions, which isolate the MT from thermal losses. This means that the electrostatic interaction overcome thermal agitation. It seems theoretically plausible, albeit yet unverified, that such thermally isolated exterior areas can also operate as *cavity regions*, in a manner similar to the areas interior to MTs. At this point it is unclear whether there exists the necessary coherent dipole quanta in the ionic areas. Further experimental and theoretical (simulation) work needs to be done regarding this issue and this is in progress.

Once such an isolation is provided, one can treat the thin interior regions as electromagnetic cavities in a way similar to that of QED cavities.[a] QED cavities are well-known for their capacity to sustain in their interior coherent modes of electromagnetic radiation. Similarly, one expects that such coherent cavity modes will occur in the thin interior regions of MTs bounded by the protein dimer walls. Indeed, as we discussed in Ref. 1, these modes are provided by the interaction of the electric dipole moments of the *ordered water* molecules in the interior of MT with the quantized electromagnetic radiation.[15,16] Such coherent modes are termed *dipole quanta*. It is the interaction of such cavity modes with the electric dipole excitations of the dimers that leads to the formation of coherent (dipole) states on

[a]Note that the role of MT as *waveguides* has already been proposed by S. Hameroff some time ago.[14] On the other hand, we are interested in isolated regions inside the MT which play the role of *QED cavities*.

(f) The thin interior layer that is to be treated as a QED cavity.

the tubulin dimer walls of MTs. A review of how this can happen, and what *purely quantum* effects can emerge from the QED nature of MTs, will be the main topic of this communication.

In Sec. 2 we present a concise exposé of our mechanism[1] that justifies the application of quantum physics to the treatment of certain aspects of MT dynamics. We also develop an analogy of our mechanism to the experimental setup used by Julsgaard *et al.* In Sec. 3 we present a straight forward calculation of how quantum teleportation of states can occur in MTs, in direct analogy to the suggested experimental quantum teleportation in optical cavities that has been observed recently.[17,18] We also draw a parallel between certain geometrical features of MTs such as their ordered structure which obeys a potentially information-encoding code and suggest how this can be exploited for (quantum) error-correction and dense coding. Section 4 contains our conclusions and outlook.

2. Quantum Coherence in Biological Matter?

2.1. *Tubulin, microtubules and coherent states*

Tubulin is a common polar protein found mainly in the cytoskeleton of eukariotic cells which is especially enriched in brain tissue. Many of its properties have been studied both experimentally and theoretically because of its importance in mitosis, its role as the building block of microtubules and its relevance to several diseases including Cancer and Alzheimer's. Measurements[19] have confirmed earlier data suggesting that the tubulin heterodimer has dimensions $46 \times 80 \times 65$ Angstrom [Fig. 1(b)]. Under normal physiological conditions, tubulin is found as a heterodimer, consisting of two nearly identical monomers called the α- and β-tubulin each of molecular weight of about 55 kDalton.[19] MTs are hollow [25 nm-outer diameter, 14 nm inner diameter — see Fig. 1(a)] tubes forming the main component of the cytoskeleton and apart from giving shape and support to the cell, they also play a major role in cellular transport and have been hypothesized to be central in cellular information processing. The interior of the MT, seems to contain *ordered water* molecules,[1] which implies the existence of an electric dipole moment and an electric field. We stress that the intracellular *ordered water* which is full of proteins and other molecules is different from ordinary water in various respects, e.g. as is implied in Ref. 20. It is to be understood that unless otherwise specified, from now on by "tubulin" we refer to the $\alpha\beta$-dimer. Free tubulin can self-assemble into MTs both *in vivo* and *in vitro* where the most common arrangement of the tubulin dimers is such that, if one treats them as points, they resemble triangular lattices on the MT surface. The β-tubulin monomer of the heterodimer can bind guanosine $5'$ triphosphate (GTP) in which case it exists in an energy-rich form that favors polymerization, or it can bind guanosine $5'$ diphosphate (GDP-tubulin) thus being in an energy-poor form (GDP-tubulin) that favors dissociation. The structure of MTs has been the subject of comprehensive study and it transpires that MTs come in a variety of arrangements the predominant of which is a 5-start, period-13 helical tube of dimers which resembles a corn ear [Fig. 1(a)] made out of 13 offset protofilaments. Certain interesting phenomena arise during the (de-)polymerization of tubulin such as length oscillations, treadmilling, etc. are generally referred to as "dynamic instability" and these have been studied extensively[21,22] but are not directly relevant to our analysis at this stage as such phenomena are suppressed in the remarkably stable axonal neural cytoskeleton. It has been shown that the GDP-GTP exchange (hydrolysis) releases approximately 0.42 eV per molecule and is accompanied by a conformational change.[23] This change has been modelled as resulting in a $27°42'$ angle[24] between the original line connecting the centers of the α and β monomers and the new center-to-center line [Fig. 1(d)]. As a result of this change in the geometry of the tubulin molecule, the orientation of the electric dipole moment also changes magnitude and direction. It has been put forward that each dimer has two hydrophobic protein pockets, containing 2×18 unpaired electrons[2] that have at least two possible configurations associated with the GTP and GDP

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

states of tubulin, which we will call ↑ and ↓ electron (or equivalently electric dipole moment) conformations respectively.

Using the fact that a typical "distance" for the transition between the ↑ and ↓ conformations is of the order of the distance between the two hydrophobic dimer pockets, i.e. $\mathcal{O}(4\,\text{nm})$, a simplistic estimate of the free tubulin electric dipole moment d can be obtained based on a mobile charge of 36 electrons multiplied by this separation of 4 nm, giving a magnitude of $d = 2.3\times10^{-26}$ C · m (or 700 Debye) while using a more sophisticated molecular simulation, d has been quoted at 1714 Debye.[25] It is evident that an experimentally determined electric dipole moment for the tubulin molecule and its dynamics are important areas of study that have to be undertaken if these studies are to move forward.

If we account for the effect of the water environment that screens the electric charge of the dimers by the relative dielectric constant of the water, which is $\varepsilon/\varepsilon_0 \sim 80$, we arrive at a value of

$$d_{\text{dimer}} \sim 3 \times 10^{-28}\ \text{C} \cdot \text{m} \tag{1}$$

Note that under physiological conditions, the unpaired electric charges in the dimer may lead to even further suppression of d_{dimer} (1).

At physiological pH (= 7.2) MTs are negatively charged[26] due to the presence of a 15-residue carboxyl-terminus "tail" and there have been suggestions that this C-terminus is important in polymerization, protein interactions and perhaps charge conduction.[13] This terminus has not been included in the electron crystallography data of Nogales and Downing[19] so all values concerning the dipole moment are quoted with the understanding that d has been calculated ignoring the effect of the C-terminus. It is also known that at pH 5.6 MTs become neutral. Finally, there have been some preliminary experiments aimed at measuring the electric field around MTs[27–29] indicating that MTs could be ferroelectric, as we have suggested in our model.[1,12] Note that although the "caps" of the MT contain both GTP and GDP tubulin, it is well-known experimentally[24] that the tubulin comprising the "trunk" of the MT is GDP-tubulin incapable of acquiring a phosphate and becoming GTP tubulin. However, this does not preclude electric-dipole moment flip wave propagation down the MT, as a flip at the cap can be propagated without phosphorylation or hyrdolysis but rather via the mechanism suggested below. In view of this, the value of the yet undetermined electric dipole moment direction flip angle θ_{flip} is much smaller than the $27°42'$ value for free tubulin. The ↑ and ↓ states still exist though, but are hard to observe experimentally as they are not associated with a large-scale geometrical mass shift. Note that virtually all of the alternative suggested MT-based "quantum brain" hypotheses today, fail to take this into account and instead wrongly suggest that θ_{flip} is of the order of 27° and that such large distortions occur in the trunk of the polymerized MT.

In standard models for the simulation of MT dynamics,[10] the physical degree of freedom which is relevant for the description of energy transfer is the projection of the electric dipole moment on the longitudinal symmetry axis (x-axis) of the MT

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

cylinder. The θ_{flip} distortion of the $\downarrow$-conformation leads to a displacement u_n along the x-axis. This way, the effective system is one-dimensional (spatial), and one has the possibility of being quantum integrable.[1]

It has been suggested for quite some time that information processing via interactions among the MT protofilament chains can be sustained on such a system, if the system is considered as a series of interacting Ising chains on a triangular lattice. For such schemes to work, one must first show that the electromagnetic interaction among the tubulin dimers are strong enough to overcome thermal noise. It is due to this problem that such models for intra-neuronal information processing have been critisized as unphysical.[30] We shall return to this issue later. Classically, the various dimers can only be in the $\uparrow$ and $\downarrow$ conformations. Each dimer is influenced by the neighboring dimers resulting in the possibility of a transition. This is the basis for classical information processing, which constitutes the picture of a (classical) cellular automaton.

If we assume (and there is good theoretical basis for such an assumption[1]) that each dimer can in fact find itself in a superposition of $\uparrow$ and $\downarrow$ states, a *quantum nature* results. Tubulin can then be viewed as a typical *two-state* quantum mechanical system, where the dimers couple to conformational changes with $10^{-9} - 10^{-11}$ sec transitions, corresponding to an angular frequency $\omega \sim \mathcal{O}(10^{10}) - \mathcal{O}(10^{12})$ Hz. In the present work we assume the upper bound of this frequency range (in order of magnitude) to represent the characteristic frequency of the dimers, viewed as a two-state quantum-mechanical system:

$$\omega_0 \sim \mathcal{O}(10^{12}) \text{ Hz} \tag{2}$$

As we shall see below, such a frequency range is not unusual in biology.

Let u_n be the displacement field of the nth dimer in a MT chain. The continuous approximation proves sufficient for the study of phenomena associated with energy transfer in biological cells, and this implies that one can make the replacement

$$u_n \to u(x,t) \tag{3}$$

with x a spatial coordinate along the longitudinal symmetry axis of the MT. There is a time variable t due to fluctuations of the displacements $u(x)$ as a result of the dipole oscillations in the dimers.

The effects of the neighboring dimers (including neighboring chains) can be phenomenologically accounted for by an effective potential $V(u)$. In the model of Ref. 10 a double-well potential was used, leading to a classical kink solution for the $u(x,t)$ field. More complicated interactions are allowed in the picture of Ref. 1, where we have considered more generic polynomial potentials.

The effects of the surrounding water molecules can be accounted for by a viscous force term that damps out the dimer oscillations,

$$F = -\gamma \partial_t u \tag{4}$$

with γ determined phenomenologically at this stage. This friction should be viewed as an environmental effect, which however does not lead to energy dissipation, as

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

a result of the nontrivial solitonic structure of the ground-state and the nonzero constant force due to the electric field. This is a well-known result, directly relevant to energy transfer in biological systems.[9]

The effective equation of motion for the relevant field degree of freedom $u(x,t)$ reads:

$$u''(\xi) + \rho u'(\xi) = P(u) \tag{5}$$

where $\xi = x - vt$, v is the velocity of the soliton, $\rho \propto \gamma$ in Ref. 10, and $P(u)$ is a polynomial in u, of a certain degree, stemming from the variations of the potential $V(u)$ describing interactions among the MT chains.[1] In the mathematical literature[31] there has been a classification of solutions of equations of this form. For certain forms of the potential[1] the solutions include *kink solitons* that may be responsible for dissipation-free energy transfer in biological cells[9]:

$$u(x,t) \sim c_1(\tanh[c_2(x-vt)] + c_3) \tag{6}$$

where c_1, c_2, c_3 are constants depending on the parameters of the dimer lattice model. For the form of the potential assumed in the model of Ref. 10 there are solitons of the form

$$u(x,t) = c_1' + \frac{c_2' - c_1'}{1 + e^{c_3'(c_2'-c_1')(x-vt)}}\,,$$

where again $c_i', i = 1, \ldots, 3$ are appropriate constants.

A semiclassical quantization of such solitonic states has been considered in Ref. 1. The result of such a quantization yields a modified soliton equation for the (quantum corrected) field $u_q(x,t)$[32]

$$\partial_t^2 u_q(x,t) - \partial_x^2 u_q(x,t) + \mathcal{M}^{(1)}[u_q(x,t)] = 0 \tag{7}$$

with the notation

$$M^{(n)} = e^{\frac{1}{2}(G(x,x,t) - G_0(x,x))\frac{\partial^2}{\partial z^2}} U^{(n)}(z)|_{z=u_q(x,t)} \quad \text{and} \quad U^{(n)} \equiv d^n U/dz^n\,.$$

The quantity U denotes the potential of the original soliton Hamiltonian, and $G(x,y,t)$ is a bilocal field that describes quantum corrections due to the modified boson field around the soliton. The quantities $M^{(n)}$ carry information about the quantum corrections. For the kink soliton (6) the quantum corrections (7) have been calculated explicitly in Ref. 32, thereby providing us with a concrete example of a large-scale quantum coherent state.

A typical propagation velocity of the kink solitons (e.g. in the model of Ref. 10) is $v \sim 2$ m/sec, although, models with $v \sim 20$ m/sec have also been considered.[33] This implies that, for moderately long microtubules of length $L \sim 10^{-6}$ m, such kinks transport energy without dissipation in

$$t_F \sim 5 \times 10^{-7}\ \text{sec}\,. \tag{8}$$

Energy will be transferred super-efficiently via this mechanism only if the decoherence time is of the order of, or longer than, this time. We shall see in fact that

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

indeed such time scales are comparable to, or smaller in magnitude than, the decoherence time scale of the coherent (solitonic) states $u_q(x,t)$. This then implies that fundamental quantum mechanical phenomena may be responsible for frictionless, dissipantionless super-efficient energy (and signal) transfer and/or transduction across microtubular networks in the cell.

2.2. *Microtubules as cavities*

In Ref. 1 we have presented a microscopic analysis of the physics underlying the interaction of the water molecules with the dimers of the MT, which is responsible for providing the friction term (4) in the effective (continuum) description. Below we briefly review this scenario.

As a result of the ordered structure of the water environment in the interior of MTs, there appear *collective* coherent modes, the so-called dipole quanta.[15] These arise from the interaction of the electric dipole moment of the water molecule with the quantized radiation of the electromagnetic field,[16] which may be self-generated in the case of MT arrangements.[1,33] Such coherent modes play the role of "cavity modes" in the quantum optics terminology. These in turn interact with the dimer structures, mainly through the unpaired electrons of the dimers, leading to the formation of a quantum coherent solitonic state that may extend even over the entire MT network. As mentioned above, such states may be identified[1] with semiclassical solutions of the friction equation (5). These coherent, almost classical, states should be viewed as the result of the *decoherence* of the dimer system due to its interaction/coupling with the water environment.[11]

Such a dimer/water coupling can lead to a situation analogous to that of atoms interacting with coherent modes of electromagnetic radiation in *quantum optical cavities*, namely to the so-called *Vacuum-Field Rabi Splitting* (VFRS) effect.[4] VFRS appears in both the emission and absorption spectra of atoms[5] in interaction with a coherent mode of electromagnetic radiation in a cavity. For our purposes below, we shall review the phenomenon by restricting ourselves for definiteness to the absorption spectra case.

Consider a collection of N atoms of characteristic frequency ω_0 inside an electromagnetic cavity. Injecting a pulse of of frequency Ω into the cavity causes a doublet structure (splitting) in the absorption spectrum of the atom-cavity system with peaks at:

$$\Omega = \omega_0 - \frac{\Delta}{2} \pm \frac{1}{2}(\Delta^2 + 4N\lambda^2)^{1/2} \tag{9}$$

where $\Delta = \omega_c - \omega_0$ is the detuning of the cavity mode, of frequency ω_c, compared to the atomic frequency. For resonant cavities the splitting occurs with equal weights

$$\Omega = \omega_0 \pm \lambda\sqrt{N}\,. \tag{10}$$

Notice here the *enhancement* of the effect for multi-atom systems $N \gg 1$. The quantity $2\lambda\sqrt{N}$ is called the "Rabi frequency".[4] From the emission-spectrum

analysis an estimate of λ can be inferred which involves the matrix element, $\underline{d}$, of atomic electric dipole between the energy states of the two-level atom[4]:

$$\lambda = \frac{E_c \underline{d} \cdot \underline{\epsilon}}{\hbar} \tag{11}$$

where $\underline{\epsilon}$ is the cavity (radiation) mode polarization, and

$$E_c \sim \left(\frac{2\pi\hbar\omega_c}{\varepsilon V}\right)^{1/2} \tag{12}$$

is the r.m.s. vacuum (electric) field amplitude at the center of a cavity of volume V, and of frequency ω_c, with ε the dielectric constant of the medium inside the volume V. In atomic physics, the VFRS effect has been confirmed by experiments involving beams of Rydberg atoms resonantly coupled to superconducting cavities.[6]

In the analogy between the thin cavity regions near the dimer walls of MTs with electromagnetic cavities, the role of atoms in this case is played by the unpaired two-state electrons of the tubulin dimers[1] oscillating with a frequency (2). To estimate the Rabi coupling between cavity modes and dimer oscillations, one should use (11) for the MT case.

We have used some simplified models for the *ordered water* molecules, which yield a frequency of the coherent dipole quanta ("cavity" modes) of order[1]:

$$\omega_c \sim 6 \times 10^{12}\ \mathrm{s}^{-1} \tag{13}$$

Notably this is of the same order of magnitude as the characteristic frequency of the dimers (2), implying that the dominant cavity mode and the dimer system are almost in resonance in our model of Ref. 1. Note that this is a feature shared by atomic physics systems in cavities, and thus we can apply the pertinent formalism to our system. Assuming a relative dielectric constant of water w.r.t to that of vacuum ϵ_0, $\varepsilon/\varepsilon_0 \sim 80$, one obtains from (12) for the case of MT cavities:

$$E_c \sim 10^4\ \mathrm{V/m}\,. \tag{14}$$

Electric fields of such a magnitude can be provided by the electromagnetic interactions of the MT dimer chains, the latter viewed as giant electric dipoles.[10] This suggests that the coherent modes ω_c, which in our scenario interact with the unpaired electric charges of the dimers and produce the kink solitons along the chains, owe their existence to the (quantized) electromagnetic interactions of the dimers themselves.

The Rabi coupling for the MT case then is estimated from (11) to be of order:

$$\text{Rabi coupling for MT} \equiv \lambda_{\mathrm{MT}} = \sqrt{\mathcal{N}}\lambda_0 \sim 3 \times 10^{11}\ \mathrm{s}^{-1} \tag{15}$$

which is, on the average, an order of magnitude smaller than the characteristic frequency of the dimers (2).

In the above analysis, we have assumed that the system of tubulin dimers interacts with a *single* dipole quantum coherent mode of the *ordered water* and hence we ignored dimer-dimer interactions. More complicated cases, involving interactions

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

either among the dimers or of the dimers with more than one radiation quantum, which undoubtedly occur *in vivo*, may affect the above estimate.

The presence of such a coupling between water molecules and dimers leads to quantum coherent solitonic states of the electric dipole quanta on the tubulin dimer walls. To estimate the decoherence time we remark that the main source of dissipation (environmental entanglement) comes from the imperfect walls of the cavities, which allow leakage of coherent modes and energy. The time scale, T_r, over which a cavity-MT dissipates its energy, can be identified in our model with the average life-time t_L of a coherent-dipole quantum state, which has been found to be[1]: $T_r \sim t_L \sim 10^{-4}$ sec. This leads to a first-order-approximation estimate of the quality factor for the MT cavities, $Q_{\rm MT} \sim \omega_c T_r \sim \mathcal{O}(10^8)$. We note, for comparison, that high-quality cavities encountered in Rydberg atom experiments dissipate energy in time scale of $\mathcal{O}(10^{-3}) - \mathcal{O}(10^{-4})$ sec, and have Q's which are comparable to $Q_{\rm MT}$ above. The analysis of Ref. 1 then yields the following estimate for the collapse time of the kink coherent state of the MT dimers due to dissipation:

$$t_{\rm collapse} \sim \mathcal{O}(10^{-7}) - \mathcal{O}(10^{-6}) \text{ sec}\,. \tag{16}$$

This is larger than the time scale (8) required for energy transport across the MT by an average kink soliton in some models.[10,33] The result (16), then, implies that quantum physics is relevant as far as dissipationless energy transfer across the MT is concerned.

In view of this specific model, we are therefore in stark *disagreement* with the conclusions of Tegmark,[30] i.e. that only classical physics is relevant for studying the energy and signal transfer in biological matter. Tegmark's conclusions did not take proper account of the possible isolation against environmental interactions, which seems to occur inside certain regions of MTs with appropriate geometry and properties MT.

We would now like to discuss the feasibility of the above, admittedly speculative, ideas by making a brief report on recent progress made by experimentally demonstrating macroscopic quantum entanglement at room temperature in atomic physics.

2.3. *On ordered water in biological systems*

The above scenario may find some support by independent studies of water in biological matter, which we summarize below. Recent experimental spectroscopic studies of resonant intermolecular transfer of vibrational energy in liquid water[34] have established that energy is transfered extremely rapidly and along many water molecules before it dissipates. This energy is in the form of OH-stretch excitations and is thought to be mediated by dipole-dipole interactions in addition to a yet unknown mechanism which speeds up the transfer beyond that predicted by the so-called Förster expression for the energy transfer rate between two OH oscillators, k.

$$k = T_1^{-1} \left(\frac{r_0}{r}\right)^6 \tag{17}$$

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

where T_1 is the lifetime of the excited state, r the distance between the oscillators and r_0 the Förster radius. The Förster radius, which is a parameter experimentally determined for each material, characterizes the intermolecular energy transfer and has been determined by Woutersen *et al.*[34] to be $r_0 = 2.1 \pm 0.05$ Å while the typical intermolecular distance (at room temperature) for water is ~ 2.8 Å. It is evident from these data that the energy transfer in pure water will be extremely fast (of order 100 ps) and yet experimentally it is determined to be even faster than that. Woutersen *et al.* speculate that this extremely high rate of resonant energy transfer in liquid water may be a consequence of the proximity of the OH groups in liquid water which causes other, higher-order-uples to also exchange energy. We propose another mechanism to explain the rapidity of the energy transfer, namely kink-soliton propagation. This proposition is based on the phenomenological realization that this is exactly the kind of energy transfer that one would expect to see experimentally as a result of the existence of kink-solitons. It is evident that such a mechanism, regardless of exact origin, is *ideal* for loss-free energy transfer between OH groups located on either different biomolecules or along extended biological structures such as MTs which would be covered (inside and out) with water. Note also that such a mechanism would predict that OH groups in hydrophobic environments would be able to remain in a vibrationally excited state longer than OH groups in hydrophilic environment lending credence to our working assumption that the electrons inside the hydrophobic pockets of the tubulin molecules are sufficiently isolated from thermal noise.

It must be stressed though that such solitonic states in water may not be quantum in origin in the case of microtubules. The 25 nm diameter of the MT is too big a region to allow for quantum effects to be sustained throughout, as we discussed above. Such solitons may be nothing other than the ones conjectured in Ref. 35, which may be responsible for the optical transparency of the water interior of MTs. However, such classical solitons in the bulk of the water interior may co-exist with the quantum coherent states on the dimer walls.[1]

2.4. *Error correction and long-lived quantum entanglement of macroscopic sample at room temperature*

As we have seen above, under appropriate environmental isolation, it is possible to obtain quantum coherence on *macroscopic populations* of tubulin dimers in microtubule systems, which can be sustained for long enough times so that dissipationless energy and signal (information) transfer can occur in a cell.

In a recent article[7] Julsgaard *et al.* describe the macroscopic entanglement of two samples of Cs atoms at room T^0. The entangling mechanism is a pulsed laser beam and although the atoms are far from cold or isolated from the environment, partial entanglement of bulk spin is unambiguously demonstrated for 10^{12} atoms for ~ 0.5 ms. The system's resilience to decoherence is in fact *facilitated* by the existence of a large number of atoms as even though atoms lose the proper spin orientation

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

continuously, the *bulk* entanglement is not immediately lost. Quantum informatics, the science that deals with ways to encode, store and retrieve information written in qubits has to offer an alternative way of interpreting the surprising resilience of the Cs atoms by using the idea of "redundancy". Simply stated, information can be stored in such a way that the logical (qu)bits correspond to many physical (qu)bits and thus are resistant to corruption of content. Yet another way of looking at this is given in the work by Kielpinski *et al.*[36] where they have experimentaly demonstrated a decoherence-free quantum memory of one qubit by encoding the qubit into the "decoherence-free subspace" (DFS) of a pair of trapped Berrilium $^9Be^+$ ions. They achieved this by exploiting a "safe-from-noise-area" of the Hilbert space for a *superposition* of two basis states for the ions, thus encoding the qubit in the superposition rather than one of the basis states. By doing this they achieved decoherence times on average an order of magnitude longer.

Both of the above works show that it is possible to use DFS, error correction and high redundancy to both store information and to keep superpositions and entanglements alive for biologically relevant times in macroscopic systems at high temperature.

Thus it may not be entirely inappropriate to imagine that in biological *in vivo* regimes, one has, under certain circumstances, such as specified above, similar entanglement of tubulin/MT arrangements.

3. Possible Implications of Quantum Coherence to the Functioning of Cells

The above raises the question of how such phenomena can affect the functioning of cells. In other words, would the existence of such coherent states and the emergence of quantum mechanical entanglement be somehow useful or beneficial to biological function? Is it then reasonable to propose that in certain cases, natural selection may have favored molecules and cellular structures that exhibited such phenomena? If we accept the notion that according to the laws of quantum physics certain macroscopic arrangements of atoms will exhibit such effects, is it not reasonable then to expect that biomolecules and (by extension) cellular structures and whole cells have "found" a use for such phenomena and have evolved to incorporate them? We stress that at a given instant in time, the different microtubule coherent states participating in a specific bulk entanglement would be almost identical due to the fact that they are related/triggered by a specific "external agent" (e.g. the passing of a specific train of action potentials.) This is of outmost importance since it increases the system's resilience to decoherence (by entangling a large number of nearly identical states), in addition to facilitating "sharp decision making" (i.e. rapid choice among a vast number of very similar states) as explained in Ref. 37 which is presumably a trait favored by natural selection. Here we *digress* to investigate one possible use of such effects by noting a straight-forward application of entanglement to *teleportation* of coherent quantum states across and between cells.

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

We define teleportation as the complete transfer of the *coherent state* of an MT *without any direct transfer of mass or energy.* This means that the "receiver" MT finds itself in an identical state to the "sender" MT. We will demonstrate that given the possibility for entangled states, teleportation between microtubule A and microtubule C can happen as follows:

A coherent state in microtubule A (referred to as simply A and designated as $|\Psi(A)\rangle)$ of the (collective) dipole moment(s) being in either of the two classically allowable states with probability amplitude ω_0 and ω_1 can be written as:

$$|\Psi(A)\rangle = \omega_0|0\rangle + \omega_1|1\rangle\,. \tag{18}$$

Step 1: The cell finds itself with *microtubule B and microtubule C* — which can be close together or collinear in an entangled state written as:

$$|\Psi(B,C)\rangle = \frac{1}{\sqrt{2}}(|1_B, 0_C\rangle + |0_B, 1_C\rangle)\,. \tag{19}$$

The combined state of A, B, C can be written as:

$$|\Psi(A,B,C)\rangle = |\Psi(A)\rangle \otimes |\Psi(B,C)\rangle \tag{20}$$

which upon expanding the outer product can be written as:

$$\begin{aligned}|\Psi(A,B,C)\rangle = \frac{1}{\sqrt{2}}(&\omega_0(|0_A, 1_B, 0_C\rangle + |0_A, 0_B, 1_C\rangle)\\ &+ \omega_1(|1_A, 1_B, 0_C\rangle + |1_A, 0_B, 1_C\rangle))\,.\end{aligned} \tag{21}$$

We can also express the combined state $|\Psi(A,B,C)\rangle$ in a different basis, known as the "Bell basis". Instead of $|0\rangle$ and $|1\rangle$, the basis vectors will now be,

$$|\Psi^{\pm}(A,B)\rangle = \frac{1}{\sqrt{2}}(|0_A, 1_B\rangle \pm |1_A, 0_B\rangle) \tag{22}$$

and

$$|\Phi^{\pm}(A,B)\rangle = \frac{1}{\sqrt{2}}(|0_A, 0_B\rangle \pm |1_A, 1_B\rangle)\,. \tag{23}$$

In this new basis, our state of the three microtubules $|\Psi(A,B,C)\rangle$ is written as:

$$\begin{aligned}|\Psi(A,B,C)\rangle = \frac{1}{2}(&|\Psi^+(A,B)\rangle \otimes (\omega_0|0_C\rangle + \omega_1|1_C\rangle) + |\Phi^+(A,B)\rangle \otimes (\omega_0|1_C\rangle\\ &+ \omega_1|0_C\rangle) + |\Psi^-(A,B)\rangle \otimes (\omega_0|0_C\rangle - \omega_1|1_C\rangle)\\ &+ |\Phi^-(A,B)\rangle \otimes (\omega_0|1_C\rangle - \omega_1|0_C\rangle))\,.\end{aligned} \tag{24}$$

This concludes the first step of teleporting the state of MT A to MT C.

Step 2: Notice that so far, MT A has not been manipulated by the cell, i.e. the coherent state of A which we designated as $|\Psi(A)\rangle = \omega_0|0\rangle + \omega_1|1\rangle$ has not been touched. Now the part of the cell containing A and B (let us call it the "sender part") makes a "measurement" — which in our case can be an electromagnetic

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

interaction with a passing action potential or the binding of a MAP molecule. If this "measurement" or forced collapse is done in the Bell basis, on $|\Psi^{\pm}(A,B)\rangle$ it will project the state in MT C (!) to:

$$|\Psi^{\pm}(C)\rangle = \langle\Psi^{\pm}(A,B)|\Psi(A,B,C)\rangle = \omega_0|0_C\rangle \pm \omega_1|1_C\rangle\,, \tag{25}$$

similarly

$$|\Phi^{\pm}(A,B)\rangle \to |\Phi^{\pm}(C)\rangle = \omega_0|1_C\rangle \pm \omega_1|0_C\rangle\,. \tag{26}$$

This effectively concludes the teleportation of the state of MT A to MT C with one caveat. There is a probabilistic nature to this process, which means that MT C may receive the exact copy of the state of MT A i.e. $|\Psi^{+}(C)\rangle$ *or* it may receive a state which is a unitary transformation away from the original $|\Psi(A)\rangle$ (one of the other three possibilities: $|\Psi^{-}\rangle$ or $|\Phi^{\pm}\rangle$. MT C can reproduce the state of MT A if there is a "hardwired" condition that when MT C receives $|\Psi^{+}\rangle$ it does nothing further, yet if it receives one of the other three, it performs the correct unitary transformation to obtain the correct state from A. This "hardwired" behavior can be implemented through the use of codes, not unlike the Koruga bioinformation[38] code that MTs follow.

Teleportation is a direct consequence of the existence of entanglement and can be imagined as the basis of intra- and inter-cellular correlation which leads to yoked function (e.g. intracellulary during translation and intercellulary during yoked neuron firing). Experiments to check for such teleportation of states can be designed based on the Surface Plasmon Resonance (SPR) paradigm[39] as applied to sheets of polymerized tubulin immobilized on a dextran-layered gold film.

Note that our use of pure state vectors, $|\Psi\rangle$, to describe the coherent states along a MT arrangement is justifiable since they do not obey the ordinary Schrödinger evolution equation. Instead, they obey the stochastic equations of open systems, of the form discussed in Ref. 40. Nowhere in our proof of teleportation above did we make use of the presice form of the evolution equations. As argued in Ref. 40, by using appropriate stochastic (Langevin type) equations one may recover, for instance, the standard Lindblad form of evolution equations for the corresponding density matrices $\rho = \mathrm{Tr}_{\mathcal{M}}|\Psi\rangle\langle\Psi|$, where $\mathcal{M}$ is an appropriate subset of environmental degrees of freedom, non-accessible to the observer.

4. Conclusions and Outlook

In Ref. 1 we have put forward a comprehensive model conjecture treating certain regions inside MTs as *isolated* high-Q(uality) QED *cavities*. We also presented a scenario according to which the presence of *ordered water* in the interior of MTs results in the appearance of electric dipole quantum coherent modes, which couple to the unpaired electrons of the MT dimers via Rabi vacuum field couplings. The situation is analogous to the physics of Rydberg atoms in electromagnetic cavities.[4] In quantum optics, such couplings may be considered as experimental proof of

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

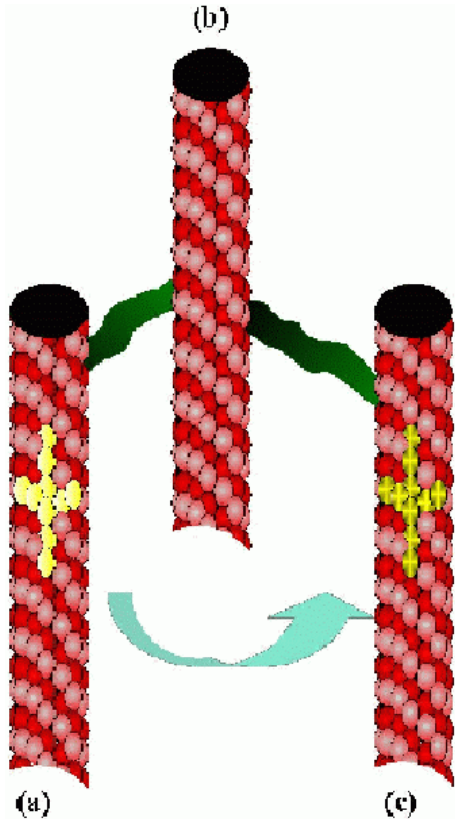

Fig. 2. Schematic of a microtubular quantum teleportation of states. MT (a) sends its state (represented by a cross) to MT (c) without any transfer of mass or energy. Both MT (a) and MT (c) are entangled with MT (b) (entanglement represented by presence of connecting MAPs.

the quantized nature of the electromagnetic radiation. In our case, therefore, if experimentally detected, such couplings would indicate the existence of coherent quantum modes of electric dipole quanta in the *ordered water* environment of MT, as conjectured in Refs. 15 and 16, and used here.

To experimentally verify such a situation, one must first try to detect the emergent ferroelectric properties of MTs, which are predicted by this model and are potentially observable. Measurement of the dipole moment of the tubulin dimers is also an important step. A suggestion along these lines has been put forward in Ref. 12.

In addition, one should verify the aforementioned vacuum field Rabi coupling (VFRS), $\lambda_{\rm MT}$, between the MT dimers and the *ordered water* quantum coherent modes. The existence of this coupling, could be tested experimentally by the same methods used to measure VFRS in atomic physics,[6] i.e. by using the MTs themselves as *cavity environments*, in the way described above, and considering tunable

Int. J. Mod. Phys. B 2002.16:3623-3642. Downloaded from www.worldscientific.com
by UNIVERSITY OF ALBERTA on 02/19/19. Re-use and distribution is strictly not permitted, except for Open Access articles.

probes to excite the coupled dimer-water system. Such probes could be pulses of (monochromatic) light coupling to MTs. This would be the *analogue* of an external field in the atomic experiments mentioned above. The field would then resonate, not at the bare frequencies of the coherent dipole quanta or dimers, but at the *Rabi splitted* ones, leading to a double peak in the absorption spectra of the dimers.[6] By using MTs of different sizes one could thus check on the characteristic $\sqrt{N}$-enhancement of the (resonant) Rabi coupling (10) for MT systems with N dimers.

In the quantum-mechanical scenario for MT dynamics discussed above, as suggested in Ref. 1, a quantum-hologram picture for information processing of MT networks emerges. Further, the existence of solitonic quantum-coherent states along the MT dimer walls implies a role for these biological entities as logic gates.[41] Consider, for instance, a node (junction) of three MTs connected by microtubule associated proteins (MAPs) see Fig. 3. The quantum nature of the coherent states makes the junction interaction *probabilistic*. Therefore at any tube junctions, one is facing a *Probabilistic Boolean Interaction*.[b] The probability for having a solitonic coherent state in a MT branch does depend on its geometric characteristics (such as length). By modulating the length of the tubes and the binding sites of the MAPs one, a bias can be introduced between bit states which can affect the probabilistic final outcomes. This has obvious implications for information processing by MT networks.

Such a binary information system can then provide the basic substrate for quantum information processing inside a (not exclusively neural) cell. In a typical MT network, there may be about 10^{12} tubulin dimers. Such a number is macroscopic, and one is tempted to express doubt as to whether, in realistic biological situations, such macroscopic populations of "particles" can be entangled quantum mechanically, with the entangled state being maintained for a relatively long period of time. It is worth stressing again that in atomic physics the experiments of Ref. 7 have demonstrated *experimentally* the existence of long-lived entangled states of *macroscopic* populations of Cs gas samples, each sample containing 10^{12} atoms. In such experiments entanglement is generated via interaction with pules of light. Thus it is not impossible that *in vivo* one has, under certain circumstances as specified above, similar entanglement of MT coherent quantum states.

If it is experimentally confirmed that treating MTs as QED cavities is a fair approximation to their function, then it may not be so foolhardy to imagine that nature has provided us with the necesasary structures (microtubules) to operate as the basic substrate for *quantum computation* either *in vivo*, e.g. in the way the brain works, or *in vitro*, i.e. it would allow us to construct quantum computers by using microtubules as building blocks, in much the same way as QED cavities in quantum optics are currently being used in successful attempts at implementing qubits.[18]

[b]We would like to thank Dr. Deeph Chana for suggesting this terminology.

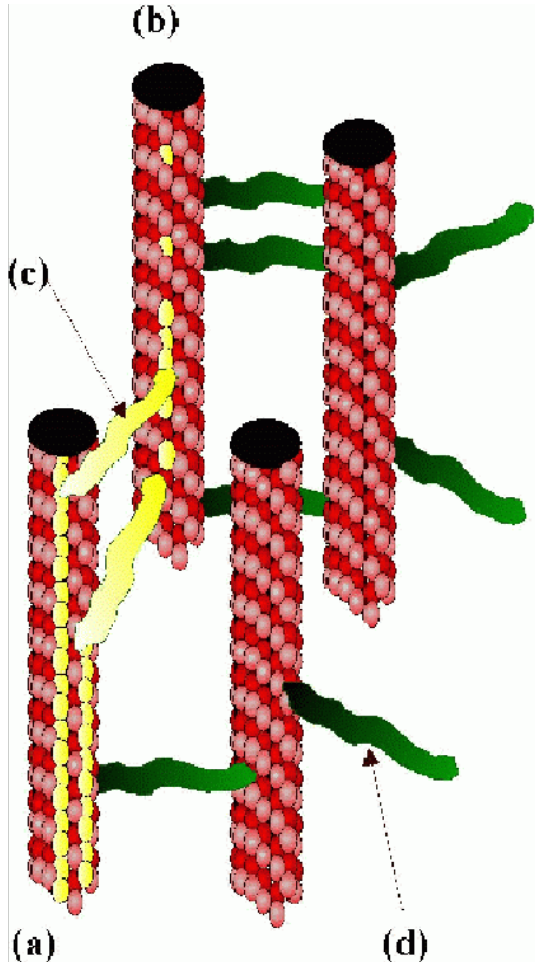

Fig. 3. Example of a microtubular logic gate: A XOR logic gate where "0" is represented by absence of soliton and "1" by presence of soliton. (a) Input MT. (b) Output MT. (c) A MAP transmitting a soliton. (d) A "quiet" MAP. MT (a) has two solitons travelling, encountering two MAPs that transmit both solitons to MT (b). (b) In this hypothetical scenario, the solitons arrive out of phase at MT (b) and cancel each other out. The truth table for XOR reads: $0,0 \to 0; 0,1 \to 1; 1,0 \to 1, 1,1 \to 0$. and in this case is realized by MTs if the MAPs are arranged such that each can transmit a soliton independently but if they both transmit, the solitons cancel out.

Acknowledgments

We would like to thank Prof. S. Zubairy for useful discussions concerning quantum teleportation by QED cavities. We would also like to thank Dr. P. Eagles, Prof. M. Holwill, Dr. M. Damzen, Prof. A. Michette, Dr. K. Powell and Prof. Sarben Sarkar for discussions and their interest in further pursuing some of the experimental aspects of our work.

The Penrose-Hameroff orchestrated objective reduction (orch. OR) model assigns a cognitive role to quantum computations in microtubules within the neurons of the brain. Despite an apparently ''warm, wet, and noisy'' intracellular milieu, the proposal suggests that microtubules avoid environmental decoherence long enough to reach threshold for ''self-collapse'' (objective reduction) by a quantum gravity mechanism put forth by Penrose. The model has been criticized as regards the issue of environmental decoherence, and a recent report by Tegmark finds that microtubules can maintain quantum coherence for only 10^{-13} s, far too short to be neurophysiologically relevant. Here, we critically examine the decoherence mechanisms likely to dominate in a biological setting and find that (1) Tegmark's commentary is not aimed at an existing model in the literature but rather at a hybrid that replaces the superposed protein conformations of the orch. OR theory with a soliton in superposition along the microtubule; (2) recalculation after correcting for differences between the model on which Tegmark bases his calculations and the orch. OR model (superposition separation, charge vs dipole, dielectric constant) lengthens the decoherence time to 10^{-5}–10^{-4} s; (3) decoherence times on this order invalidate the assumptions of the derivation and determine the approximation regime considered by Tegmark to be inappropriate to the orch. OR superposition; (4) Tegmark's formulation yields decoherence times that increase with temperature contrary to well-established physical intuitions and the observed behavior of quantum coherent states; (5) incoherent metabolic energy supplied to the collective dynamics ordering water in the vicinity of microtubules at a rate exceeding that of decoherence can counter decoherence effects (in the same way that lasers avoid decoherence at room temperature); (6) microtubules are surrounded by a Debye layer of counterions, which can screen thermal fluctuations, and by an actin gel that might enhance the ordering of water in bundles of microtubules, further increasing the decoherence-free zone by an order of magnitude and, if the dependence on the distance between environmental ion and superposed state is accurately reflected in Tegmark's calculation, extending decoherence times by three orders of magnitude; (7) topological quantum computation in microtubules may be error correcting, resistant to decoherence; and (8) the decohering effect of radiative scatterers on microtubule quantum states is negligible. These considerations bring microtubule decoherence into a regime in which quantum gravity could interact with neurophysiology.

I. INTRODUCTION

In the conventional biophysical approach to understanding cognitive processes, it has been generally accepted that the brain can be modeled, according to the principles of classical physics, as a neural network [1–5]. Investigations in this field have delivered successful implementations of learning and memory along lines inspired by neural architectures and these have promoted optimism that a sufficiently complex artificial neural network would, at least in principle, incur no deficit in reproducing the full spectrum and extent of the relevant brain processes involved in human cognition and consciousness.

However, physical effects in the functioning of the nervous system, which lie outside the realm of classical physics, suggest that such simulations may ultimately prove insufficient to the task. One finds ample support for this in an analysis of the sensory organs, the operation of which is quantized at levels varying from the reception of individual photons by the retina [6,7] to thousands of phonon quanta in the auditory system [8]. Of further interest is the argument that synaptic signal transmission has a quantum character [9,10], although the debate on this issue has not been conclusive [11]. We note that using the thermal energy at room temperature in the position-momentum uncertainty relation, and assuming a 1 Å uncertainty for quantal effects, Beck and Eccles [9] concluded that a particle whose mass is just six proton masses would cease to behave quantum mechanically and become classical for all intents and purposes. This seems a serious underestimate, based on the de Broglie wavelength alone. In any case, it is known that quantum modes of behavior exist in much larger structures, such as peptides, DNA, and proteins [12]. For instance, Roitberg *et al.* [13] demonstrated functional protein vibrations that depend on quantum effects centered in two hydrophobic phenylalanine residues, and Tejada *et al.* [14] have evidence to suggest that quantum coherent states exist in the protein ferritin. Finally, new developments in magnetic resonance imaging of the brain demonstrate that induced quantum coherences of proton spins separated by distances ranging from micrometers to 1 mm are sustained for tens of milliseconds and longer [15–17]. While these unentangled quantum couplings are not the type of quantum processes that are likely to prove useful in brain function, they nonetheless demonstrate that mesoscopic quantum coherence can indeed survive in the brain's milieu. Similarly, the aforementioned quantum

modes in peptides, DNA, and proteins are not the stable, entangled superpositions required for quantum computation, but show that biology can take advantage of quantum modes in clever ways.

The inadequacy of classical treatments is further suggested at the cognitive level, not only as regards longstanding difficulties related to, for instance, accounts of semantics [18], binding [19], and the neural correlate of consciousness, but even in the rather modest goal of reproducing cognitive computational characteristics. Penrose, in particular, has argued that human understanding must involve a noncomputational element [20,21] inaccessible to simulation on classical neural networks and this might be realized through a biological instantiation of quantum computation.[1] Along these lines, Penrose and Hameroff have put forth a specific model [22–24]—orchestrated objective reduction (orch. OR)—positing quantum computation in microtubule protein assemblies in the neurons of the brain.

Microtubules are hollow cylinders whose walls consist of 13 columns (protofilaments) of the protein tubulin arranged in a skewed hexagonal lattice (see Fig. 1). Along with other structures, microtubules comprise the internal scaffolding—the ''cytoskeleton''—in cells including neurons. Determinants of both structure and function, cytoskeletal structures are dynamically active, performing a host of activities instrumental to cellular organization and intelligence [25]. Earlier models (see, for instance, [26–32]) proposed classical information processing among the tubulin ''dimers'' composing microtubules—molecular-level automata regulating real-time cellular behavior. More recently, arguments have been made for quantum computation at the level of individual proteins [33]. In particular, functional protein conformational states are mediated by quantum van der Waals (London) forces [34], the relevance of which is demonstrated by the mechanism of action of the general anesthetic gases that reversibly ablate consciousness. Anesthetics act by disturbing such forces in the hydrophobic pockets of various brain proteins [35,36]. Microtubules are thus poised to mediate between a tubulin-based quantum computation and the classical functioning of neurons.

The Penrose-Hameroff proposal suggests that coherent superpositions of tubulin proteins are inherently unstable and subject to self-collapse under a quantum gravitational criterion (Penrose objective reduction or OR). In the orch. OR model [22,23], the phase of quantum superposition/computation is a preconscious process, and each self-collapse event corresponds to an instantaneous ''moment of conscious experience.'' The mode of collapse, i.e., the fate of proposed superpositions, is a separate issue, the question here being the duration of microtubule quantum states in the face of environmental decoherence. To have an impact on cognitive processes, microtubule superpositions need to survive long enough to interact with the brain's neurophysiological events, typically in the range of milliseconds to hundreds of milliseconds. Calculations indicate that superpositions of these durations would indeed reach self-collapse by quantum gravity in the context of the brain [22,23,37,38]. Quantum coherence that persists, or has influence over such a neurophysiologically relevant time frame, could regulate neural processes, in a manner accounting for the noncomputational element, by ''orchestrating'' state vector reductions to perform quantum computation.

According to the orch. OR model, the neuronal cytoplasm in which microtubules are embedded alternates between phases of (1) isolated quantum superposition/computation (solid, or gelatinous ''gel,'' actin polymerization) and (2) classical states of input/output communication (liquid solution or ''sol''). The input to and output from each OR event evolve as classical microtubule cellular automata—in the form of patterns of tubulin conformational states—to regulate synaptic function, membrane activities, and attachment sites for microtubule-associated proteins (MAPs). Input from synaptic activities may be provided by metabotropic receptors, which interface between membrane synaptic functions and the internal cytoskeleton/microtubules. For example, when the prevalent brain neurotransmitter acetylcholine binds to its postsynaptic receptor, a cascade of activities results in the microtubule-associated protein MAP2 decoupling from microtubules. Woolf [39] has suggested that such decoupling initiates isolation of quantum states in microtubules from the membrane and outside environment. MAPs also interconnect microtubules in bundles, or networks, and are suggested to regulate, or orchestrate, microtubule quantum states prior to OR by their particular attachment sites on the microtubular lattice.

An apparent vulnerability of the orch. OR model and other models of quantum processes relevant to cognition is the question of environmental decoherence. Specifically, can environmental decoherence be avoided and quantum super-

[1]It has been noted that fundamentally analog mechanisms, based on continuous rather than traditional discrete (Turing) computation, might also constitute noncomputation in the relevant sense and equally evade Penrose's argument. However, the essentially discrete nature of exocytosis implies that no such description can be framed in terms of the neurochemical basis of synaptic function.

position sustained long enough for the system to reach threshold for OR? In the original orch. OR formulation, it was assumed that decoherence would have to be avoided for periods long enough to be consistent with membrane electrophysiological events, i.e., 10^{-3}–10^{0} s. However, it has been suggested recently [40] that orch. OR events of far briefer duration may be sufficient. For example, sequences of many orch. OR events in the range of 10^{-7}–10^{-6} s may culminate in electrophysiological events in the 10^{-2}–10^{0} s range.

Recently, Tegmark [41] has responded to this and other models of brain function invoking a quantum element by contending that the relevant degrees of freedom cannot reasonably be sufficiently shielded from environmental, and particularly thermal, influence to maintain quantum superpositions until self-collapse. It is well known that technological quantum devices often require extremely low temperatures to avoid decoherence through environmental interaction. The survival of a delicate quantum coherence in the warm, wet, and noisy milieu of the brain long enough for quantum computation to play a neurophysiological role, therefore, seems unlikely to many observers. Tegmark maintains that orthodox mechanisms of decoherence would destroy a superposed microtubule-associated quantum state on a time scale of the order of 10^{-13} s, much shorter than that associated with events, such as neural firings. In the following, we critically review the assumptions, calculations, and claims that have been made in order to ascertain whether existing treatments accurately reflect the potential for quantum computation in the brain.

II. DECOHERENCE RATES

Tegmark considers in his paper [41] two different scales at which quantum computation might occur in the brain—one involving superpositions of neurons firing and not firing (with calculated decoherence times of 10^{-20} s), and another involving microtubules (calculated decoherence times of 10^{-13} s). We agree that superpositions at the level of neural firing are unlikely, and in fact play no role in the orch. OR or any other contemporary quantum model. In the orch. OR approach, neural firings are entirely classical, though they may be initiated by the outputs of microtubule quantum processes in the neuronal interior. We therefore focus our attention on Tegmark's assertions regarding decoherence times for microtubule-associated quantum superpositions.

Though Tegmark specifically implicates Penrose, his criticisms target neither the Penrose-Hameroff orch. OR model—the only detailed, quantitative model of quantum processes in microtubules with which Penrose is associated—nor any other that is currently or has been under investigation. His remarks appear to be directed against a spuriously quantum version of a classical model, put forth by Sataric *et al.* [29], to treat lossless energy transfer in microtubules in terms of kink solitons traveling along their length.

Tegmark considers a model in which kink soliton solutions, such as those of Sataric *et al.* [29], exist in a quantum superposition of different positions along the microtubule. The actual orch. OR model, on the other hand, is framed in terms of superpositions of the conformational state of a tubulin dimer, as illustrated in Fig. 2, in which superposition separation occurs at the level of each of the protein's atomic nuclei. The separated states are coupled to delocalizable electrons residing in the hydrophobic pocket of the tubulin dimer protein, pointing to a process of conformational change in the dimer controlled by quantum van der Waals (London) forces. There is thus a considerable conceptual disparity between this model and that considered by Tegmark. Nevertheless, it is equally critical to the actual orch. OR model that the mechanisms of decoherence analyzed do not destroy quantum coherence prematurely, before a quantum gravity-induced self-collapse can come into play. Below, we consider both numerical and theoretical concerns that bear on the results presented by Tegmark.

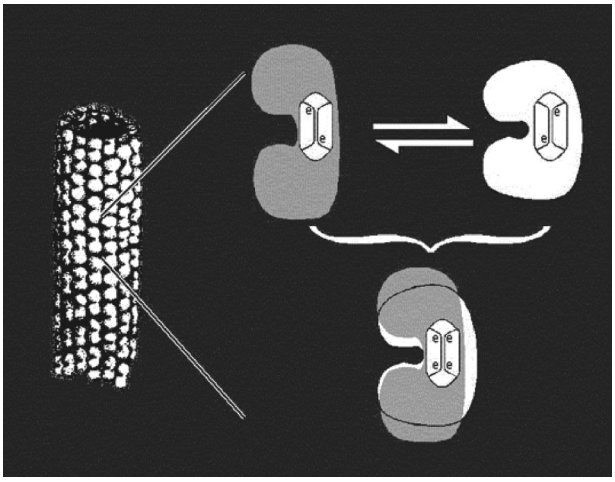

FIG. 2. Each tubulin dimer composing a microtubule can switch between two (or more) conformations coupled to van der Waals (London) forces in the hydrophobic pocket of each. In the orch. OR model, it is posited that tubulin can also exist in a superposition of both conformational states.

In the microtubule case, Tegmark determines the time to decoherence, τ, due to the long-range electromagnetic influence of an environmental ion to be

$$\tau \sim \frac{4\pi\epsilon_0 a^3\sqrt{mkT}}{Nq_e^2 s}, \tag{1}$$

where T is the temperature, m is the mass of the ionic species, a is the distance to the ion from the position of the superposed state, N is the number of elementary charges comprising that state, and s is the maximal ''separation'' between the positions of the tubulin mass in the alternative geometries of the quantum superposition. Since any difference in the mass distributions of superposed matter states will impact upon the underlying space-time geometry, such alternative geometries must presumably be permitted to occur within the superposition.

A. Superposition separation

Superposition occurs not only at the level of a mass distribution separated from itself, but concomitantly at the level of the underlying space-time geometry. According to Pen-

rose's quantum gravitational criterion for objective reduction, superpositions involving different space-time geometries are considered inherently unstable, with the rate of collapse determined by a measure of difference in the geometries. As this measure approaches the order of a Planck length, it becomes problematic to determine a consistent standard by which to match up points in the superposed geometries. Yet if the superposed spaces cannot be resolved into one and the same space, then the different matter states in the superposition must occur in separate spaces and the meaning of superposition in this context becomes obscure. Thus the rate of collapse in Penrose's suggestion for objective reduction must become significant before the measure of difference in superposed space-time geometries grows to the Planck scale. Since gravitational forces are inherently weak, however, the mass distributions of the superposed matter states can be substantially ''separated'' before incurring a large measure of difference in the associated space-time geometries.

Tegmark assumes that this separation s must be at least as large as the diameter of a microtubule, $D=24$ nm, for superpositions spanning many tubulin dimers. This estimate is based on a picture of tubulin dimers literally ''beside themselves'' in superposition. However, in the orch. OR theory, the authors contemplate separation only at the level of the individual atomic nuclei of amino acids comprising the protein.

Hameroff and Penrose [42] surveyed three different levels at which separation related to the protein conformational state of the tubulin dimers might occur: (1) partial separation (10%) of protein spheres, (2) complete separation of atomic nuclei, and (3) complete separation of nucleons. The gravitational self-energy in each instance is taken to be inversely proportional to the decoherence time according to the energy-time uncertainty relation. In the case of protein spheres, the energy E for partial separation is obtained from

$$E=\frac{GM^2s^2}{2r^3}\left(1-\frac{3s}{8r}+\frac{s^3}{80r^3}\right), \tag{2}$$

where M is the monomer mass of 55 kDa, r is the radius of a monomer sphere, and $s=\frac{1}{10}r$ is the superposition separation. For complete separations at the level of either atomic nuclei or nucleons, the contribution to the self-energy determined in separating the mass distributions to a distance of one diameter (the contact position in a spherical approximation of the masses) is of the same order as that determined by increasing the separation further, even to infinity, so the contribution in moving from coincidence to contact is a good order of magnitude estimator of the self-energy for complete separations.

Mass separation of granular arrays of atomic nuclei yields the highest energies of the three cases, and hence the shortest decoherence times, and it is this level that will thus dominate in an orchestrated reduction.[2] Thus mass separation is effected at separations the size of the nucleus, on the order of femtometers, some seven orders of magnitude smaller than Tegmark's estimate.

B. Polarization and charge

In his analysis of the polarization associated with the microtubule, Tegmark defines $p(x)$ to be the average component, in the direction parallel to the microtubule axis, of the electric dipole moment due to the tubulin dimers, a polarization function given in units of (charge) $\times$ (length). The subsequent claim that $-p'(x)$ represents the net charge per unit length along the microtubule, cannot then, on dimensional grounds alone, be well founded. Nevertheless, on this basis, Tegmark integrates over the length of the microtubule across the kink to obtain a net charge that incorrectly bears the units of an electric dipole moment. This, in effect, treats the microtubule as a line of uniform charge rather than a polarized line, and this is how he obtains the magnitude of the *polarization* function by simply summing the *charge* of the ions arrayed around the microtubule at the level of the kinklike propagation. The value of N that figures in his estimate of the decoherence time is then this sum expressed in units of the electron charge q_e. Aside from the dimensional incongruities in this procedure, Tegmark accounts only for the presence of 18 Ca^{2+} ions, bound to the C terminus of the tubulin on each of 13 protofilaments in a cross section of the microtubule. This overlooks the negative charges borne by amino acid side groups and numerous other charges associated with tubulin, all of which attract counterions from the surrounding medium.

Tubulin has been imaged to atomic resolution only within the last two years, following 20 years of difficult work with this protein. Nogales *et al.* published the structure of α- and β-tubulin, co-crystallized in the heterodimeric form [44]. The work establishes that the structures of α and β tubulin are nearly identical and confirms the consensus speculation. A detailed examination shows that each monomer is formed by a core of two β sheets that are surrounded by α helices. The monomer structure is very compact, but can be divided into three functional domains: the amino-terminal domain containing the nucleotide-binding region, an intermediate domain containing the taxol-binding site, and the carboxy-

[2]Estimates of the time to self-collapse (decoherence time) due to such a quantum gravitational mechanism will depend on the number of participating tubulin subunits. For example, calculating energies based on a separation at the level of atomic nuclei, a decoherence time of 500 ms is obtained for 10^9 participating tubulin, or about 10^3 neurons if it is assumed that 10% of the tubulin contained becomes involved (there are roughly 10^7 tubulin per neuron [43]). For a decoherence time of 25 ms (i.e., for coherent 40 Hz oscillations), 2×10^{10} tubulin, or about 20 000 neurons, would be involved. Orch. OR events with a decoherence time of 10^{-6} s would involve roughly 10^{14} tubulin, or about 10^8 neurons (approximately 0.1%–1% of the entire brain). A series of such fast orch. OR events could culminate in membrane depolarization or synaptic transmission.

TABLE I. Calculated values of some electrostatic properties of tubulin.

Tubulin property		Calculated value
Charge		$-10q_e$
Dipole moment		1714 D
Dipole	p_x	337 D
Moment	p_y	-1669 D
Components	p_z	198 D

terminal (C-terminus) domain, which probably constitutes the binding surface for motor proteins [44].

Recently, tubulin's electrostatic properties, including its potential energy surface, were calculated [45] with the aid of the molecular dynamics package TINKER. This computer program serves as a platform for molecular dynamics simulations and includes a facility to use protein-specific force fields. With the C-terminus tail excluded, the electrostatic properties of tubulin are summarized in Table I, following Brown [45].

Since 1 debye$=\frac{1}{3}\times10^{-29}$ C m, we find that the total dipole moment is approximately 5.7×10^{-27} C m, but only a fifth of it is oriented along the protofilament axis.[3]

It turns out that tubulin is quite highly negatively charged at physiological pH, but that much of the charge is concentrated on the C-terminus. This is the one portion of the tubulin dimer which was not imaged by Nogales *et al.* [44] due to its freedom to move following formation of the tubulin sheet. This tail of the molecule extends outward away from the microtubule and into the cytoplasm and has been described by Sackett [46]. At neutral *p*H, the negative charge on the carboxy terminus causes it to remain extended due to the electrostatic repulsion within the tail. Under more acidic conditions, the negative charge of the carboxy-terminal region is reduced by associated hydrogen ions. The effect is to allow the tail to acquire a more compact form by folding.

Any exposed charge in a cytoplasm will be screened by counterions forming a double layer. The screening distance provided by these counterions and water is the Debye length and, in the case of microtubules, its value is typically 0.6–1.0 nm under physiological conditions. Due to the exposure of negatively charged amino acids in the C terminus, a Debye layer is formed as shown in Fig. 3, screening thermal fluctuations due to the stronger Coulomb interactions over distances within the Debye length.

Ionic forces thus tend to cancel over even relatively short distances so that the forces mediating between tubulin and its environment should instead be characterized by dipolar interactions. This suggests that Tegmark's derivation of the decoherence time in Eq. (1) should be replaced with one that

[3]The x direction coincides with the protofilament axis. The α monomer is in the direction of increasing x values, relative to the β monomer. This is opposite to the usual identification of the β monomer as the "plus" end of the microtubule, but all this identifies is whether the microtubule is pointed towards or away from the cell body.

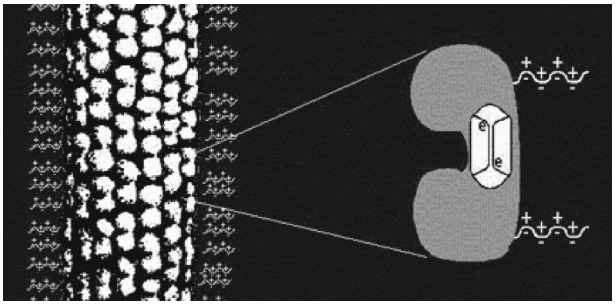

FIG. 3. Negative charges on the C-terminus tail of the tubulin dimer are screened under physiological conditions by counterions forming a Debye layer around the microtubule, as described by Sackett [46].

characterizes tubulin in terms of its electric dipole moment, thus avoiding the need to make a rather arbitrary cut in selecting which charges are to be constitutive of the overall charge of the kinked microtubule and which are to be neglected. Such a modification is accomplished by replacing the Coulomb potential, $V_{\text{Coulomb}}=q^2/4\pi\epsilon_0|\mathbf{r}_1-\mathbf{r}_0|$, describing the interaction of a quantum state of charge q at $\mathbf{r}_0$ and a similarly charged environmental ion at $\mathbf{r}_1$, in favor of a dipole potential, $V_{\text{dipole}}=q\mathbf{p}\cdot(\mathbf{r}_1-\mathbf{r}_0)/4\pi\epsilon_0|\mathbf{r}_1-\mathbf{r}_0|^3$, parametrized by $\mathbf{p}$, the electric dipole moment due to tubulin of the kinked microtubule. The interaction is well approximated, for the purposes of an order-of-magnitude estimate, by this dipole potential in the case that a, the distance between the environmental ion and the superposed state, is greater than the separation of charges in the determination of the electric dipole moment. This separation will not generally be larger than the length of a tubulin dimer, 8 nm, whereas $a=\frac{1}{2}D+n^{-1/3}\approx14$ nm for the same ionic density used by Tegmark, $n=\eta n_{\text{H}_2\text{O}}$ with $\eta\approx2\times10^{-4}$.

As in the Coulomb case of interacting charges, the force resulting from the dipole potential contributes only a phase factor in the evolution of the (reduced) density matrix, traced over the environmental degrees of freedom. These are thus tidal effects that determine the leading contribution to the rate of decoherence. In terms of the vector $\mathbf{a}\equiv\mathbf{r}_1^0-\mathbf{r}_0^0$, between the initial average positions of the environmental ion and the polarized quantum state, these tidal effects are given by the Hessian matrix of second derivatives of the interaction potential

$$\mathbf{M}=\frac{3qp}{4\pi\epsilon_0 a^4}[(5\hat{\mathbf{a}}\hat{\mathbf{a}}^T-\mathbf{I})(\hat{\mathbf{p}}\cdot\hat{\mathbf{a}})-(\hat{\mathbf{a}}\hat{\mathbf{p}}^T+\hat{\mathbf{p}}\hat{\mathbf{a}}^T)]. \tag{3}$$

Under the same assumptions that give rise to Eq. (1), the dipole case yields a decoherence time scale of

$$\tau\sim\frac{4\pi\epsilon_0 a^4\sqrt{mkT}}{3q_e ps}\Omega_{\text{dipole}}, \tag{4}$$

where

$$\Omega_{\text{dipole}}=(5\cos^2\theta\cos^2\varphi-4\cos\theta\cos\varphi\cos\psi+\cos^2\theta+\cos^2\varphi+\cos^2\psi)^{-1/2}$$

is a geometric factor fixed in terms of the angles between **p**, **a**, and **s**,

$$\cos\theta = \hat{\mathbf{a}}\cdot\hat{\mathbf{s}},$$

$$\cos\varphi = \hat{\mathbf{p}}\cdot\hat{\mathbf{a}},$$

$$\cos\psi = \hat{\mathbf{s}}\cdot\hat{\mathbf{p}}.$$

In our calculations, Ω_{dipole} is taken to be of order one.[4]

The calculation of the decoherence time scale in Eq. (4) can be made more realistic by taking into account the dielectric permittivity of tubulin in cytosol, neglected in the original calculation. Since the intracellular medium is primarily water, its dielectric constant can be quite high. The precise value of the permittivity of water is both temperature and frequency dependent but can be as high as $\epsilon \approx 80$ [47,48]. Conservatively estimating the dielectric constant of the surrounding medium by $\epsilon \approx 10$, and using the values given in Table I for the component of tubulin's electric dipole moment along the microtubule axis, together with the correction to the separation s discussed in Sec. II A, yields a decoherence time, $\tau \approx 10^{-5}$–10^{-4} s, that is already eight or nine orders of magnitude longer than that suggested by Tegmark, and sufficient for orch. OR events in the range of 10^{-6} s.

We also wish to point out that Mavromatos and Nanopoulos [38] estimated decoherence times for dipolar excitations in microtubules. Depending on the set of assumptions adopted, the value of τ obtained ranged from as low as 10^{-10} s using a conformal field theory method to as high as 10^{-4} s using a coherent dipole quantum state. For a kink state similar to that discussed by Tegmark, that value is of the order of 10^{-7}–10^{-6} s. Table II summarizes the relevant decoherence time scales.

TABLE II. Relevant decoherence time scales.

Proposed quantum superpositions	Calculated decoherence times
Superposition of neural firing (Tegmark)	10^{-20} s
Soliton superposition (Tegmark)	10^{-13} s
Orch. OR superpositions (corrected)	$10^{-5}-10^{-4}$ s
Coherent dipole state [38]	10^{-4} s
	of magnitude?

C. Dynamical time scales, shielding and error correction

Given the sizeable discrepancy between these estimates and those of Tegmark, it seems reasonable to reevaluate whether the assumptions and conclusions of his calculations are valid. In particular, the derivation requires that the decoherence time scale should fall far short of any relevant dynamical time scale for either the quantum object or the ionic environment, if the noninteracting contribution to the Hamiltonian is to be neglected relative to the interaction contribution. With the substantially modified decoherence times calculated above, this assumption is no longer justified, even by Tegmark's own estimates that place the dynamical time scale for a kinklike excitation traversing a microtubule at $\tau_{\text{dyn}} \approx 5 \times 10^{-7}$ s. The results of the derivation thus fail to be consistent with its assumptions, and Tegmark's formulation of the decoherence time must be rejected as inappropriate to the superposition under consideration. Without this crucial assumption validated, Tegmark's calculation fails to achieve self-consistency in the approximation regime considered, and must be rejected as inappropriate to the superpositions of interest in the orch. OR theory.

Two possible avenues might be envisioned in the framework of the orch. OR theory by which to overcome the influence of decoherence due to scattering and tidal effects, such that decoherence by quantum gravitational effects might play a role. The most obvious solution is to require that the shortest decoherence times be those due to quantum gravity. An equally viable approach, however, is to require that decoherence due to other mechanisms be effectively countered by dynamical processes operating on time scales more rapid than that of the relevant form of decoherence. This is the means by which quantum systems, such as lasers, maintain quantum coherence against thermal disruption at room temperature. The lasing phenomenon is about a supply of energy that is transformed from incoherent to coherent form, with an attendant reduction in entropy and increase in order. The introduction of nonequilibrium conditions impacts decisively on the conclusions that one might derive from calculations of the decoherence rate, which assume that equilibrium conditions hold sway. The significance of nonequilibrium situations in addressing phenomena in living media—decidedly not in equilibrium—cannot be overstated. Whereas the dynamical time scale for lasers is determined by the rate at which the system is pumped by an incoherent source of energy, appropriate dynamical time scales in the microtubule case might be determined by the characteristic rates at which incoherent metabolic energy is provided to processes that might counteract decoherence by scattering, such as actin gelation in sol-gel cycles and the ordering of water, both discussed below. Relevant rates could include that of GTP hydrolysis (known to control the stability of microtubules [49,50]), dephosphorylation of microtubule-associated proteins, and ATP hydrolysis (required for actin polymerization).

The transition between the alternating phases of solution and gelation in cytoplasm depends on the polymerization of actin (see Fig. 4), and the particular character of the actin gel in turn depends on actin cross linking. Of the various cross-linker related types of gels, some are viscoelastic, but others (e.g., those induced by the actin cross-linker avidin) can be

[4]Though Ω_{dipole} increases without bound as the three vectors, $\hat{\mathbf{a}}$, $\hat{\mathbf{p}}$, and $\hat{\mathbf{s}}$, approach mutual orthogonality, randomly oriented vectors rarely come close enough to satisfying this condition to make an order of magnitude difference in the decoherence time.

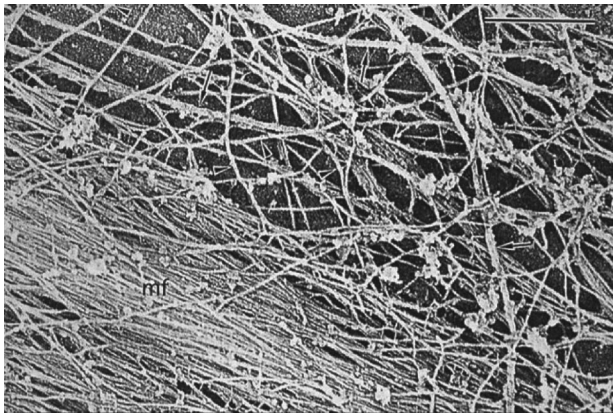

FIG. 4. Immunoelectron micrograph of cytoplasm showing microtubules (arrows), intermediate filaments (arrowheads), and actin microfilaments (mf). A dense actin gel (lower left) completely obscures the microtubules below. Scale bar at upper right represents 500 nm. With permission from Svitkina *et al.* [80].

deformed by an applied force without response [51]. Cycles of actin gelation can be rapid [52], and in neurons, have been shown to correlate with the release of neurotransmitter vesicles from presynaptic axon terminals [53,54]. In dendritic spines, whose synaptic efficacy mediates learning, rapid actin gelation and motility mediate synaptic function, and are sensitive to anesthetics [55–57].

In the orch. OR model, actin gelation encases microtubules during their quantum computation phase. Afterwards, the gel liquifies to an aqueous form suitable for communication between microtubule states and the external environment. Such alternating phases can explain how input from, and output to, the environment can occur without disturbing quantum isolation.

The water within cells is itself not truly liquid, but has been shown to be, to a large extent, ordered [58]. Most of the ordered water in the cell in fact surrounds the cytoskeleton [59]. Neutron diffraction studies indicate several layers of ordered water on such surfaces, with several additional layers of partially ordered water. Tegmark himself allows that the dynamical process of ordering water in the vicinity of the microtubule[5] could protect the quantum system from short-range sources of decoherence, such as the scattering of nearby molecules.

In fact, there is a long history to the hypothesis that macroscopic quantum coherence might be supported biologically by maintaining a supply of energy at a rate exceeding a threshold value [60–62]. The collective effects responsible for the ordering of water arise in the context of a supply of metabolic energy [58]. Empirical evidence indicates that, in the presence of an activation energy approximating the amount required for the formation of a soliton on the microtubule ($\approx$0.3 eV), the surrounding water can be easily brought to an electret state [63,64]. Spontaneous breaking of the dipole rotational symmetry in the interaction of the electric dipole moment of water molecules with the quantized electromagnetic field would then give rise to the dipolar wave quanta that are postulated to mediate collective effects [65–67].

In the gel phase, the water-ordering surfaces of a microtubule are within a few nanometers of actin surfaces that also order water. Thus bundles of microtubules encased in actin gel may be effectively isolated with the decoherence-free zone *a* extending over the radius of the bundle, of the order of hundreds of nanometers. If the *a* dependence of the decoherence time is accurately reflected in the previously corrected version (4) of Tegmark's equation, an order of magnitude increase in the decoherence-free zone results in an increase of three orders of magnitude in the decoherence time for the microtubule bundle.

Technological quantum computing is, in general, feasible because of the use of quantum error correction codes. It has been suggested that error correction may be facilitated by topologies—for instance, toroidal surfaces [68,69]—in which global, topological degrees of freedom are protected from local errors and decoherence. Topological quantum computation and error correction have been suggested in microtubules.[6]

D. Temperature dependence

An examination of the temperature dependence in the formulation of decoherence time casts further doubt on the validity of the reasoning that led Tegmark to claim an ultrarapid decoherence rate due to long-range forces. If the adoption of Eq. (1), even in the modified form, Eq. (4), were justified, it would require that the decoherence time be a monotonically *increasing* function of temperature; decoherence times would tend to grow as the square root of temperature. The apparent implication is that one should expect to find longer-lived quantum coherent states at higher temperatures, contrary to the intuition from thermodynamics, statistical mechanics, and kinetic theory, that increased thermal agitation should have a disruptive effect on the formation and preservation of quantum coherence (at least in thermal equilibrium, the only paradigm considered in [41]).

It might be objected that this intuition proceeds from a consideration of the increased impact of ionic and radiative

[5]While the point is conceded with respect to the water *inside* the microtubule, Tegmark finds it more contentious as regards the water *outside* the microtubule, which ''fills the entire cell volume.'' Geometric considerations aside, the mechanism of ordering is independent of whether the water is inside or outside the microtubule, and is only contended for the water closely approaching the microtubule.

[6]The microtubule lattice features a series of helical winding patterns that repeat on longitudinal protofilaments at 3,5,8,13,21 and higher numbers of subunit dimers (tubulins). These particular winding patterns (whose repeat intervals match the Fibonacci series) define attachment sites of the microtubule-associated proteins (MAPs), and are found in simulations of self-localized phonon excitations in microtubules [70]. They suggest topological global states in microtubules which may be resistant to local decoherence [71]. Penrose [72] has suggested that the Fibonacci patterns on microtubules may be optimal for error correction.

(see subsequent Sec. II E) scatterers at higher temperatures. Since we are investigating tidal influences of long-range forces, influences that are not amenable to formulation in terms of scattering states, one might choose to disregard such intuitions. Noting that it is only the shortest decoherence time, amongst those calculated for competing decohering processes, that will be observable, it might be argued that a counterintuitive temperature dependence in the decoherence rate due to a particular process would remain invisible if this rate were not the fastest. For instance, if the decoherence rate, R_s due to a species of scatterers beat the decoherence rate R_d, due to the tidal influence of distant ions, we would have no physical indication of the temperature dependence in R_d. While this allows us to preserve our physical intuitions, it defeats the purpose of calculating R_d. In [41], R_d is calculated because it is expected to be the dominant rate given that R_s is suppressed by the ordering of water near microtubules.

Nevertheless, it might be contended that R_d dominates decoherence only within a range of temperatures that does not include very low temperatures—where our experience with quantum coherent states argues against the counterintuitive temperature dependence in Eq. (1)—and also does not include very high temperatures, where thermal considerations must eventually reassert themselves over other effects. This could only be maintained, however, if the temperature dependence in R_d were not monotonic and increasing without bound in the low temperature limit (as is Tegmark's). In that case, R_d would eventually overtake R_s as temperature decreases, with the result that we would not observe the longest-lived quantum superpositions at the lowest temperature. Further, it does not seem possible, in order to escape this conclusion, to claim that the temperature dependence in R_s is also counterintuitive since this is precisely the case in which we must expect the strictures of thermodynamics and statistical mechanics to be binding. It should be noted in this context that even the formulas derived in [41] to account for the effect of scattering determine decoherence times that increase with increasing temperature, rather than decrease.

Tegmark's Eq. (1) suggests that low temperatures, at which decohering environmental interactions presumably have the least impact, are deemed most inhospitable to quantum coherence, contrary to experience. Though the equation is formulated to be valid at room temperature, the stated assumptions appear to remain valid in the low temperature limit. Both object and environment should be well localized in this limit and, unless it is imagined that the dynamical time scale goes to zero in the low temperature limit even more rapidly than the decoherence scale—entailing a dynamical rate that increases without bound as absolute zero is approached—the requirement that the decoherence scale must lie well below the dynamical scale is also met. Accounting for the temperature dependence implicit in a, which must decrease to a minimum in the absence of thermal agitation, only exacerbates the counterintuitive trend.

While the equations derived in [41] in the case of ion-ion and ion-water scattering do not exhibit the expected temperature dependence over the range of temperatures in which they are deemed valid, it may be possible to recover the appropriate dependence in the low temperature limit. The approximation regime valid at room temperature will no longer be appropriate in the low temperature limit since the de Broglie wavelength λ of the scatterer is no longer expected to be much smaller than the superposition separation s of the quantum state. Making the alternate approximation, $s \ll \lambda$, which should be valid at sufficiently low temperatures, the ion-water scattering case recovers the intuitive temperature dependence, but the ion-ion scattering case does not, suggesting that the problems in the derivation lie deeper. Even in the ion-water case, adjusting the approximation regime relieves the counterintuitive temperature dependence only at temperatures near absolute zero. Moreover, in the case of interest here—that of decoherence due to tidal influences of long-range forces—there is no analogous approximation to adjust at low temperatures.

Regardless of any deviations from the predicted trend that might mitigate the failure of the low temperature limit in the neighborhood of absolute zero, the functional dependence of the decoherence time, across the range of temperatures in which the calculation is deemed valid (and in particular at room temperature), runs contrary to the expectation that the onset of decoherence should, in general, be more rapid at higher temperatures.

E. Other mechanisms of decoherence

Since any process that irreversibly conveys a flow of information from the system to the environment acts as a source of decoherence, our remarks concerning the threat of decoherence through the tidal effects of long-range forces, while addressing an important source of decoherence, clearly do not exhaust the potential for disruptive environmental influence. In particular, we would like to have some quantitative estimate of the decoherence time associated with ubiquitous radiative scatterers.

A decoherence formalism for apparent wave function collapse due to scattering has been developed in [73], and is summarily reviewed below. The treatment adopts the assumption that the interaction between the system and scatterer can be treated as approximately instantaneous relative to the dynamical time scales of the Hamiltonian governing the evolution of the system. Note that in this approximation, it is these interaction times (this might be given by the transit time of the scatterer through the system), not decoherence times, that are presumed short in comparison to dynamical times, and hence this is not the same approximation whose validity was questioned in Sec. II C.

The change in the density matrix ρ for the system and scatterer together is given in terms of a transition matrix T by $\rho \rightarrow \rho' = T\rho T^{\dagger}$. If T conserves energy and momentum, then the transition matrix element has the form

$$\langle \mathbf{p}'\mathbf{k}' | T | \mathbf{p}\mathbf{k} \rangle = \delta(\mathbf{p}' + \mathbf{k}' - \mathbf{p} - \mathbf{k}) a_{\mathbf{pk}}(\mathbf{p}' - \mathbf{p}), \qquad (5)$$

where $|\mathbf{pk}\rangle$ denotes the state in which the system has momentum $\mathbf{p}$ and the scatterer has momentum $\mathbf{k}$, and $a_{\mathbf{pk}}(\mathbf{p}' - \mathbf{p})$ is the probability amplitude for a momentum transfer to the system of $\mathbf{p}' - \mathbf{p}$. If the velocity of the incident scatterer is much greater than the spread of velocities in the density

matrix (which will generally be the case for the types of scatterers to be considered subsequently), the probability amplitude can be treated as independent of **p**. With the further assumption that the incident particle is in a momentum eigenstate or an incoherent mixture of momentum eigenstates, it is shown in [73] that the effect of such a scattering event on the density matrix is

$$\rho(\mathbf{x},\mathbf{x}') \rightarrow \rho'(\mathbf{x},\mathbf{x}') = \rho(\mathbf{x},\mathbf{x}')\hat{P}(\mathbf{x}'-\mathbf{x}), \tag{6}$$

where $\hat{P}(\mathbf{x}'-\mathbf{x})$ is the Fourier transform of

$$P(\mathbf{p}'-\mathbf{p}) = \int |a_{\mathbf{k}}(\mathbf{p}'-\mathbf{p})|^2 \mu(\mathbf{k}) d^3k, \tag{7}$$

representing an incoherent superposition of plane waves with momentum probability distribution $\mu(\mathbf{k})$. A generic anisotropic spectrum $\mu(\mathbf{k})$ will result in radiation pressure, itself a potential source of decoherence [74]. Forces due to radiation pressure, however, are in general significantly weaker than those due to scattering and are unlikely to yield a faster rate of decoherence. Consideration is thus limited to an isotropic spectrum,

$$\mu(k) = \lambda_0 \nu(\lambda_0 k)/4\pi k^2, \tag{8}$$

where $k = |\mathbf{k}|$, λ_0 is a characteristic wavelength and ν is a probability distribution over the real line. In particular, we will be interested in the Planck distribution

$$\nu(x) = \frac{1}{2\zeta(3)} \frac{x^2}{e^x - 1} \tag{9}$$

for radiative scatterers in ambient visible light, in the flux of thermal radiation from our surroundings, and in the cosmic microwave background radiation, spectra corresponding to blackbody temperatures of 5800 K, 300 K, and 2.7 K, respectively.

With a flux Φ of scatterers and a total cross section σ the incidence of scattering events is governed by a Poisson distribution with intensity, $\Lambda = \sigma\Phi$. If it were scattering processes alone that evolved the density matrix, it would thus be subject to

$$\dot{\rho}(\mathbf{x},\mathbf{x}',t) = -\Lambda(1-\hat{P}(\mathbf{s}))\rho(\mathbf{x},\mathbf{x}',t), \tag{10}$$

where we have defined $\mathbf{s} = \mathbf{x}' - \mathbf{x}$. If the time scale given by Λ^{-1} is short compared to all the dynamical time scales in the system Hamiltonian, this is approximately the case that prevails. The solution to Eq. (10),

$$\rho(\mathbf{x},\mathbf{x}',t) = \rho(\mathbf{x},\mathbf{x}',t_0) e^{-\Lambda t(1-\hat{P}(\mathbf{s}))}, \tag{11}$$

will then adequately capture the behavior of the density matrix for the short times over which the usual Schrödinger evolution can be neglected.

In the isotropic case, the mean of the distribution, $\hat{P}(\mathbf{s})$, vanishes and the covariance matrix is proportional to the identity matrix, $S_{ij} = v\,\delta_{ij}$ with the constant of proportionality given by the variance v. This allows us to make the following Gaussian approximation in the solution above:

$$\rho(\mathbf{x},\mathbf{x}',t) \approx \rho(\mathbf{x},\mathbf{x}',t_0)\exp[-\Lambda t(1-e^{-s^2/2\lambda_{\text{eff}}^2})], \tag{12}$$

where $s = |\mathbf{s}|$ is the superposition separation of Sec. II A, and $\lambda_{\text{eff}} = 1/\sqrt{v}$ is given by

$$\lambda_{\text{eff}} = \frac{\lambda_0}{\sqrt{-g''(0)\langle x^2\rangle}}. \tag{13}$$

Here, $\langle x^2\rangle = 4!\zeta(5)/2!\zeta(3)$, denotes the expectation value of x^2 over the Planck distribution $\nu(x)$, and the function

$$g(x) = \frac{\sin x}{x} \int_0^{2\pi} \int_{-1}^{1} e^{\imath x u} f(\arccos u, \varphi) du d\varphi \tag{14}$$

results from the Fourier integral in $\hat{P}(\mathbf{s})$ over the momentum probability distribution in Eq. (8), such that

$$\hat{P}(\mathbf{s}) = \int_0^\infty g\left(\frac{ws}{\lambda_0}\right) \nu(w) dw. \tag{15}$$

The differential cross section $f(\theta,\varphi)$ in Eq. (14) has been normalized so as to integrate to 1. In the case of *s*-wave scattering, appropriate for treating opaque systems much larger than the wavelength of the scattering photons, $f(\theta,\varphi) = 1/4\pi$, so $g(x) = \sin^2 x/x^2$ and $g''(0) = -2/3$. According to Eq. (13), one then calculates $\lambda_{\text{eff}} = 0.381\lambda_0$. In the case of photons scattering from dielectric spheres much smaller than the wavelength of the photons, the appropriate normalized differential cross section [75] is $f(\theta,\varphi) = 3(1 + \cos^2\theta)/16\pi$, which determines

$$g(x) = \frac{3\sin x}{2x^3}\left(\cos x + (x^2-1)\frac{\sin x}{x}\right), \tag{16}$$

and $g''(0) = -11/15$. The effective wavelength in this case is then $\lambda_{\text{eff}} = 0.363\lambda_0$.

In the near-diagonal approximation appropriate when $s \ll \lambda_{\text{eff}}$, the solution in Eq. (12) reduces to

$$\rho(\mathbf{x},\mathbf{x}',t) \approx \rho(\mathbf{x},\mathbf{x}',t_0)\exp(-\Lambda s^2 t/2\lambda_{\text{eff}}^2), \tag{17}$$

which identifies the decoherence time as

$$\tau \sim \frac{\lambda_{\text{eff}}^2}{\Lambda s^2}. \tag{18}$$

Table III summarizes estimates, adapted from [73], for Λ, Φ, and λ_{eff} for each of the scattering sources under consideration, and gives values of τ calculated on the basis of Eq. (18). For Λ and τ the results are expressed over a range extending from the case of a single electron in superposition to that of a mote 10 μm in size. The cross section σ for interaction with an electron is estimated at roughly 5×10^{-29} m^2, and for interaction with a 10 μm mote at 5×10^{-10} m^2. Even in the case of a superposed system as

TABLE III. Characteristic values, adapted from [73], for several scattering processes. Decoherence times are quoted in the near-diagonal approximation $\tau=\lambda_{\mathrm{eff}}^2/\Lambda s^2$ appropriate to the superposition separations, s, given in Sec. II A.

		Ambient visible light	300 K photons	Cosmic microwaves
Λ (s^{-1})	Electron	5×10^{-8}	5×10^{-6}	5×10^{-12}
	10 μm mote	5×10^{11}	5×10^{13}	5×10^{7}
Φ (m^{-2} s^{-1})		10^{21}	10^{23}	10^{17}
λ_{eff} (m)		9×10^{-7}	2×10^{-5}	2×10^{-3}
τ (s)	Electron	10^{25}	10^{26}	10^{36}
	10 μm mote	10^{6}	10^{7}	10^{17}

large as 10 μm, decoherence times due to radiative scatterers are substantially longer than those postulated to result from the effects of quantum gravity in the orch. OR theory, a result attributable to the fact that the superposition separation is so small. The decohering effect of radiative scatterers thus does not appear to pose a significant threat to the proposed mechanism.

III. OUTLOOK

Among the many features of brain function not currently understood, subjectivity remains the most problematic, motivating both classical and quantum explanations. Quantum approaches, in particular the orch. OR model in microtubules, are potentially able to account for features like the unified nature of conscious experience and subjectivity [76–78], but are based on speculative quantum level activities and appear on the surface to suffer from a decoherence problem.

The mechanisms of decoherence discussed here, however, fail to rule out biologically instantiated quantum coherence of the sort envisioned in the orch. OR hypothesis, particularly when proposed biological mechanisms of coherent pumping, screening, and quantum error correction are considered. When appropriately revised, both theoretically and numerically, decoherence times due to the tidal influence of Coulomb forces appear to be in line with the relevant dynamical times, in the range 10^{-5}–10^{-4} s, in accord with biological phenomena. These revisions place the microtubule decoherence time in a range invalidating Tegmark's assumption that the decoherence time scale is much shorter than relevant physiological dynamical time scales, and suggest that the approximation scheme used is inappropriate to the superposition under consideration. Further, the temperature dependence of Tegmark's formulation fails to confirm, in the case of both tidal influences of Coulomb forces and decoherence due to scattering, the intuition that increased thermal disruption should have a deleterious effect on the formation and maintenance of quantum coherent states. These intuitions are expected to be particularly robust in thermal equilibrium, which is the context that Tegmark considers. Consideration of other mechanisms of decoherence, such as that due to radiative scattering, indicate that these play no role in the determination of the decoherence rate. Thus the issue of organized quantum processes in the brain remains open, and subject to experimental verification, an indication that there is cause for optimism that some of the enigmatic features of the cognitive processes occurring in consciousness might yet be understood in a quantum theoretical framework.

Abstract— **We study biologically 'orchestrated' coherent quantum processes in collections of protein microtubules of brain neurons, which correlate with, and regulate, neuronal synaptic and membrane activity. In this situation the continuous Schrodinger evolution of each such process terminates in accordance with the specific Diosi–Penrose (DP) scheme of 'objective reduction' ('OR') of the quantum state. This orchestrated OR activity ('Orch OR') is taken to result in moments of conscious awareness and/or choice. We analyze Orch OR in light of advances and developments in quantum physics, computational neuroscience and quantum biology. Much attention is also devoted to the 'beat frequencies' of faster microtubule vibrations as a possible source of the observed electroencephalographic ('EEG') correlates of consciousness.**

Keywords— **quantum information processes, quantum consciousness, protein microtubules of brain neurons.**

I. INTRODUCTION

All living cells of plants, animals and humans continuously emit ultraweak biophotons (ultraweak electromagnetic waves) in the optical range of the spectrum, which is associated with their physiological states and can be measured using special equipment. Neural cells also continuously emit biophotons. The intensity of biophotons is in direct correlation with neural activity, cerebral energy metabolism, EEG activity, cerebral blood flow and oxidative processes [1, 2]. According to Van Wijk et al [3], there are significant correlations between the fluctuations in biophoton emission and fluctuations in the strength of electrical alpha wave production in the brain. Some unpublished observations suggest that the state of the biophoton field of a person may be connected to the state of the brain as measured by the EEG (e.g., degree of synchronization and coherence) [4]. Certain meditative states characterized by a high degree of coherence in the EEG may well be accompanied by a high degree of coherence in the biophoton field [4], although measurements correlating the coherence of the biophoton field and the EEG readings have not been made yet. In this situation it is very important to study the interaction of biomolecules with biophotons of brain neurons and to quantitatively investigate possible connections between the EEG and the biophoton production.

There is no doubt that EEG waves are deeply involved with the basic functioning of the brain. The EEG waves associated with two distant neurons are strongly correlated and this supports the view that EEG waves are related to the properties of the brain as a coherent quantum system.

In modern optogenetics much attention is devoted to the possibility to manipulate neurons with light [5-7]. In this situation spatially-precise neuronal control and monitor the activities of individual brain neurons are realized with the help of optogenetic actuators (channelrhodopsin, halorhodopsin, archaerhodopsin) and temporally-precise recordings can be made with the help of optogenetic sensors for calcium (Aequorin, Cameleon, GCaMP), chloride (Clomeleon) or membrane voltage (Mermaid).

DOI: 10.1007/978-981-287-736-9_60

At present much attention is devoted to the nature of consciousness and mechanism by which it occurs in the brain [8]. In this situation consciousness depends on biologically 'orchestrated' coherent quantum processes in collections of microtubules within brain neurons [9]. It is very important to unify micro and macro levels: quantum-statistical properties of quantized fields insight MTs and EEG signals [10], because superradiant optical computing in networks of microtubules may provide a basis for biomolecular cognition and a substrate for consciousness [11], fMRI and SPECT (single-photon emission computed tomography) are also very important tools for investigation of cooperative processes in protein microtubules of brain neurons. There has been a strong recent interest in applying quantum theory in cognitive science [12]. It should be noted that special evaluation of altered states of consciousness (ASC), induction of ASC by different physical methods: electrical stimulation (direct and alternating current), magnetic stimulation, sound (binaural) stimulation compared with placebo in healthy volunteers will give more insight about nature of consciousness from quantum biophysical point of view [13-15].

II. Fluctuation Function of Protein Microtubules

At present much attention is paid to the coupling between fluctuation function $S_z(t)$ of protein MTs and EEG signal, influence of coherence in biophoton field (Fig. 1) on coherence in neuronal system and correlations between the fluctuations in biophoton emission and fluctuations in the strength of electrical alpha wave production in the brain [10]

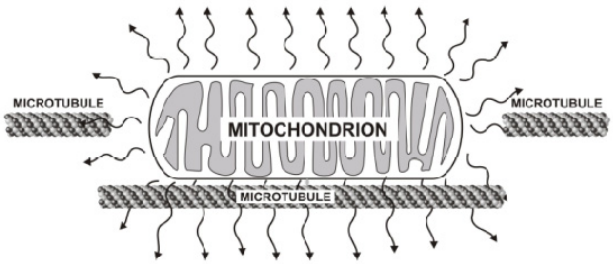

Fig. 1 Representation of biophotons produced by mitochondria and the interaction of biophotons with microtubules

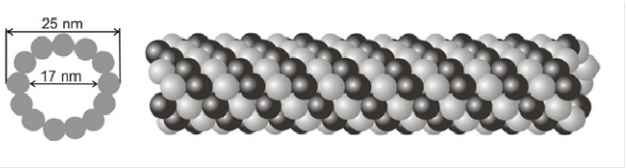

Fig. 2 MTs are hollow cylinders composed of protein units called tubulin. The inner diameter of an MT is 17 nm and the outer diameter is 25 nm. The lengths of MTs vary widely from nanometers to micrometers. MTs have been considered to act as QED-cavities [16, 17]

It should be emphasized that MTs have been considered as optical cavities (Fig. 2) [16] with quantum properties [17], capable of supporting only a single mode [18] or perhaps a few widely spaced (in the frequency domain) modes. Rahnama et al [10] is successfully applied a fully quantum mechanical formalism of the Jaynes-Cummings model (JCM) [19-21]. It is noticed that MTs are biological hollow cylinders with a 17 nm inner diameter and a 25 nm outer diameter (Fig. 2) [22], composed of units called tubulin dimers, each of which has the dimensions $4\text{nm}\times 8\text{nm}\times 6\text{nm}$ [16]. Tubulin can be viewed as a typical two-state quantum mechanical system, where the dimers couple to conformational changes with 10^{-9} - 10^{-11} sec transitions due to electron transitions in hydrophobic pockets, corresponding to an angular frequency in the range $\omega_0 \sim O(10^{10}) - O(10^{12}) Hz$ [16]. Using a first-order-approximation estimate of the quality factor for the MT cavities (i.e. Q_{MT}), it has been found that $Q_{MT} \sim O(10^8)$ [16]. High-quality cavities encountered in Rydberg atom experiments dissipate energy on time scales of $O(10^{-3}) - O(10^{-4})$ sec and have Q's which are comparable to Q_{MT} [16]. Frequencies of visible light are on the order of THz and Wang et al [23] have detected visible light in the brain as biophotons. Also, transition frequencies in tubulins are on the order of THz [16]. In order to get more physical insight about Quantum Brain Dynamics it is necessary to

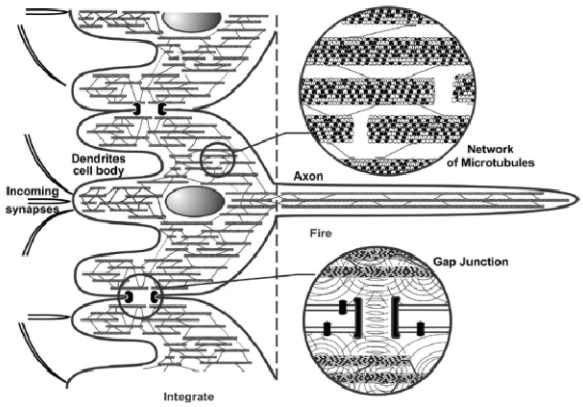

Fig. 3 An 'integrate-and-fire' brain neuron, and portions of other such neurons are shown schematically with internal microtubules. In dendrites and cell body/soma (left) involved in integration, microtubules are interrupted and of mixed polarity, interconnected by microtubule-associated proteins (MAPs) in recursive networks (upper circle, right). Dendritic–somatic integration (with contribution from microtubule processes) can trigger axonal firings to the next synapse. Microtubules in axons are unipolar and continuous. Gap junctions synchronize dendritic membranes, and may enable entanglement and collective integration among microtubules in adjacent neurons (lower circle right). In Orch OR, microtubule quantum computations occur during dendritic/somatic integration, and the selected results regulate axonal firings which control behavior.

carefully examine properties of a single protein microtubule [24] from quantum-mechanical point of view. This will give new possibilities for realization and manipulation of quantum information processes with the help of entanglement and non-local canals in the ensemble of microtubules of brain neurons (Fig. 3).

Let us investigate quantum brain dynamics and analyze fluctuation function of MTs in the case, in which MT has three energy states: ground state $|g\rangle$, first excited $|e_1\rangle$ and second excited $|e_2\rangle$ biomolecular states. In this situation it is assumed that at the initial moment t = 0 MT is situated in the first excited state $|e_1\rangle$ and quantized electromagnetic field in Holstein–Primakoff SU(1,1) coherent state [19, 20]

$$|\psi(0)\rangle_{biophotons} = (1-|\xi|^2)^k \sum_{m=0}^{\infty} \left\{ \frac{\Gamma(m+2k)}{m!\Gamma(2k)} \right\}^{1/2} \xi^m |m,k\rangle \tag{1}$$

where $|m,k\rangle$ are the eigenvectors of the Casimir operator

$$C = K_0^2 - \frac{K_+K_- + K_-K_+}{2} = k(k-1)I \tag{2}$$

k is the so-called Bargmann index and $\xi = |\xi| \exp(i\varphi)$ $(0 \le |\xi| \le 1)$. In the present model k=½ and SU(1,1) CS can be written through oscillator number states

$$|\psi(0)\rangle_{biophotons} = (1-|\xi|^2)^{1/2} \sum_{n=0}^{\infty} \xi^n |n\rangle = \sum_{n=0}^{\infty} Q_n |n\rangle \tag{3}$$

In this case the initial state – vector of the coupled MT - field system takes the following form

$$|\psi(t=0)\rangle = |\xi\rangle \otimes |e_1\rangle = \sum_{n=0}^{\infty} Q_n |e_1, n\rangle \tag{4}$$

Exact analytical solution for state-vector of the MT - field system can be obtained by using Schrodinger equation:

$$\begin{aligned} |\psi(t)\rangle = & \sum_{n=0}^{\infty} e^{-i\omega_0\{S_z+n\}t} Q_n \{\cos(\sqrt{n^2+\alpha^2(n+1)^2}\,\tau)|e_1,n\rangle \\ & - \frac{i\alpha(n+1)}{\sqrt{n^2+\alpha^2(n+1)^2}} \sin(\sqrt{n^2+\alpha^2(n+1)^2}\,\tau)|g,n+1\rangle \\ & - \frac{in}{\sqrt{n^2+\alpha^2(n+1)^2}} \sin(\sqrt{n^2+\alpha^2(n+1)^2}\,\tau)|e_2,n-1\rangle\} \end{aligned} \tag{5}$$

where dimensionless time is $\tau = \lambda_1 t$, $\alpha = \lambda_2 / \lambda_1$, λ_1 and λ_2 are MT - field coupling constants [10].

By using solution (5) one can obtain exact analytical solution for fluctuation function $S_z(t)$ in the following manner

$$\begin{aligned} S_z(t) = & -\left(1-|\xi|^2\right) \sum_{n=0}^{\infty} \left(|\xi|^2\right)^n \\ & \times \sin^2(\sqrt{n^2+\alpha^2(n+1)^2}\,\tau) \frac{n^2-\alpha^2(n+1)^2}{n^2+\alpha^2(n+1)^2} \end{aligned} \tag{6}$$

In figure 4 we show $S_z(t)$ as a function of time for cases $|\xi|$=0.6 and 0.9, α = 0.1 and 0.01. In this situation it is observed that the higher the initial mean biophoton number n(t = 0)=$|\xi|^2/(1-|\xi|^2)$, the higher $S_z(t)$. There are also some jumps in the fluctuation function, in which a strong energy exchange between the MTs and field subsystems takes place.

It should be noted that present JCM with intensity-dependent coupling [19, 20] in the best way describes quantum vibrations of MTs of brain neurons and gives more insight about faster microtubule vibrations as a possible source of the observed EEG correlates of consciousness from quantum biophysical point of view.

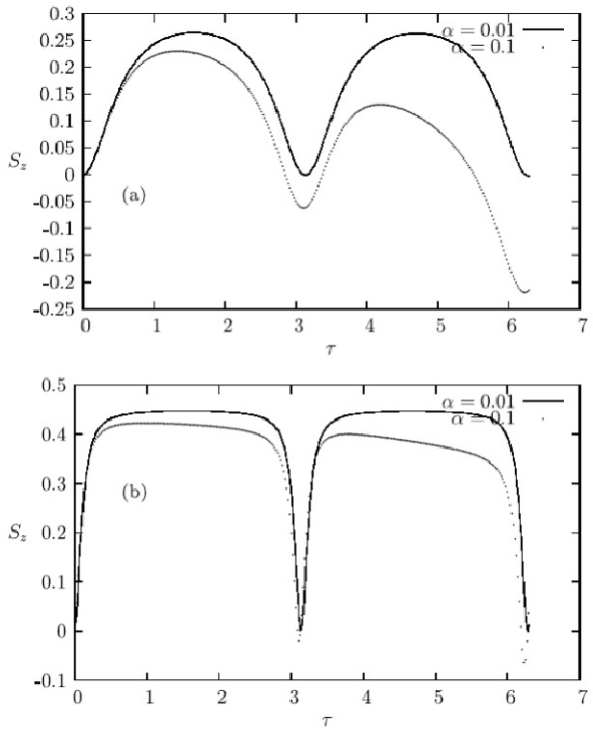

Fig. 4 Sz(t) as a function of the dimensionless time τ for cases α = 0.1 and 0.01: (a) |ξ|=0.6, (b) |ξ|=0.9.

III. Quantum Entanglement and Non-local Models of Quantum Information Processes in Microtubules of Brain Neurons

Quantum entanglement is, according to Erwin Schrodinger in 1935, the essence of quantum physics and inspires fundamental questions about the principles of nature. By testing the entanglement of particles we are able to ask fundamental questions about realism and locality in nature. Local realism imposes certain constraints in statistical correlations of measurements on multi-particle systems. Quantum mechanics, however, predicts that entangled systems have much stronger than classical correlations that are independent of the distance between the particles and are not explicable with classical physics.

In non-local models of quantum mechanics quantum system behaves as a whole no matter how far separated its components. In other words, correlations between electrons or photons, composing the whole quantum system exist at distances much larger than the dimensions of composed parts. It should be noted that experimental demonstration of quantum correlations over more than 10 km was realized by Tittel et al [25]. Moreover, quantum entanglement distribution over 100-kilometre free-space channels is successfully demonstrated by Yin et al [26]. It should be emphasized that quantum entanglement takes place also in living species, in which biophotons are generated by mitochondria [10]. In this situation each living cell is giving off, or resonating, a biophoton field of coherent energy. If each cell is emitting this field, then the whole living system is, in effect, a resonating field-a ubiquitous nonlocal field. And since biophotons are the entities through which the living system communicates, there is near-instantaneous intercommunication throughout, which is the basis for coherent biological organization - referred to as quantum coherence. In this case much attention is devoted to the timeless approaches and quantum vacuum [27, 28]. Capacity for evolution rests not on aggressive struggle and rivalry but on the capacity for communication and cooperation. In this sense the built-in capacity for species evolution is not based on the individual but rather living systems that are interlinked within a coherent whole: Living systems are thus neither the subjects alone, nor objects isolated, but both subjects and objects in a mutually communicating universe of meaning. Experiments with non-local signal transfer between seeds, plant organisms and bio-hybrid systems confirm this point [29-32]. Just as the cells in an organism take on different tasks for the whole, different populations enfold information not only for themselves, but for all other organisms, expanding the consciousness of the whole, while at the same time becoming more and more aware of this collective consciousness.

Because protein microtubules of brain neurons are quantum optical devices [9-11], [16, 17] it is instructive to study the generation of squeezing and entanglement in microtubules to obtain more insight about nature of consciousness from quantum biophysical point of view. In this situation non-local correlations takes place between different microtubules of brain neurons and therefore quantum information in the brain may be transmitted through non-local canals (https://www.youtube.com/watch?v=0fu_k8_tae0).

IV. Conclusions

In the present paper the possibility of quantum information processes in MTs of brain neurons is investigated. Much attention is devoted to the quantum-statistical properties of protein microtubules. It is shown that fluctuation function of MTs $S_z(t)$ has the tendency towards oscillations but exact periodicity of $S_z(t)$ oscillations is violated. It should be noted that exact periodicity of $S_z(t)$ oscillations takes place when one of the dipole moment matrix transition elements between neighbouring biomolecular levels tends to zero. In this situation fluctuation function determines number of generated biophotons in protein microtubules and is connected with oscillations of EEG signal. Moreover, entanglement and non-local correlations exist between biophotons and tubulin structures of different MTs of brain neurons, situated at distances much larger than their own dimensions.

Conflict of Interest

The authors declare that they have no conflict of interest.

Abstract

'Laser-like,' long-range coherent quantum phenomena may occur biologically within cytoskeletal microtubules. This paper presents a theoretical prediction of the occurrence in biological media of the phenomena which we term 'superradiance' and 'self-induced transparency'. Interactions between the electric dipole field of water molecules confined within the hollow core of microtubules and the quantized electromagnetic radiation field are considered, and microtubules are theorized to play the roles of non-linear coherent optical devices. Superradiance is a specific quantum mechanical ordering phenomenon with characteristic times much shorter than those of thermal interaction. Consequently, optical signalling (and computation) in microtubules would be free from both thermal noise and loss. Superradiant optical computing in networks of microtubules and other cytoskeletal structures may provide a basis for biomolecular cognition and a substrate for consciousness.

1. Introduction

Several features of brain activity have prompted connections to quantum physics. One feature is that the physical correlates of consciousness, presumably patterns composed of many states of many entities, are distributed throughout the brain. Despite this extension in space, consciousness has a 'unity' that is difficult to explain by classical means (Marshall, 1989). Non-local quantum coherence may provide the unity necessary to break the impasse known as the 'binding problem' in neurophysiological terms (Crick and Koch, 1990; Singer, 1993).

look for the binding problem in neuroscience

Another feature, as argued by Penrose (1989), is that many brain functions are non-algorithmic and non-computational, and thus inexplicable by serial and/or parallel neural processing. Quantum coherence (in microtubules specifically, according to Penrose (1994)) can account for these functions. Other links between consciousness and quantum theory include probabilistic synaptic functions (Eccles, 1986; Beck and Eccles, 1992), holography (Pribram, 1966, 1971, 1991; Gabor, 1968), and general application of the uncertainty principle (Bohm, 1951; Bohr, 1958).

In the mid 1960s the advent of optical holography heralded a new departure in understanding the relationship between brain, memory and perception. The resistance of aspects of memory and of perception to relatively extensive brain damage indicated that memory storage and perceptual processing are distributed procedures. Before the engineering instantiations of Gabor's holographic equations were available, it was difficult to imagine what such a distributed procedure would be like.

Over the next decades computer programs inspired by holography were developed that reflected some of the associative characteristics of the parallel distributed processes that constitute the essence of holographic optical procedures. These 'connectionist', 'neural network' procedures made it possible to stimulate in vitro many perceptual and memory processes and to explore the extent and limitations of the simulations.

Meanwhile, it was recognised that an unmodified holographic metaphor was an inappropriate model for brain processing because its spread function is unlimited (infinite). Data from neurophysiological experiments showed that the cortical function modelled by holography is better represented by a sinusoid limited by a Gaussian envelope — a mathematical formulation put forward by Gabor (1946) to measure the maximum efficiency with which a telephone message could be sent across the Atlantic cable. Gabor (1948, 1968) used the same equations used by Heisenberg to describe units in microphysics and, therefore, called the unit of communication a 'quantum of information'.

A major interest confronting brain science is, therefore, to probe the possible mechanisms that lead to the processing of quanta of information by the brain.

A specific quantum field theoretical approach was originated by Ricciardi and Umezawa (1967). Without reference to the structural constituents of brain cells, they formulated a relationship between quantum physics and memory. They emphasized that each neuron specifies a spatially distributed system with quantum mechanical degrees of freedom whose physical properties can be understood by quantum field theory. Quantum field theory is a framework of quantum physics capable of describing fundamental processes of elementary particle physics as well as condensed matter physics (Umezawa, 1993). Ricciardi and Umezawa (1967) suggested that memory is a quantum vacuum state that violates an original dynamical symmetry property of the full complement of the spatially-distributed quantum mechanical degrees of freedom in each brain cell.

The introduction of quantum theory in brain science is perhaps analogous to the recent advent of the new field, quantum cosmology. The fundamental equations of cosmology, recast as quantum theoretical operator expressions acting on a 'wavefunction of the universe' permit an interpretation in which the universe is born in imaginary time. A quantum tunnelling process would then allow the universe to evolve into real time, according to a proposal by Hawking. Similarly, the model advanced by Ricciardi and Umezawa (1967) relies on the quantum theoretical concept of a vacuum state which violates a dynamical symmetry property. While the marriage of quantum theory and cosmology is uneasy so long as quantum theory remains uninterpretable outside the context of a classical environment, the union of brain science with quantum concepts is consistent with currently accepted interpretations. Memory of an external stimulus is imprinted as an ordering of the vacuum state (i.e. the lowest energy state or the ground state). If this ordered vacuum state no longer manifests the original dynamical symmetry property, the Nambu–Goldstone theorem suggests creation of long-range correlation

waves with zero energy requirement which participate in the system's quantum dynamics (Ricciardi and Umezawa, 1967).

Such a long-range correlation wave can be seen as a Bose quantum ('Goldstone boson' or 'massless boson'). Ricciardi and Umezawa were perhaps the first to suggest the existence of a spatially distributed system with the full range of quantum mechanical degrees of freedom in brain cells, and also introduced quantum ordering and spontaneous symmetry breaking as tools to investigate the biological system. Slightly later, Fröhlich (1968) proposed a similar idea for biological cells in general but with more explicit materialistic formulation. Focusing on a thin layer just beneath the cell membrane, Fröhlich theorized that energy can be stored without thermal loss in this two-dimensional region in coherent, dipolar propagating waves. Biological molecules with dipolar vibrational activity adjacent to cell membranes may thus manifest a globally coherent mode of dynamics so that the thin layer could be seen as a biological superconducting medium or a biological plasma effectively isolated from thermal environments. Fröhlich waves are predicted to appear in a frequency region between 10^{11} and 10^{12} s^{-1} called the Fröhlich frequency. It can be concluded that energy supplied to biological cells with magnitude equal to the 'Fröhlich frequency' times the Planck constant may not be completely thermalized but stored in a highly ordered fashion.

Experimental evidence for Fröhlich excitations in biological systems include observation of GHz-range phonons in proteins (Genberg et al., 1991), sharp-resonant non-thermal effects of microwave irradiation on living cells (Grundler and Keilmann, 1983), GHz-induced activation of microtubule pinocytosis in rat brain (Neubauer et al., 1990), and resonance Raman detection of Fröhlich frequency energy (Genzel et al., 1976; Webb et al., 1977; Webb and Stoneham, 1977; Webb, 1980).

Fröhlich waves need not be restricted to thin layers adjacent to cell membranes. Dipolar oscillations maintained by hydrogen bonds and non-localized electrons trapped in hydrophobic regions of protein molecules may manifest a collective mode considered as a Fröhlich wave propagating in a one-dimensional medium. Davydov described dipolar solitary waves propagating along alpha-helices within proteins. This mode of solitary wave propagation, known in quantum field theory to carry energy and information without loss due to thermalization, is called the Davydov soliton or dipolar soliton (Davydov, 1979).

About 10 years after the original idea of 1967, Umezawa together with two colleagues, Takahashi and Stuart, proposed a refined physical model of a spatially-distributed system with fully quantum mechanical degrees of freedom, not only within each brain cell but also among brain cells (Stuart et al., 1978, 1979). The system extended among brain cells is thought to be composed of two kinds of spatially distributed degrees of freedom subject to quantum dynamics. As a consequence of spontaneous symmetry breaking, these two modes are distinguished as the 'corticon' field and an exchange boson field which interact as a quantum dynamical system — a theoretical model of non-local memory storage and recall processes. More recently, Jibu and Yasue presented a physically realistic picture of the system of corticon and exchange boson fields, and proposed to call the new quantum field theoretical framework 'Quantum Brain Dynamics' ('QBD') (Jibu and Yasue, 1992a,b, 1993a,b). They describe corticon and exchange boson fields as dipolar vibrational fields distributed along protein filaments of the cytoskeleton and extracellular matrices and associated water fields. Marshall (1989) proposed that Fröhlich's 'pumped phonons' result in a Bose–Einstein condensate in brain which is the substrate for consciousness.

Inspired by application of quantum theoretical methods to brain and other biological cells initiated by Ricciardi and Umezawa and by Fröhlich in the 1960s, other scientists began to view brain functioning from the microscopic view of quantum physics during the 1980s. Several groups focused especially on networks of filamentous proteins which dynamically organize the interiors of living cells: the cytoskeleton (Hameroff and Watt, 1982; Del Giudice et al., 1983). Among cytoskeletal filamentous polymers (actin, interme-

Such a condition may be present in the isolated cores of microtubules surrounded by ordered water molecules

diate filaments, etc.), microtubules are the most central to cellular organization and information processing. Consisting of skewed hexagonal lattices of subunit protein dimers called tubulin, microtubules self-assemble into hollow cylinders 25 nm across, adapt, transport and govern cellular activities. Their hollow geometry and periodic lattice structure have suggested several quantum field aspects. Hameroff (1987) applied Fröhlich's coherent excitations to tubulin subunits in microtubules as the basis of computational cellular automata. Rasmussen et al. (1990) showed that networks of such microtubule automata are capable of learning. Considering the layer of ordered water outside and inside microtubules, Del Giudice et al. (1986) proposed that the formation of microtubules' cylindrical structure from 'tubulin' subunits may be understood by the concept of self-focussing of electromagnetic energy by ordered water. Like the Meissner effect for superconducting media, electromagnetic energy would be confined inside filamentous regions around which the tubulin subunits gather. Del Giudice et al. (1986) showed that this self-focussing should result in filamentous beams of radius 15 nm, precisely the inner diameter of microtubules (see Figs 1–4).

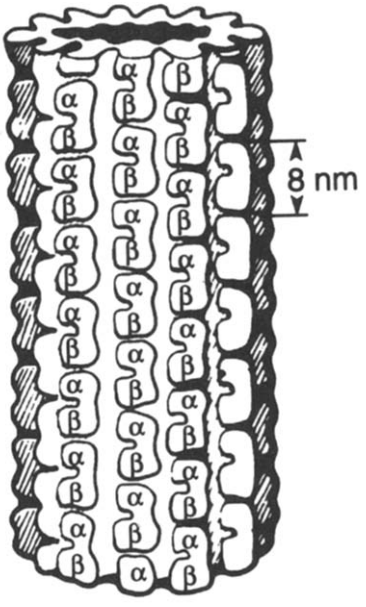

Fig. 2. Microtubule (MT) structure from X-ray crystallography (Amos and Klug, 1974). Tubulin subunits are 8-nm dimers comprised of α and β monomers.

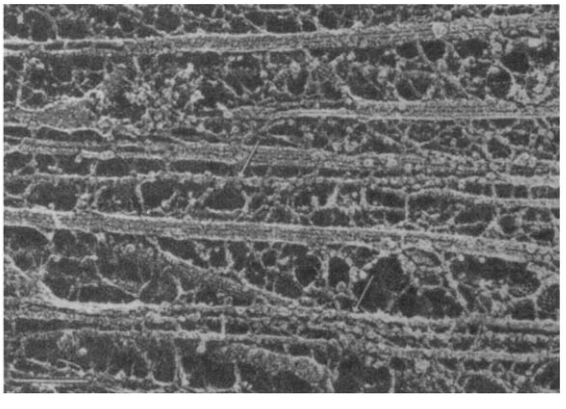

Fig. 1. Electron micrograph of quick frozen, deep, etched neuronal microtubules (MTs) and neurofilaments polymerized with microtubule associated proteins (MAPs). Arrows point at neurofilaments; larger diameter structures are microtubules. Scale bar, 100 nm. (With permission from Hirokawa, 1991).

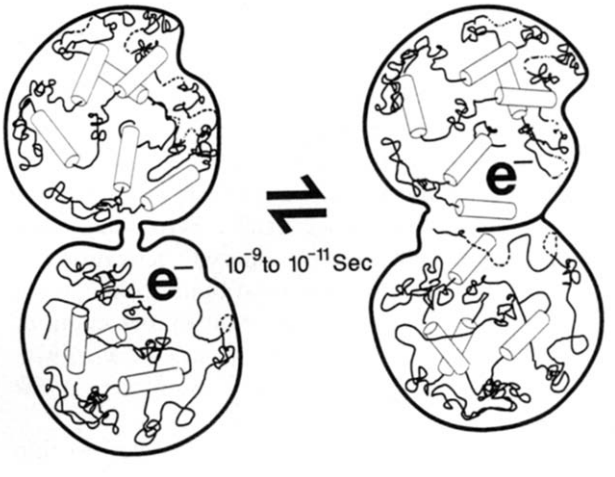

Fig. 3. The tubulin dimer protein has two states in which a quantum event (electron mobility, quasi-particle phonon) within a hydrophobic region couples to conformational change with 10^{-9}–10^{-11}-s transitions. Cylinders within protein are α-helical regions. (Original drawing by Djuro Koruga).

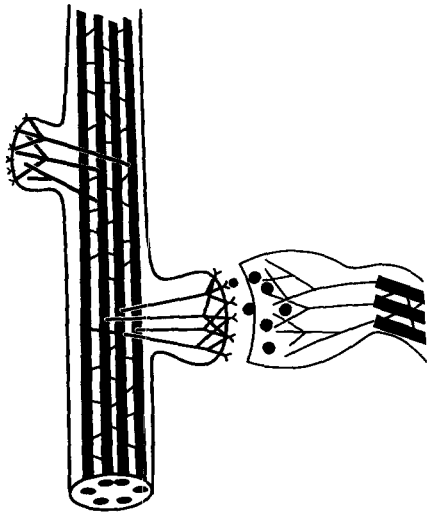

Fig. 4. Schematic drawing of a synapse showing underlying cytoskeletal structures. Right: axon terminal with MT-MAP network connecting with synapsin filaments involved in release of neurotransmitter vesicles (circles) into synaptic cleft. Left: ventrical dendrite with MT-MAP network, two dendritic spines with cytoskeletal structures connected to receptors in synaptic membrane. (Adapted from Hirokawa, 1991).

A waveguide is a structure that guides waves, such as electromagnetic waves or sound, with minimal loss of energy by restricting expansion to one dimension or two.

Another perspective was proposed by Hameroff (1974) in which microtubules were thought to act like 'dielectric waveguides' for photons, that is, quantum dynamical modes of an electromagnetic wave. Indeed, living tissue transmits light more readily than non-living material; in experiments with mammalian brains, temporal poles and hippocampus manifest the maximum light penetration (Hameroff, 1987). This evidence led Hameroff to consider microtubules as waveguides for photons. Furthermore, he proposed that cytoplasmic interference of coherent sources from and among multiple microtubules may lead to a holographic information processing mechanisms. Holographic patterns stored in cytoplasmic sol-gel states may become 'hardwired' by calcium-induced assembly of finer components of the cytoskeleton such as actin, actin-binding proteins and the micro-trabecular lattice. Lechleiter et al. (1991) imaged coherent cytoplasmic spiral waves of calcium induced by acetylcholine binding to membrane receptors of living cells. Coherent sources of either charge carriers or conformational waves in microtubules suggest a revival of holographic brain theory of Pribram and others (Pribram, 1966, 1971, 1991; Gabor, 1968; Margenau, 1984; Eccles, 1986; Marshal, 1989). Our current view is that coherence manifests at the molecular, quantum level rather than (or in addition to) coherence at the level of neural firing (Singer, 1993).

Hameroff suggested in very general terms two key concepts in understanding cytoskeletal brain activity from the point of view of quantum physics: microtubules acting as waveguides for photons and as holographic information processors. Holography is an optical phenomenon related to interference of coherent electromagnetic waves or photons. The microtubule may be seen as a waveguide for photons, and Fröhlich's theory suggests coherent excitations in microtubules. Further, the periodic lattice structure of microtubules may provide periodically arrayed 'slits' (spaces between dimers) through which photons may pass. No proof of coherent photon generation or emission necessary for optical holography has been found in microtubules or any microscopic biological structure. However, self-focused photons and self-trapped, non-thermalizing wave entities should be difficult to detect (see Section 4). In any case, no thorough theoretical investigation of these concepts has occurred from the standpoint of physics except the water laser (Del Giudice et al., 1988).

In the present paper, we propose a new quantum theoretical framework suggesting microtubules possess ordered and systematic properties yielding cooperative quantum dynamics called superradiance and self-induced transparency. Specifically, the quantum dynamical system of water molecules and the quantized electromagnetic field confined inside the hollow microtubule core can manifest a specific collective dynamic called superradiance by which the microtubule can transform any incoherent, thermal and disordered molecular, electromagnetic or atomic energy into coherent photons inside the microtubule. Furthermore, it will also be shown that such coherent photons created by superradiance penetrate perfectly along the internal hollow core of the microtubule as if

the optical medium inside it were made 'transparent' by the propagating photons themselves. This is a quantum theoretical phenomenon called self-induced transparency.

Superradiance and self-induced transparency in cytoskeletal microtubules can lead to 'optical' neural holography. Neurons (and other cells) may contain microscopic coherent optical supercomputers with enormous capacity like the fictional but famous HAL 9000 of '2001: A Space Odyssey' with holographic memory manipulation (Clarke, 1968).

This paper is a result of the long-range cooperation among physicists and brain scientists providing several by-products:

1. Superradiance and self-induced transparency of microtubules may be understood to predict theoretically the existence of a peculiar phenomenon: weak coherent photon emission from living matter.
2. Quantum coherence among microtubules spaced hundreds of micrometers apart (which in turn can have quantum coherence with other microtubules hundreds of micrometers away, etc.) can solve the unity and binding problems which plague classical theories of consciousness.
3. A source of coherence at the biomolecular level can lead to quantum interference and holographic information representation at the sub-cellular level.
4. General anesthesia may be explained by blockade of quantum level events which affect collective cooperative macro-level events.

2. Superradiance in microtubules

Let us look at a typical microtubule in the cytoskeletal structure of brain cells or general biological cells. It is a hollow cylinder about 25 nm in diameter whose wall is a polymerized array of protein subunits ('tubulins'). Its length may range from tens of nanometers to micrometers, and possibly further to meters in nerve axons of large animals. For the purpose of simplifying the physical formulation, we consider the microtubule as a hollow cylinder with radius r_{MT} and length l_{MT}. Their real values would be $r_{MT} \approx 12$ and $l_{MT} \approx 10^2$–10^3 in nanometers. We denote the spatial region inside the microtubule cylinder by V and restrict our discussion to quantum mechanical dynamics taking place in this spatial region V.

Let us introduce a Cartesian system of coordinates O_{xyz} with the xy-plane attached parallel to one of the two ends of the microtubule cylinder so that the origin O coincides with the centre of the end cap. The z-axis lies naturally along the longitudinal center axis of the microtubule cylinder. Then, any position in the region V can be labelled by giving its coordinates $\boldsymbol{r} = (x,y,z)$.

The spatial region V inside the microtubule is not empty, but is likely to be filled with water molecules. Of course, there may be other molecules, although their population is relatively small. We consider the ideal case in which the existence of molecules other than those of water can be neglected. However, below we will consider the more realistic case in which we have impurities among water molecules such as anesthetic molecules. It is most likely that the density of water confined inside the microtubule cylinder remains almost constant. Therefore, we may be allowed to fix the total number of water molecules inside the region V, say N.

Let us take a look at a typical water molecule, say the jth water molecule. Here, j running from 1 to N denotes the fictitious number labelling the N water molecules in question. Its position is given by coordinates $\boldsymbol{r}^j = (x^j,y^j,z^j)$. From a physical point of view, a water molecule has a constant electric dipole, and so it can be seen as a quantum mechanical spinning top with an electric dipole moment. The average moment of inertia and electric dipole moment of a water molecule are estimated to be $I = 2m_p d^2$ with $d \approx 0.82$ Å and $\mu = 2e_p P$ with $P \approx 0.2$ Å, respectively. Here, m_p denotes the proton mass and e_p the proton charge.

Due to the electric dipole moment μ, the water molecule interacts strongly with the quantized electromagnetic field in the spatial region V. Although the water molecule has many energy eigenstates as a quantum mechanical spinning top and so it can exchange energy between the quantized electromagnetic field in many different

values, we restrict our discussion to the most likely case in which only the two principal energy eigenstates take part in the energy exchange. This coincides with the conventional two-level approximation in describing the energy exchange between atoms and the quantized electromagnetic field in laser theory.

Then, one sees immediately that the quantum dynamics of the jth water molecule can be well described by a spin variable $s^j = 1/2\sigma$, where $\sigma = (\sigma_x,\sigma_y,\sigma_z)$ and the σ_x are Pauli spin matrices denoting the three components of the angular momentum for spin 1/2. Let ϵ be the energy difference between the two principal energy eigenstates of the water molecule. Its real value is $\epsilon \approx 200$ cm^{-1} (Franks, 1972). Then, the Hamiltonian governing the quantum dynamics of the jth water molecule is given by ϵs^j_z, and so the total Hamiltonian for N water molecules becomes

$$H_{WM} = \epsilon \sum_{j=1}^{N} s_z^j \qquad (1)$$

s = spin
e = energy

So the Hamiltonian for the water molecules becomes sum of the respective energies of the spin of the individual water molecules

Two energy eigenvalues of the former Hamiltonian are $-1/2\epsilon$ and $1/2\epsilon$ reflecting the fact that only the two principal energy eigenstates with energy difference ϵ are taken into account.

Now, let us consider the quantized electromagnetic field in the spatial region V. It is convenient to describe the quantized electromagnetic field in terms of an electric field operator $\boldsymbol{E} = \boldsymbol{E}(\boldsymbol{r},t)$. Let us assume for simplicity that the electric field is linearly polarized, obtaining $\boldsymbol{E} = \boldsymbol{e}E$, where $\boldsymbol{e}$ is a constant vector of unit length pointing in the direction of linear polarization. Then, the quantized electromagnetic field in question comes to be well described by a scalar electric field $E = E(\boldsymbol{r},t)$ governed by the usual Hamiltonian

r = (x,y,z).

$$H_{EM} = \frac{1}{2}\int_V E^2 d^3r \qquad (2)$$

Next, we take the interaction between the quantized electromagnetic field and the totality of water molecules by which they can exchange energy in terms of creation and annihilation of photons. Let us divide the electric field operator into positive and negative frequency parts

$$E = E^+ + E^- \qquad (3)$$

Then, the interaction Hamiltonian of the quantized electromagnetic field and the totality of water molecules becomes

$$H_I = -\mu \sum_{j=1}^{N} \{E^-(\boldsymbol{r}^j,t)s_-^j + s_+^j E^+(\boldsymbol{r}^j,t)\} \qquad (4)$$

where

$$s_\pm^j = s_x^j \pm i s_y^j \qquad (5)$$

The total Hamiltonian governing the quantum dynamics of the electromagnetic field, the dipolar vibrational field of water molecules, and their interaction is given by

$$H = H_{EM} + H_{WM} + H_I. \qquad (6)$$

Since the spatial region V inside the microtubule cylinder may be considered as a cavity for the electromagnetic wave, it is convenient to introduce the normal mode expansion of the electric field operator $E = E^+ + E^-$, obtaining

$$E^\pm(\boldsymbol{r},t) = \sum_{\boldsymbol{k}} E^\pm_{\boldsymbol{k}}(t) e^{\pm i(\boldsymbol{k}\cdot\boldsymbol{r} - \omega_k t)} \qquad (7)$$

Here, ω_k denotes the proper angular frequency of the normal mode with wave vector $\boldsymbol{k}$. We are mainly interested in the ordered collective behavior among the water molecules and the quantized electromagnetic field in the cavity region V. Let us introduce hence collective dynamical variables $S^\pm_{\boldsymbol{k}}(t)$ and S for water molecules by

$$S^\pm_{\boldsymbol{k}}(t) = \sum_{j=1}^{N} s^j_\pm(t) e^{\pm i(\boldsymbol{k}\cdot\boldsymbol{r}^j - \omega_k t)} \qquad (8)$$

and

$$S = \sum_{j=1}^{N} s_z^j \qquad (9)$$

Then, the total Hamiltonian (Eq. 6) becomes

$$H = H_{EM} + \epsilon S - \mu \sum_k (E_k^- S_k^- + S_k^+ E_k^+) \qquad (10)$$

It seems worthwhile to note here that this total Hamiltonian for the system of N water molecules and the quantized electromagnetic field in the region V inside the microtubule cylinder is essentially of the same form as not only Dicke's Hamiltonian for the laser system but also that of Stuart et al. for Quantum Brain Dynamics (Dicke, 1954; Stuart et al., 1979). Therefore, it can be expected that each microtubule in the cytoskeletal structure of brain cells manifests not only the memory printing and recalling mechanism in QBD but also a laser-like coherent optical activity. The former seems not so surprising because Jibu and Yasue (1992a, 1993a,b) developed a physical picture of QBD in terms of water molecules and protein filaments. Hence, we will not discuss this in the present paper. On the other hand, the latter seems highly surprising because it may open a completely new picture of the fundamental process of brain functioning, drastically different from the conventional one. Namely, in addition to the usual pathway conduction of neural impulses in terms of transmembrane ionic diffusions among nerve cells, the brain system may possibly use another but much more microscopic and elaborated fundamental physical process in terms of coherent photon emission and transfer in the microtubule just like the optical computer with lasers, optical fibers and other optical devices. It is this very surprising possibility we are going to discuss throughout the present paper.

However, it is difficult to look for the possibility of realizing laser devices in brain cells even though the microtubule may manifest the same quantum dynamical behavior, in terms of water molecules and the electromagnetic field, as is governed by the Hamiltonian of a typical laser system. This is because we need initially to pump up the majority of water molecules to the higher energy eigenstate by certain incoherent but high intensity light. In actual artificial laser devices, for example, the initial pumping is due to xenon flash lamps. In other words, the laser system cannot emit coherent photons without some pumping mechanism. We can hardly expect the existence of such a pumping light in the brain. We are, therefore, forced to look for another possibility with the total Hamiltonian (Eq. 10) leading to a different mechanism of coherent photon emission without pumping light.

Fortunately, a physical inspection of the form of the total Hamiltonian (Eq. 10) reveals that it manifests a dynamical symmetry property not evident in the ground state and so the resulting quantum dynamics is known to involve certain long-range order creating phenomena due to spontaneous symmetry breaking (Stuart et al., 1979). The spatial dimension of this long-range order, that is, the coherence length l_c can be estimated to be inversely proportional to the energy difference ϵ, obtaining $l_c \approx$ hundreds of micrometers. Among those long-range order creating phenomena we may find a specific one in which the collective dynamics of the majority of water molecules inside the microtubule cylinder V can give rise to cooperative spontaneous emission of photons without any pumping light. Any incoherent and disordered energy distribution among the water molecules due to the macroscopic thermal dynamics of the polymerized array of protein subunits (i.e. tubulins) forming the wall of microtubule cylinder can be gathered collectively into coherent and ordered dynamics ready to emit coherent photons cooperatively. This laser-like process of coherent photon emission without pumping light was first introduced by Dicke (1954) and called superradiance.

Let us investigate the superradiance in the microtubule cylinder V starting from the total Hamiltonian (Eq. 10). We assume for simplicity that only one normal mode with a specific wave vector, say $\boldsymbol{k}_0$, has a proper angular frequency $\omega_{\boldsymbol{k}_0}$ resonating to the energy difference ϵ between the two principal energy eigenstates. Namely we have

$$\epsilon = \hbar \omega_{\boldsymbol{k}_0} \qquad (11)$$

and all the other normal modes are neglected. In the conventional laser theory, this is known as a single mode laser. What we analyse below may hence be considered as a single mode superradiance in the microtubule.

Since we have only one normal mode with wave

vector k_0, we may omit all the wave vector indices of the dynamical variables. Then, the total Hamiltonian (Eq. 10) becomes

$$H = H_{EM} + \epsilon S - \mu(E^- S^- + S^+ E^+). \tag{12}$$

The corresponding Heisenberg equations of motion for the three collective dynamical variables, S and $S^\pm$, for water molecules and the two variables, $E^\pm$, for the quantized electromagnetic field are given by:

$$\frac{dS}{dt} = -i\frac{\mu}{\hbar}(E^- S^- - S^+ E^+) \tag{13}$$

$$\frac{dS^\pm}{dt} = \pm i\frac{2\mu}{\hbar} S E^\mp \pm i\frac{\epsilon}{\hbar} S^\pm \tag{14}$$

and

$$\frac{dE^\pm}{dt} = \pm i\frac{2\pi\epsilon\mu}{\hbar V} S^\mp \tag{15}$$

Because of the short length of the microtubule cylinder — $l_{MT} \approx 10^2$–10^3 nm — the pulse mode propagating along the microtubule cylinder in the direction of the z-axis stays in the cavity region V only for a short transit time $t_{MT} \equiv l_{MT}/c$, where c stands for the speed of light. As this transit time of the pulse mode is much shorter than the characteristic time of thermal interaction due to the disordered environment, the system of water molecules and quantized electromagnetic field in this single mode superradiance is free from thermal loss and can be considered as a closed system well-described by the Heisenberg equations of motion (Eqs. 13–15). Furthermore, the time derivative of the dynamical variables $E^\pm$ of the quantized electromagnetic field can be approximated by $E^\pm/l_{MT}$ in the case of a pulse mode propagating along the longitudinal axis of the microtubule. Eq. 15 then yields

$$E^\pm = \pm i\frac{2\pi\epsilon\mu l_{MT}}{\hbar V} S^\mp \tag{16}$$

This means that a pulse mode of the quantized electromagnetic field in the microtubule cylinder cavity follows the collective dynamics of water molecules inside the microtubule. In other words, once a collective mode with long-range order is created in the dynamics of water molecules due to spontaneous symmetry breaking, coherent emission of pulse modes of the quantized electromagnetic field — that is, photons — follows. This is the mechanism of superradiance.

The last question is whether such a collective mode can be realized in the dynamics of water molecules starting from incoherent and disordered initial conditions. Notice that such an incoherent and disordered initial dynamical configuration of water molecules is due to the interaction between water molecules and thermally disordered states of the conformational dynamics of tubulins. The onset of this collective mode can be seen by rewriting the three Heisenberg equations for the collective variables of water molecules (Eqs. 13 and 14) by substituting Eq. 16. Namely, we have

$$\frac{dS^\pm}{dt} = \beta S S^\pm \pm i\epsilon S^\pm \tag{17}$$

and

$$\frac{dS}{dt} = -\beta S^+ S^- \tag{18}$$

where

$$\beta = \frac{4\pi\epsilon\mu^2 l_{MT}}{\hbar^2 V}.$$

These are coupled non-linear differential equations for non-commuting operators S and $S^\pm$ subject to certain commutation relations, and it is not so easy to find their solutions. However, if we regard these equations as ordinary coupled non-linear differential equations for classical (i.e. commuting) dynamical variables, we can find special solutions with respect to any incoherent and disordered initial conditions. They are known as semi-classical approximations of the quantum

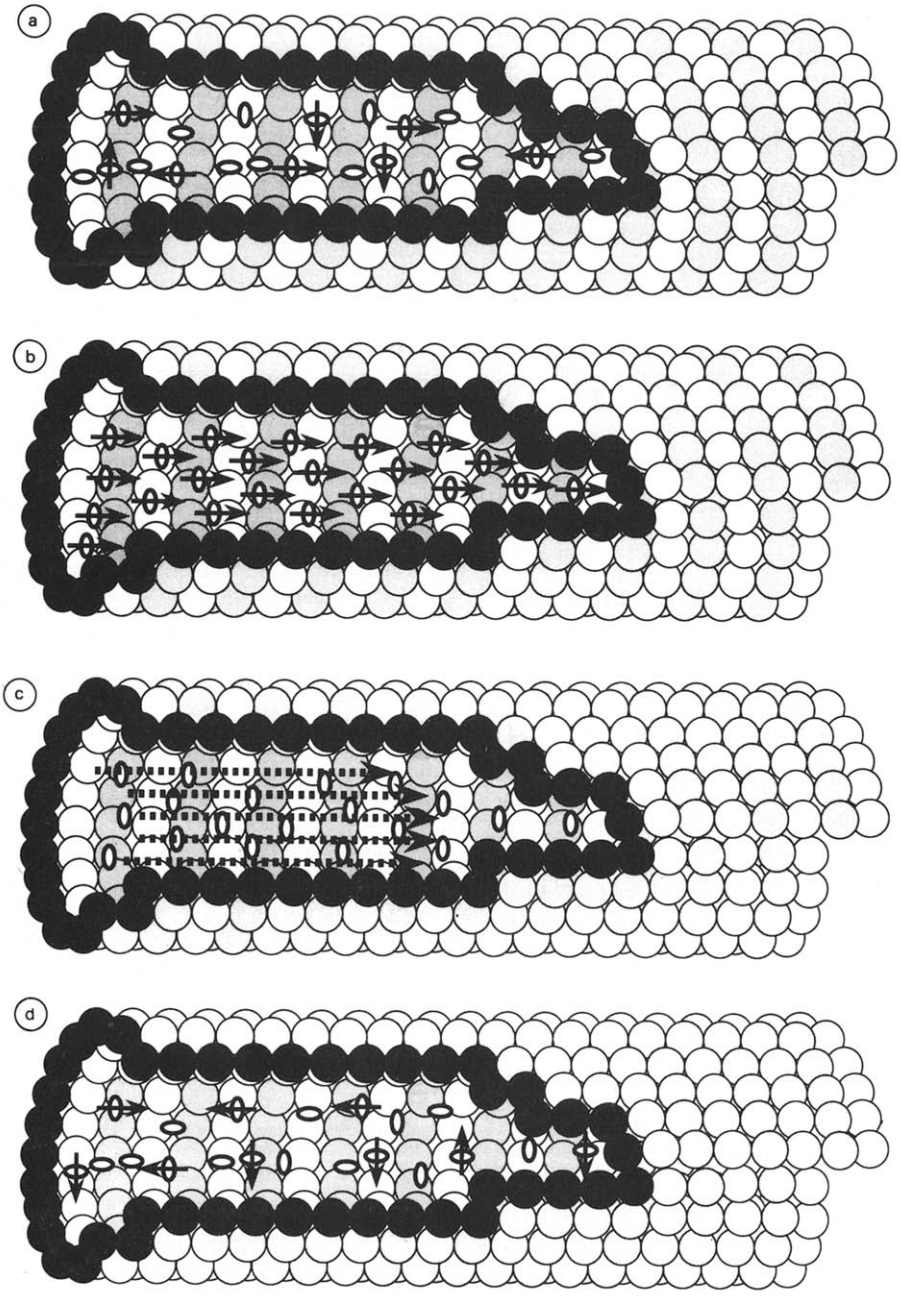

Fig. 5. A schematic representation of the process of superradiance in a microtubule. Each oval without an arrow stands for water molecule in the lowest rotational energy state. Each oval with an arrow stands for a water molecule in the first excited rotational energy state. The process is cyclic (a → b → c → d → a → b), and so on. (a) Initial state of the system of water molecules in a microtubule. Energy gain due to the thermal fluctuation of tubulins increases the number of water molecules in the first excited rotatinal energy state. (b) A collective mode of the system of water molecules in rotationally excited states. A long-range coherence is achieved inside a microtubule by means of spontaneous symmetry breaking. (c) A collective mode of the system of water molecules in rotationally excited states loses its energy collectively, and creates coherent photons in the quantized electromagnetic field inside a microtubule. (d) Water molecules, having lost their first excited rotational energies by superradiance, start again to gain energy from the thermal fluctuation of tubulins, and the system of water molecules recover the initial state (a).

dynamical system of superradiance (Agarwal, 1971). A straightforward calculation yields that the intensity of coherent photon emission in the microtubule cylinder due to superradiance can be given in this approximation by

$$I = \frac{\hbar^2}{(4t_R\mu)^2}\mathrm{sech}^2\frac{t - t_0}{2t_R} \tag{19}$$

where

$$t_R = \frac{c\hbar^2 V}{4\pi\mu^2\epsilon N l_{MT}}$$

and $t_0 = t_R \ln 2N$ denotes the life time and delay of the superradiance, respectively. Notice that the intensity of superradiance is proportional to N^2 and its delay time is inversely proportional to N. These facts are characteristic to the long-range order creating process involving N water molecules (see Fig. 5).

We have found that the quantum collective dynamics of water molecules and a quantized electromagnetic field inside the microtubule cylinder manifests the long-range cooperative phenomenon of superradiance in which collective excitation of water molecules can be induced by incoherent and disordered perturbations due to the macroscopic thermal dynamics of protein molecules forming the wall of the microtubule cylinder. This fact ensures that each microtubule in the cytoskeletal structure of brain cells, that is, neurons and astrocytes, may play an important role in the optical information processing regimen of brain function as a superradiant device which converts the macroscopic disordered dynamics of water molecules and protein molecules into the long-range ordered dynamics of water molecules and a quantized electromagnetic field involving a pulse mode emission of coherent photons. In other words, each microtubule is a coherent optical encoder in a dense microscopic optical computing network in the cytoplasm of each brain cell, if such a network is realized in actual cytoplasmic structure. This last point is far from evident and deserves to be discussed in the following section.

3. Self-induced transparency in microtubules

We have shown the possibility of a completely new mechanism of fundamental brain functioning in terms of coherent photon emission by superradiance in microtubules. Unlike a laser, superradiance is a specific quantum mechanical ordering process with a characteristic time much shorter than that of thermal interaction. Therefore, microtubules may be thought of as ideal optical encoders providing a physical interface between (1) the conventional macroscopic system of classical, disordered and incoherent neural dynamics in terms of transmembrane ionic diffusions as well as thermally perturbed molecular vibrations and (2) the as yet unknown microscopic optical computing network system of ordered and coherent quantum dynamics free from thermal noise and loss. As Feynman (1985) proposed, the optical computing network is the most realizable quantum mechanical computer among many possibilities such as a superconducting computer. However, it is not clear whether the pulse mode coherent photons created in the microtubule cylinder by superradiance can be safely transmitted, preserving its long-range coherence. It seems most likely that even coherent photons emitted by superradiance will lose immediately their coherence and long-range order due to the noisy thermal environment. In any case, we absolutely require some quantum dynamical mechanism to maintain the coherent transmission of photons in the as yet unknown microscopic optical computing network in brain cells. In this section, we will show that it is again the microtubule in the cytoskeletal structure of brain cells which provides us with such a mechanism.

Let us suppose that the pulse mode coherent photons are created in a small segment of the microtubule cylinder by superradiance. Then, those photons propagate along the longitudinal axis of the microtubule cylinder, that is, the z-axis. If the region V inside the microtubule cylinder were maintained at vacuum, they would transmit through the region just as they do along a waveguide. However, the region is filled up with water molecules, and it is not evident at all whether the pulse mode coherent photons can be

safely transmitted through the region without absorption or loss of coherence.

For the purpose of describing the transmission of pulse mode coherent photons along the region inside the microtubule cylinder, it seems convenient to work with a semi-classical approximation in which the long-range ordered dynamics of water molecules is described by quantum mechanics but the electromagnetic field is described classically. This approximation becomes reliable when the intensity of the pulse mode coherent photons is large, and this is indeed the case for superradiance emission (Feynman et al., 1957).

Let us consider the Maxwell equation for the scalar electric field $E = E(z,t)$, standing for the pulse mode coherent photons propagating along the z-axis coupled to the collective dynamical variables $S^{\pm}$ of water molecules inside the microtubule cylinder,

$$\frac{\partial E^{\pm}}{\partial z} + \frac{\partial E^{\pm}}{\partial t} = \mp i \frac{2\pi\epsilon\mu}{\hbar V} S^{\mp} \tag{20}$$

This equation is valid under the condition that the collective dynamical variables $S^{\pm}$ are slowly varying, that is,

$$\frac{\partial S^{\pm}}{\partial t} \ll i\omega S^{\pm} \tag{21}$$

Then, taking the expectation of those quantum mechanical variables in this Maxwell equation and the Heisenberg equations of motion (Eqs. 13 and 14), eliminating all the expectation values of those variables referring to water molecules, and introducing new variables for the scalar electric field by

$$\theta^{\pm}(z,t) = \frac{2\mu}{\hbar} \int_{-\infty}^{t} E^{\pm}(z,u)\mathrm{d}u \tag{22}$$

we can obtain dynamical equations for the electromagnetic field in the region V inside the microtubule cylinder

$$\frac{\partial^2 \theta^{\pm}}{\partial\tau\partial\zeta} = -\sin\theta^{\pm} \tag{23}$$

Here,

$$\tau = \sqrt{\frac{2\pi\epsilon\mu^2 N}{\hbar^2 V}} \left(t - \frac{z}{c}\right)$$

and

$$\zeta = \sqrt{\frac{2\pi\epsilon\mu^2 N}{\hbar^2 V}} \frac{z}{c}$$

This is a typical non-linear partial differential equation called the Sine–Gordon equation, and several exact solutions are obtained by means of the inverse scattering method of soliton equations (Ablowitz et al., 1974).

The most interesting solution of the Sine–Gordon equation (Eq. 23) gives rise to an explicit form of the time evolution of the scalar electric field E in the region V inside the microtubule cylinder

$$E = \sqrt{\frac{2\pi\epsilon N v_0}{V(c - v_0)}} \operatorname{sech} \sqrt{\frac{2\pi\epsilon\mu^2 N v_0}{\hbar^2 V(c - v_0)}} \left(t - \frac{z}{v_0}\right) \tag{24}$$

This is nothing but a soliton solution and tells us that the pulse mode photons propagate along the dielectric waveguide of the microtubule cylinder filled up with water molecules with a certain constant speed v_0 less than the speed of light in vacuum c. It is important to see that the pulse form of the soliton solution is kept unchanged due to the non-linearity of the Sine–Gordon equation.

We have found that microtubules play the role of dielectric waveguides and that pulse mode coherent photons propagate through them as if they were perfectly transparent. This phenomenon is termed self-induced transparency and known to be a typical non-linear effect in quantum optics (McCall and Hahn, 1967). The microtubule may be an ideal microscopic optical device for use as a perfectly transparent pathway for pulse mode photons, free from thermal noise and loss. Combined with superradiance, this self-induced transparency of the microtubule allows us to conclude that the brain is essentially a dense assembly of

microscopic and elaborated optical computing networks of microtubules in the cytoskeletal structure of brain cells. Coherent photon emission and transfer in each microtubule are ensured by superradiance and self-induced transparency characteristic to long-range ordering phenomena in quantum dynamics.

Both superradiance and self-induced transparency may be essential to cooperative physical activity of multiple microtubules in cytoskeletal structure in single cells and among many cells. Thus biological systems in general and the brain in particular may utilise a quantum level holographic information system (Hameroff, 1987; Pribram, 1991).

4. Implications of brain function

We have developed a theoretical framework for the occurrence of quantum coherence of photons in microtubules and their associated water. Fundamental involvement of microtubules and the cytoskeleton in orchestration and control of 'real time' cell functions suggests that such quantum coherence, if it exists, could play a major role in cellular communication, signalling and information processing (Conrad, 1988).

Several aspects of quantum coherence in microtubules may be considered:

1. Superradiance and self-induced transparency occurring in ordered water within the hollow core of cylindrical microtubules behaving as waveguides will result in coherent photons. This coherence, estimated to be capable of superposition of states among microtubules spatially distributed over hundreds of micrometers, which in turn are in superposition with other microtubules hundreds of micrometers away in other directions and so on, could account for a coupling of microtubule dynamics over wide areas. This in turn could account for a unity of thought and consciousness. For example, Insinna (1992) has attributed to quantum coherence in microtubules the phenomenon of Jungian synchronicity.
2. Coherent interference leading to holographic information representation would result from quantum optical effects. At the cytoskeletal level, this could occur via calcium induced sol-gel variations causing polymerization of actin or other cytoskeletal filaments resulting in a holographic representation of short-term memory (Hameroff, 1987). The holographic paradigm suggests coherence and holographic interference across multiple scales (Pribram, 1991). At a more 'macro' level, coherence of neuronal firing among widely dispersed neurons in the 40-Hz range may be related to quantum coherence of microtubules within coherently firing neurons (Singer, 1993).
3. Sequelae of quantum events in individual microtubule subunits, acoustoconformational vibrations could propagate as signals through cytoskeletal networks and membranes and extracellular matrices. Such proposed signals (in the context of the cellular automata theory) have been shown theoretically capable of learning, logic and adaptation (Rasmussen et al., 1990; Lahoz-Beltra et al., 1993).

We have described a complex energy/information field originating in cytoskeleton and associated water and cooperatively pervading other biostructures. 'Unifying field theories' have a long and unsuccessful history in biology and biophysics and connote a derisive term: 'vitalism'. We introduce a neo-vitalistic, quantum coherent holographic field based on microtubule-derived Goldstone bosons as a medium of biological information, communication and representation of external world. In its largest 'brain-wide' scale, this should constitute consciousness.

Fueled by biochemical energy from ATP and GTP hydrolysis and protein phosphorylation, microtubule quantum coherence and self-focussing should be sensitive to general anesthesia. Anesthetic gas molecules reversibly inhibit consciousness by weak, van der Waals binding in hydrophobic regions of proteins (Franks and Lieb, 1982). If quantum optical coherence in microtubules is essential for consciousness, anesthetics must somehow inhibit it. One possible way is by membrane inhibition which could disconnect and isolate cytoskeletal dynamics from the external

milieu. Alternatively, anesthetics may directly alter cytoskeletal quantum coherence. General anesthetics do bind to microtubules and at high enough concentrations cause depolymerization (Allison and Nunn, 1968). At concentrations of anesthesia just sufficient for ablation of consciousness, inhibition of tubulin conformational dynamics could have profound effects. Wulf and Featherstone (1957) showed that anesthetic binding within protein hydrophobic regions altered protein-water binding at the protein surface. Thus, slight anesthetic effects on tubulin conformational dynamics and cooperative water binding would have significant effects on quantum coherence. Anesthesia is also known to be reversed by pressure (Halsey, 1976). By condensing a non-linear optical medium, pressure increases quantum cooperative coherent phenomena. Thus our model is consistent with the mechanism of general anesthesia.

5. Summary

This paper presents a theoretical framework for quantum optical coherence in cytoskeletal microtubules. Specifically, the quantum dynamical system of water molecules and the quantized electromagnetic field confined inside the hollow microtubule core manifests a specific collective dynamics called superradiance by which coherent photons are created inside the microtubule. Furthermore, such coherent photons created by superradiance penetrate perfectly along the internal hollow core of the microtubule as if the optical medium inside it were made transparent by the propagating photons themselves. This quantum effect is called self-induced transparency. Such effects can account for cellular signalling, holographic information processing and unity of consciousness.

6. Acknowledgements

The authors wish to thank Professors H. Umezawa, Y. Takahashi, L.M. Ricciardi and C.I.J.M. Stuart for providing us with a quantum theoretical framework for living matter. It is sad to hear of the death of C.I.J.M. Stuart. We owe him a lot and deeply mourn him. Stuart R. Hameroff is partially supported by NSF Grant No. DMS-9114503.

(Received 29 August 1983; revised manuscript received 11 April 1984)

Two physical models to explain the unusual behavior of biological systems put forward by Fröhlich and Davydov are reviewed. The Davydov Hamiltonian is transformed into normal coordinates and the Fröhlich Hamiltonian is canonically transformed into an equivalent form within the Hartree-Fock approximation. A model Hamiltonian capable of relating both theories is proposed. The resulting analysis employs only one type of second-quantized operators which describe the effect on the active dipolar modes of vibration in biological cells. An equation of motion is derived for the creation and annihilation operators that are used. When the phenomenon of Bose condensation is taken into account, the field translation variable is shown to obey a nonlinear Schrödinger equation. Its solutions are provided and their significance is discussed. Some of the solutions are shown to correspond to properties already examined by Fröhlich and Davydov. New solutions are found and interpreted as interfaces between either an ordered and a disordered phase or two ordered phases existing in the biosystem. The relationship between the two theories of biological order is demonstrated and discussed.

I. THE FRÖHLICH MODEL

Fröhlich presented, in a series of papers,[1-7] a quantum theory of long-range coherence in biological cells predicting the existence of coherent elastic vibrations in the microwave region (10^{11}–10^{12} Hz). The effect presupposes

(i) the existence of a large transmembrane potential difference,

(ii) a continuous supply of metabolic energy within a rate of supply exceeding a critical value, and

(iii) internal organization of the biosystem resulting from a spatial arrangement and a sufficient strength for the coupling constants between the component parts.

The biosystem is schematically divided into three interacting subsystems (Fig. 1):

(i) an oscillating segment of giant dipoles located along the chain formed by macromolecules,

(ii) a heat bath (containing all water and suspended ions), and

(iii) an external source of energy supply.

Following Fröhlich,[7] Wu and Austin[8-11] introduced the following Hamiltonian to adequately describe the above situation:

$$H=\sum_i \omega_i a_i^\dagger a_i+\sum_i \Omega_i b_i^\dagger b_i+\sum_i \theta_i P_i^\dagger P_i + \tfrac{1}{2}\sum_{i,j,k}(\chi a_i^\dagger a_j b_k^\dagger+\chi^* a_j a_i^\dagger b_k) + \sum_{i,j}(\lambda b_i a_j^\dagger+\lambda^* b_i^\dagger a_j)+\sum_{i,j}(\xi P_i a_j^\dagger+\xi^* P_i^\dagger a_j)\,, \quad (1)$$

where $(a_i^\dagger,a_i)$, $(b_i^\dagger,b_i)$, and $(P_i^\dagger,P_i)$ are, respectively, the cell, heat-bath, and energy-pump creation and annihilation (boson-type) operators.

Provided that the oscillating dipoles are within a narrow band of resonance frequencies ($\omega_{\min}\le\omega_i\le\omega_{\max}$) and that the coupling constants χ, λ, and ξ are large enough, the following effects are expected to occur.

(i) The existence of a strong, long-range (~ 1 μm) attractive forces between the dipoles. The effective Fröhlich potential between two interacting dipoles which vibrate with frequencies $\omega_1=\omega_2=\bar{\omega}$ is given by[4]

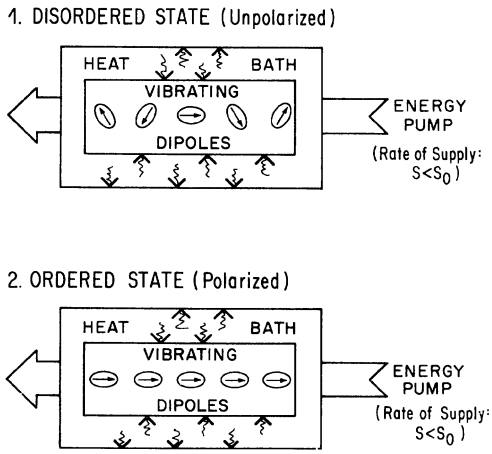

FIG. 1. Illustration of the Fröhlich model.

 ©1984 The American Physical Society

$$U(r)=-\frac{E}{r^3}+\frac{F}{r^6}\ , \tag{2}$$

where F is the London—van der Waals coefficient and E is the long-range constant given by[4]

$$E=\frac{\hbar e^2 Z\,|\,\bar{A}\,|\,\gamma}{4\bar{\omega}M}\left[\frac{1}{\epsilon'(\omega_+)}-\frac{1}{\epsilon'(\omega_-)}\right], \tag{3}$$

where M is the mass of a dipole, r is the lattice spacing, e is the electron charge, Z is the number of elementary charges on each dipole, and $\bar{A}$ is an angle constant. The quantities $\omega_\pm$ are the new dipole vibration frequencies which arise in the system as a result of the interactions

$$\omega_\pm=\left[\tfrac{1}{2}(\omega_1^2+\omega_2^2)\pm\left[\tfrac{1}{4}(\omega_1^2-\omega_2^2)+\frac{\beta_0^4}{(\epsilon'_\pm)^2}\right]^{1/2}\right]^{1/2}, \tag{4}$$

where $\beta_0=\gamma^2e^2\sqrt{Z_1Z_1}/Mr^3$ and γ is a coupling constant. Paul *et al.*[12,13] presented a detailed derivation of the dielectric constant ϵ using the Wu-Austin Hamiltonian, Eq. (1), and obtained

$$\epsilon'(\omega)=1+\frac{4\pi^2}{kT}\rho d^2 f(\omega_{ij}\,n_i)\,|\,\chi\,|^2\ , \tag{5}$$

where ρ is the density of the substance, d is the average dipole moment, and f is a complicated function of the eigenfrequencies ω_i and occupation numbers n_i. Chatterjee *et al.*[14] applied this result to cholesterol and found $\chi\sim5\times10^{-3}$.

(ii) Bose condensation of the vibrational modes ω_i to one with the lowest allowed frequency ω_0. This can be viewed as an energy redistribution in a coherent state with $\omega=\omega_0$, which is a polarized, metastable state and, consequently, has a nonzero dielectric polarization: $\langle\vec{P}\rangle\neq\vec{0}$. Further, Paul[15] showed that the nonzero polarization is a manifestation of symmetry breaking associated with Bose condensations. He also demonstrated using Eq. (1) that $\langle\langle a_l\rangle\rangle\neq0$ and $\langle\langle a_l^\dagger\rangle\rangle\neq0$, where $\langle\langle\ \rangle\rangle$ is the average employing the Hamiltonian H of Eq. (1). Since $\vec{d}_l\propto x_l\propto(a_l^\dagger+a_l)$, $\langle\langle\vec{d}_l\rangle\rangle\neq\vec{0}$, where $\vec{d}_l$ is the dipole moment connected with the lth mode.

Experimental evidence in support of Fröhlich's conjecture about the existence of nonthermal excitations was found in Raman scattering studies of *Escherischia coli*[16,17] and *Chlorella pyrenoidosa*.[18] An indirect effect of increased yeast growth upon irradiation by specific frequencies of millimeter waves[19,20] seems to indicate the importance of the Fröhlich-type excitations in growth control. Moreover, the interactions of human erythrocytes leading to the effect of rouleau formation can be understood using the Fröhlich theory.[21–26] In fact, Paul *et al.*[12] examined this phenomenon in detail and found good consistency with the theoretical model.

One question that has not been addressed in the studies involving the Fröhlich model is the propagation of order (polarization) throughout the system. However, a seemingly unrelated theory of quantum interactions in biological systems has been proposed by Davydov specifically to deal with this problem. We shall review the Davydov model in Sec. II.

II. THE DAVYDOV MODEL

Davydov and his associates, in a series of papers[27–32] and a book,[33] presented a model to explain the almost lossless energy transfer in quasi-one-dimensional biological substances such as protein and peptide chains and deoxyribonucleic acid (DNA). As an example, consider a peptide chain formed by H—N—C=O groups. Each peptide group has a constant electric dipole moment $d\sim0.4$ debye. The neighboring groups interact through a dipole-dipole potential, Eq. (2), whose coefficients differ from those given by Fröhlich since the dipoles involved have no freedom of oscillations. The Davydov constant of attraction is

$$E=(3\cos^2\theta-1)d^2\ , \tag{6}$$

where θ is the angle between the dipole $\vec{d}$ and the chain axis. The constant E reaches its maximum $2d^2$ when $\vec{d}$ is parallel to the axis. The excitation energy required for an electron to overcome the potential barrier is ~0.4 eV and electron transfer is facilitated by the presence of hydrogen bonds between the neighboring peptide groups. Furthermore, Davydov assumed strong coupling between the internal C=O vibrations and the elastic deformations of the chain.

The total Hamiltonian is written in the Heitler-London approximation as[27,28]

$$H=\tfrac{1}{2}\sum_n(M\dot{x}_n^2+\omega\rho_n^2)+\sum_n\left[(\epsilon-D_n)B_n^\dagger B_n-U(B_{n+1}^\dagger B_n+B_{n+1}B_n^\dagger)\right], \tag{7}$$

where

$$\rho_n=r-|\,x_n-x_{n-1}\,|\ , \tag{8}$$

$$D_n=D\left[1+\frac{\beta}{r}\rho_n\right], \tag{9}$$

and D,β are positive parameters of the theory, and x_n is the x coordinate of the nth site of the chain. The electronic excitation operators B_n and $B_n^\dagger$ obey the Bose-

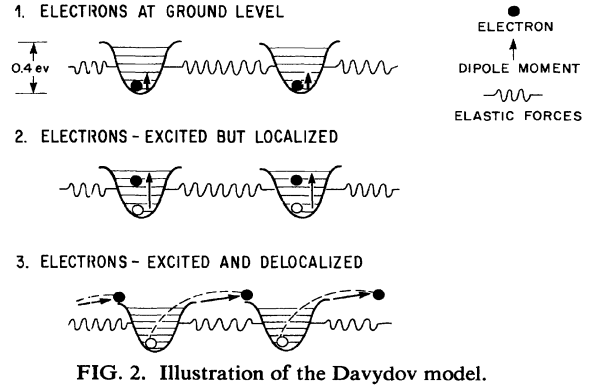

FIG. 2. Illustration of the Davydov model.

Einstein commutation relations.

Next, Davydov derived a nonlinear Schrödinger equation for the amplitude of the collective, electronic excitation $a(t)$ by using the Hamiltonian given above and the corresponding time-dependent Schrödinger equation for the wave function $|\phi(t)\rangle$:

$$i\dot{a}(t)-\lambda a(t)+U\nabla^2 a(t)+G_v|a(t)|^2 a(t)=0 . \tag{10}$$

Here, $|\phi(t)\rangle=\sum_n a_n(t)B_n^\dagger|0\rangle$ is a wave function of the total system and the remaining coefficients are

$$\lambda=\epsilon+T+U_H-D-2U$$

and

$$G_v=\frac{\beta^2 D^2}{\omega r^2[1-(v/V)^2]}$$

with U_H representing the potential energy and T the kinetic energy of the lattice vibrations. The solutions of Eq. (10) are solitary waves of permanent profile which propagate along the chain with constant velocity v (v is less than the velocity of sound V).

Davydov's model was further elaborated by Scott[34] and applied to study the properties of the green algae: *Chlorella pyrenoidosa*.[35] The contraction mechanism of tranversely strained animal muscles[36] was also elucidated with the use of this model. Moreover, it has recently been suggested[37] that this is applicable to the internal pulse in blood vessels.

We shall next explore the relationship between the Fröhlich and Davydov models. In order to compare the respective Hamiltonians [Eqs. (1) and (7)], certain transformations will be made to represent them in a compatible fashion. As a first step, we write the Davydov Hamiltonian using normal coordinates.

III. THE TRANSFORMATION OF DAVYDOV'S HAMILTONIAN TO NORMAL COORDINATES

The most apparent difference between the Wu-Austin and Davydov Hamiltonians is that the former employs normal coordinates whereas the latter is written in position coordinates. The transition from one set of coordinates to the other reflects the change from a localized to a collective picture of the excitations in the system. Davydov's Hamiltonian is transformed in the following steps.

(i) The potential energy of elastic vibrations is rewritten as

$$U_H=\frac{Nwr^2}{2}-wr\sum_{n=1}^{N}|x_n-x_{n-1}| +w\sum_{n=1}^{N}x_n^2-w\sum_{n=1}^{N}x_n x_{n-1} . \tag{11}$$

Since this represents a harmonic approximation, the length of the chain L is constant:

$$L=\sum_{n=1}^{N}|x_n-x_{n-1}| . \tag{12}$$

Using periodic boundary conditions the total energy of elastic vibrations may be written as

$$H_{\rm el}=\sum_{n=1}^{N}\left[\frac{p_n^2}{2M}+\sum_{n'=1}^{N}V_{nn'}x_n x_{n'}\right]+V_0 , \tag{13}$$

where p_n denotes the momentum operator at the nth site and

$$V_{nn'}=\begin{cases}2w & \text{if } n'=n\\ -w & \text{if } n'=n\pm1\\ 0 & \text{otherwise .}\end{cases} \tag{14}$$

The constant energy shift V_0 is

$$V_0=NrW\left|\frac{r}{2}-\frac{L}{N}\right| . \tag{15}$$

Following a standard procedure,[38] the variables x_n and p_n are Fourier transformed to obtain

$$H_{\rm el}=\sum_q\left[\frac{1}{2M}p_q p_q^\dagger+\tfrac{1}{2}M\Omega_q^2 x_q x_q^\dagger\right]+V_0 . \tag{16}$$

Here, x_q and p_q are the Fourier transforms of x_n and p_n, respectively, and $\Omega_q=2(W/M)^{1/2}\sin(q/2)$. Finally, defining the phonon annihilation operator as

$$b_q\equiv(2M\Omega_q)^{-1/2}(M\Omega_q x_q+ip_q^\dagger) \tag{17}$$

and the creation operator $b_q^\dagger$ as the Hermitian conjugate of b_q, a fully diagonalized, second-quantized operator for $H_{\rm el}$ is obtained:

$$H_{\rm el}=\sum_q\Omega_q(b_q^\dagger b_q+\tfrac{1}{2})+V_0 . \tag{18}$$

(ii) The diagonal part of the electron excitation energy

$$H_{\rm ex}=\sum_n[\epsilon-D(1+\beta)]B_n^\dagger B_n \tag{19}$$

can be transformed into normal coordinates by introducing the operators a_q and $a_q^\dagger$ as the Fourier transforms of the operators B_n and $B_n^\dagger$, respectively:

$$H_{\rm ex}=\sum_q\bar{\omega}_q a_q^\dagger a_q , \tag{20}$$

where $\bar{\omega}_q=\epsilon-D(1+\beta)$. Note that $\bar{\omega}_q$ is independent of q.

(iii) The off-diagonal part of the electronic excitation energy

$$H_{\rm off}=-\sum_n U(B_{n+1}^\dagger B_n+B_{n+1}B_n^\dagger) \tag{21}$$

is transformed in the same manner as $H_{\rm ex}$ into

$$H_{\rm off}=-\sum_q U(2\cos q\, a_q^\dagger a_q+1) . \tag{22}$$

Now, $H_{\rm ex}$ and $H_{\rm off}$ are combined to form the total electronic contribution to the Hamiltonian:

$$H_{\rm exc}=H_{\rm ex}+H_{\rm off}=\sum_q(\omega_q a_q^\dagger a_q-U) , \tag{23}$$

where the new energy eigenvalues are $\omega_q=\epsilon-D(1+\beta)-2U\cos q$. Note that ω_q is an even

function of q and $(\partial\omega_q/\partial q)_{q=0}=0$.

(iv) The remaining term of Eq. (7) represents the interactions between lattice vibrations and electronic excitations:

$$H_{\rm int}=\sum_n D\frac{\beta}{r}\,|x_n-x_{n-1}|\,B_n^\dagger B_n\ , \tag{24}$$

and, with the use of the Fourier transformations introduced before,

$$H_{\rm int}=\sum_{p,q,r}\chi_{pqr}(b^\dagger_{-p}+b_p)a_q^\dagger a_r\ , \tag{25}$$

where the coupling constant is

$$\chi_{pqr}=\frac{2D\beta}{r}\left[\frac{w}{N^2M^3}\right]^{1/4}\delta(q,r)[\sin(q/2)]^{3/2}\ .$$

Finally, we write the entire Davydov Hamiltonian, Eq. (7), in normal coordinates as

$$H=H_0+\sum_q\Omega_q b_q^\dagger b_q+\sum_q\omega_q a_q^\dagger a_q+\sum_{p,q,r}\chi_{pqr}(b^\dagger_{-p}+b_p)a_q^\dagger a_r\ , \tag{26}$$

where

$$H_0=N\left[rw\left|\frac{r}{2}-\frac{L}{w}\right|-U\right]+\tfrac{1}{2}\sum_q\Omega_q\ , \tag{27}$$

$$\Omega_q=2\sqrt{w}/M\sin(q/2)\ , \tag{28}$$

$$\omega_q=\epsilon-D(1+\beta)-2U\cos q\ , \tag{29}$$

$$\chi_{pqr}=\frac{2D\beta}{r}\left[\frac{w}{N^2M^3}\right]^{1/4}[\sin(q/2)]^{3/2}\delta(q,r)\ . \tag{30}$$

In Sec. IV we transform the Wu-Austin Hamiltonian, Eq. (1), to a form which is essentially identical to Eq. (26). As a result, we will be able to connect the two models by a single Hamiltonian.

IV. THE CANONICAL TRANSFORMATION OF THE WU-AUSTIN HAMILTONIAN

By comparing the normal coordinate representation of the Davydov Hamiltonian, Eq. (26), with the Wu-Austin Hamiltonian, Eq. (1), many similarities may be seen. However, the main differences that the Wu-Austin Hamiltonian involves are the interactions of the cell phonons with the energy pump (i.e., the terms proportional to $P_i a_j^\dagger$ and $P_i^\dagger a_j$) as well as first-order interactions with the heat bath (i.e., the terms proportional to $b_i a_j^\dagger$ and $b_i^\dagger a_j$). Fortunately, this problem may be eliminated by a canonical transformation of the Wu-Austin Hamiltonian and obtaining an equivalent operator in a form identical to the Davydov Hamiltonian.

Assuming that the *second-order* cell-phonon–heat-bath interactions are sufficiently small perturbations, we neglect them for the moment and rewrite Eq. (1) as

$$H=H_0+H_I\ , \tag{31}$$

where H_0 is the unperturbed part of the Hamiltonian

$$H_0=\sum_i\omega_i a_i^\dagger a_i+\sum_i\Omega_i b_i^\dagger b_i+\sum_i\theta_i p_i^\dagger p_i \tag{32}$$

and H_I contains the *first-order* perturbation terms:

$$H_I=\sum_{i,j}(\lambda b_i a_j^\dagger+\lambda^* b_i^\dagger a_j)+\sum_{i,j}(\xi P_i a_j^\dagger+\xi^* P_i^\dagger a_j)\ . \tag{33}$$

In order to effectively *decouple* the cell operators $a_i^\dagger, a_i$ from the heat-bath operators $b_i^\dagger, b_i$ and the energy-pump operators $P_i^\dagger, P_i$, we use the following unitary transformation:

$$\tilde{H}=e^{-S}He^{+S} \tag{34}$$

with the matrix S defined as

$$S=\sum_{i,j}(\mu b_i^\dagger a_j+\upsilon b_i a_j^\dagger)+\sum_{i,j}(\Delta P_i a_j^\dagger+\sigma P_i^\dagger a_j)\ . \tag{35}$$

Applying the Baker-Hausdorff formula

$$e^{-S}He^{+S}=H_0+H_I+[H_0,S]+[H_I,S]+\tfrac{1}{2}[[H_0,S],S]+\tfrac{1}{2}[[H_I,S],S]+\cdots \tag{36}$$

together with the requirement

$$H_I=-[H_0,S] \tag{37}$$

yields the following values of the transformation coefficients:

$$\mu=\frac{\lambda}{\Omega_i-\omega_j},\quad \upsilon=\frac{\lambda^*}{\omega_j-\Omega_i}\ , \tag{38}$$

$$\Delta=\frac{\xi}{\theta_i-\omega_j},\quad \sigma=\frac{\xi^*}{\omega_j-\theta_i}\ . \tag{39}$$

Therefore, $\sigma=-\Delta^*$ and $\upsilon=-\mu^*$. Consequently, the series expansion, Eq. (36), is evaluated up to the fifth term as

$$\tilde{H}=H_0+\Delta H\ , \tag{40}$$

where ΔH is the term representing the net effect of the first-order perturbations

$$\Delta H=\tfrac{1}{2}\sum_{i,j}\left\{\sum_k\left[|\xi|^2\left[\frac{1}{\omega_i-\theta_k}+\frac{1}{\omega_j-\theta_k}\right]+|\lambda|^2\left[\frac{1}{\omega_i-\Omega_k}+\frac{1}{\omega_k-\Omega_k}\right]\right]\right\}a_i^\dagger a_j$$

$$+\tfrac{1}{2}\sum_{i,j}\left\{\sum_k\left[|\xi|^2\left[\frac{1}{\theta_i-\omega_k}+\frac{1}{\theta_j-\omega_k}\right]\right]\right\}P_i^\dagger P_j+\tfrac{1}{2}\sum_{i,j}\left\{\sum_k\left[|\xi|^2\left[\frac{1}{\Omega_j-\omega_k}+\frac{1}{\Omega_j-\omega_k}\right]\right]\right\}b_i^\dagger b_j\ . \tag{41}$$

Although Eq. (41) contains off-diagonal terms, ΔH remains Hermitian. Moreover, ΔH preserves the total number of quasiparticles in the system. The sixth term in the expansion, Eq. (36), reintroduces the coupling between the cell phonons and the heat bath and the energy pump. However, the new coupling coefficients are proportional to $|\xi|^2\xi$ and $|\lambda|^2\lambda$ this time. Repeating the canonical transformation procedure removes these couplings beyond the fifth term in the new expansion according to Eq. (36). consequently, the operator ΔH after the second transformation still preserves the initial form given by Eq. (41) save for the energy constants which are supplemented by corrections proportional to $|\xi|^4$ and $|\lambda|^4$. Carrying out this procedure up to infinity brings the following form of $\tilde{H}$:

$$\tilde{H}=\sum_{i,j}\omega_{ij}a_i^\dagger a_j+\sum_{i,j}\Omega_{ij}b_i^\dagger b_j+\sum_{i,j}\theta_{ij}P_i^\dagger P_j\ , \tag{42}$$

where

$$\omega_{ij}=\omega_i\delta_{ij}+\tfrac{1}{2}\sum_k\left[|\xi|^2\left(\frac{1}{\omega_i-\theta_k}+\frac{1}{\omega_j-\theta_k}\right)+|\lambda|^2\left(\frac{1}{\omega_i-\Omega_k}+\frac{1}{\omega_j-\Omega_k}\right)\right]+\Sigma_{n\geq 2}(|\xi|^{2n})+\Sigma_{n\geq 2}(|\lambda|^{2n})\ , \tag{43}$$

where $\Sigma_{n\geq 2}(|\xi|^{2n})$ represents a series in $|\xi|^{2n}$, with $n=2,3,\ldots,\infty$ and $\Sigma_{n\geq 2}(|\lambda|^{2n})$ a series in $|\lambda|^{2n}$, with $n=2,3,\ldots,\infty$;

$$\Omega_{ij}=\Omega_i\delta_{ij}+\tfrac{1}{2}\sum_k|\lambda|^2\left(\frac{1}{\Omega_i-\omega_k}+\frac{1}{\Omega_j-\omega_k}\right)+\Sigma_{n\geq 2}(|\lambda|^{2n})\ ; \tag{44}$$

$$\theta_{ij}=\theta_i\delta_{ij}+\tfrac{1}{2}\sum_k|\xi|^2\left(\frac{1}{\theta_i-\omega_k}+\frac{1}{\theta_j-\omega_k}\right)+\Sigma_{n\geq 2}(|\xi|^{2n})\ . \tag{45}$$

The applicability of this procedure rests entirely on the detailed energy structure and the strength of the coupling constants which determine the radii of convergence of the series involved in Eqs. (43)–(45) denoted: ξ_1,λ_1 and ξ_2 and λ_2, respectively. All the energy constants converge if $|\xi|<\min(\xi_1,\xi_2)$ and if $|\lambda|<\min(\lambda_1,\lambda_2)$. Since the heat and energy reservoirs are assumed much larger than the cell, we approximate $\Omega_{ij}\simeq\Omega_i\delta_{ij}$ and $\theta_{ij}\simeq\theta_i\delta_{ij}$. Furthermore, in the process of quantum averaging the off-diagonal terms (those with $i\neq j$) will disappear and the entire Wu-Austin Hamiltonian may be finally presented as

$$H=H_0'+\sum_i\omega_i a_i^\dagger a_i+\sum_i\Omega_i b_i^\dagger b_i+\tfrac{1}{2}\sum_{i,j,k}(\chi a_i^\dagger a_j b_k^\dagger+\chi^* a_j a_i^\dagger b_k)\ , \tag{46}$$

where $H_0'=H_0+\sum_i\theta_i P_i^\dagger P_i$ since the energy-pump operator commutes with all the remaining operators in Eq. (46). The new cell energy constant is $\bar{\omega}_i=\omega_{ij}\delta_{ij}$ where ω_{ij} is that of Eq. (43). This Hamiltonian, Eq. (46), contains the second-order cell-phonon—heat-bath interactions as the only coupling terms. The effect of all first-order interactions is incorporated into the new energy constant $\bar{\omega}_i$.

It is concluded that, provided the interactions between the subsystems are sufficiently small, the Wu-Austin Hamiltonian can be successfully and accurately transformed into an effective operator which is exactly of the same form as the Davydov Hamiltonian, Eq. (26). Therefore, Eq. (46) can be considered a prototype Hamiltonian embracing both theories. Before deriving equations of motion for the operators involved in this Hamiltonian, another canonical transformation will be applied in order to clarify further the role of the remaining interaction term.

V. THE CANONICAL TRANSFORMATION OF THE MODEL HAMILTONIAN

We have seen thus far that the two seemingly unrelated theories of biological order can, indeed, be described using the same Hamiltonian

$$H=H_0+H_I\ , \tag{47}$$

where

$$H_0=H_0'+\sum_i\bar{\omega}_i a_i^\dagger a_i+\sum_i\Omega_i b_i^\dagger b_i \tag{48}$$

and

$$H_I=\tfrac{1}{2}\sum_{i,j,k}(\chi b_{-k}^\dagger+\chi^* b_{+k})a_i^\dagger a_j\ . \tag{49}$$

We have assumed that the indices i, j, and k refer to conserved quantities. Equation (47) can be regarded as a model Hamiltonian for the phenomena described by both theories. It employs two types of creation and annihilation operators: $\{a_i^\dagger,a_i\}$ and $\{b_i^\dagger,b_i\}$. The first type of operators refers to the active modes of the cell: dipole vibrations in the Fröhlich model or electronic excitations in the Davydov model. The second type of operators belongs to those of the thermal environment as displayed by the heat bath in the Fröhlich model or the elastic lattice vibrations in the Davydov model. Both types of operators are coupled through a second-order interaction term, Eq. (49), and it is assumed that the heat reservoir has a much larger energetic capacity than the cell. Consequently, only the cell will be noticeably affected by the coupling. The particular (dispersion) properties of the energy constants ω_i and Ω_i and of the coupling constant χ remain a characteristic feature of each model. In general, χ is assumed to be a function of i and j since the third index k is determined from a conservation law: $Q(i)-Q(j)-q(k)=0$, where Q and q refer to a conserved quantity (e.g., momentum) of the cell and heat-bath quasiparticle, respectively.

In order to see the role of the interaction term, Eq. (49), better, the model Hamiltonian, Eq. (47), is replaced by its

equivalent, in much the same way as was applied to the Wu-Austin Hamiltonian in Sec. IV. Choosing the transformation matrix S as

$$S=\sum_{i,j,k}(Ab^{\dagger}_{-k}+Bb_{+k})a_i^{\dagger}a_j \tag{50}$$

and using a Baker-Hausdorff expansion, Eq. (36), the transformation coefficients A and B are found as

$$A=-\frac{\chi_{ij}}{(\omega_i-\omega_j)+\Omega_{-k}},\quad B=-\frac{\chi^*_{ij}}{(\omega_i-\omega_j)-\Omega_k}\ . \tag{51}$$

The first nonvanishing correction term in the series, Eq. (36), is

$$\Delta H_I=\sum_{i,j,k}\Delta_{ijk}a_i^{\dagger}a_j a_k^{\dagger}a_{i-j+k}\ , \tag{52}$$

where

$$\Delta_{ijk}=|\chi_i|^2\frac{\Omega_{j-k}}{(\omega_j-\omega_k)^2-\Omega^2_{j-k}}\ .$$

This is referred to as the Hartree-Fock (or the mean-field) approximation in which the effect of the external environment is averaged out to form a homogeneous background. The coupling between both modes of excitation is reintroduced into the Hamiltonian in the sixth-order term of the expansion, Eq. (36). The same procedure may be reapplied to remove this coupling and, as a result, correction terms involving an increasing number of second-quantized operators will be added to Eq. (52). However, on the assumption that the coupling constant χ is, relatively, of small magnitude, the higher-order terms are neglected as they are proportional to $|\chi|^{2n}$ with $n=2,3,\ldots$.

We can now separate the model Hamiltonian H into two commuting (noninteracting) parts H' and H'',

$$H=H'+H''\ , \tag{53}$$

where H' is an equivalent operator representing the combined effect of the surroundings on the active modes of the cell. Using the more conventional wave number indices,

$$H'=\sum_k W_K a_k^{\dagger}a_k+\sum_{k,k',q}\Delta_{kk'q}a^{\dagger}_{k'+q}a^{\dagger}_{k-q}a_k a_{k'}\ , \tag{54}$$

where

$$W_k=\bar{\omega}_k-\left[\frac{|\chi_0|^2}{\Omega_0}N\right], \tag{55}$$

N is the total number of cell phonons, and $\Delta_{kk'q}$ is the effective coupling constant,

$$\Delta_{kk'q}=|\chi_{kk'}|^2\frac{\Omega_q}{(\omega_k-\omega_{k'})^2-(\Omega_q)^2}\ . \tag{56}$$

H'' describes the state of the external environment,

$$H''=H'_0+\sum_q\Omega_q b_q^{\dagger}b_q\ . \tag{57}$$

Since $[H',H'']=0$, H'' can be henceforth neglected in the discussion. H' contains all the relevant information about the perturbation effects on the biosystem.

VI. THE EQUATION OF MOTION

Having derived the model Hamiltonian, Eq. (53), which combines both theories of biological order, we shall investigate the ensuing time-dependent phenomena. In general this is a very complicated problem. Fortunately, however, the Hamiltonian presents certain features that can be used to advantage. It is easy to see that, if in each of the creation and annihilation operators in Eq. (53) we make the following transformations:

$$a_k\rightarrow e^{i\theta_k}a_k \tag{58}$$

$$a_k^{\dagger}\rightarrow e^{-i\theta_k}a_k^{\dagger}\ , \tag{59}$$

(where θ_k is some arbitrary phase factor), the Hamiltonian H' does *not* remain invariant. It has been shown by Umezawa and co-workers[39] that such a lack of invariance signifies the phenomenon of symmetry breaking. Paul[15] has shown that this phenomenon is accompanied by a field translation of the operators

$$a_k\rightarrow a_k+c_k,\ a_k^{\dagger}\rightarrow a_k^{\dagger}+c_k^*\ .$$

Here, the quantities c_k and c_k^* are not operators but c-numbers. The occupation number states upon which the operators a_k and $a_k^{\dagger}$ act are transformed into the Glauber coherent states. Thus

$$|n_1,n_2,\ldots\rangle\rightarrow|c_1,c_2,\ldots\rangle\equiv|\{c\}\rangle\ .$$

The $|\{c\}\rangle$ are the Glauber coherent states and are eigenstates of the annihilation operators

$$a_k|\{c\}\rangle=c_k|\{c\}\rangle\ . \tag{60}$$

The adjoint of this equation yields

$$\langle\{c\}|a_k^{\dagger}=c_k^*\langle\{c\}|\ . \tag{61}$$

The Hamiltonian for the system within the coherent-state description is given by the expectation of H' [as given by Eq. (54)]. We will adopt the symbol $\mathscr{H}'$ to designate this expectation value:

$$\mathscr{H}'=\frac{\langle\{c\}|H'|\{c\}\rangle}{\langle\{c\}|\{c\}\rangle}\equiv\mathscr{H}'(\{c\},\{c^*\})\ . \tag{62}$$

This can be readily calculated by substituting Eq. (54) in Eq. (62) and employing Eqs. (60) and (61). We now have

$$\mathscr{H}'(\{c\},\{c^*\})=\sum_k W_k c_k^*c_k+\sum_{k,k',q}\Delta_{kk'q}c^*_{k'+q}c^*_{k-q}c_k c_{k'}\ . \tag{63}$$

In this representation the Hamiltonian is no longer an operator but a c number depending upon the field-translation parameters. The equations of motion for the quantities $\{c\}$ and $\{c^*\}$ can be obtained from Hamilton's equations

$$i\dot{c}_l=\frac{\partial\mathscr{H}'}{\partial c_l^*},\quad -i\dot{c}^*_l=\frac{\partial\mathscr{H}'}{\partial c_l}\ . \tag{64}$$

By inserting $\mathscr{H}'$ from Eq. (62) and carrying out the differentiation we get, along with its complex conjugate,

$$i\dot{c}_l=W_l c_l+\sum_{k,k'}Y_{kk'}c^{\dagger}_{k+k'+l}c_k c_{k'}\ , \tag{65}$$

where

$$Y_{kk'}=\Delta_{k,k',l-k'}+\Delta_{k,k',k-l} \ . \tag{66}$$

Similarly, an equation of motion for c_l^* can be derived.

It is easy to see that within the coherent-state description the expectation value of the annihilation and creation operators do not vanish, but propagate throughout the system without loss of energy. Before demonstrating these solutions (in Sec. III) it should be mentioned that if only one of the following conditions is met, ordinary waves exhibiting diffusion will result instead of solitons.

$$\frac{\langle\{c\}|a_k|\{c\}\rangle}{\langle\{c\}|\{c\}\rangle}=c_k^* \ , \tag{67}$$

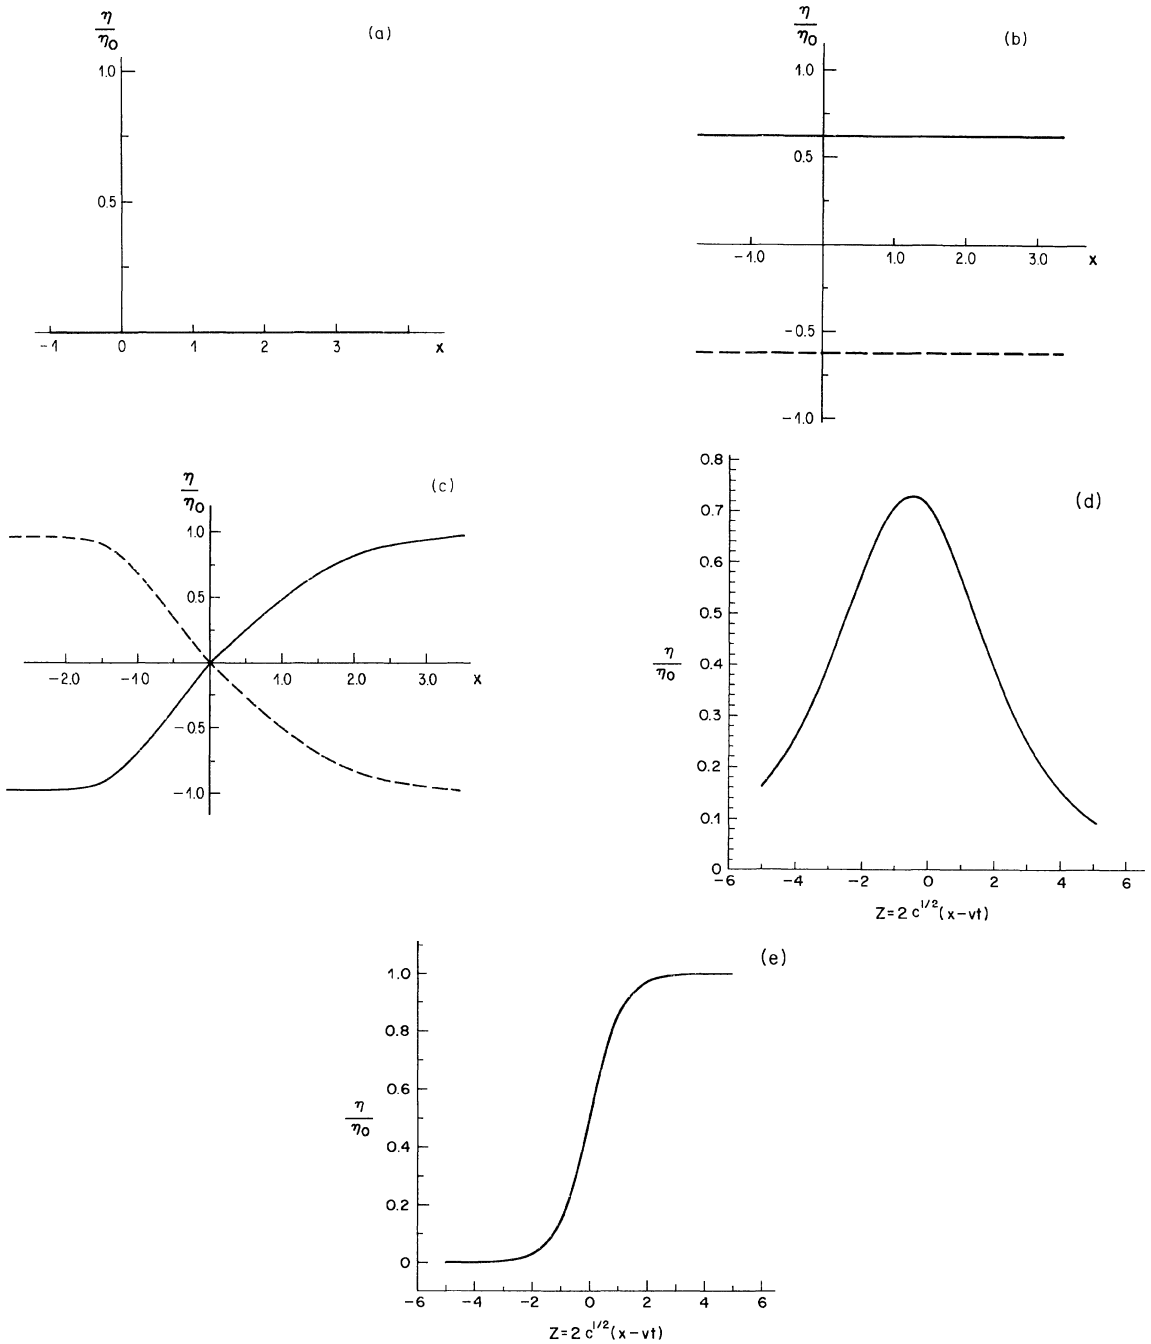

FIG. 3. (a) Solution 1 (static) representing the disordered phase. (b) Solution 2 (static) representing the two possible ordered phases. (c) Solution 3 (static) representing domain walls between the two possible ordered phases. (d) Solution 4 (dynamic) representing the kink-antikink couple. (e) Solution 5 (dynamic) representing the moving kink connecting the ordered and disordered phases.

(i) The third- or a higher-order term in the expansion of W_k in a series of k is significant and cannot be neglected.

(ii) The first-order term W_1 does not vanish, as, for example, in the case of acoustic phonons where $W(k) \propto \sin(k/2)$.

(iii) The Bose condensation does not occur and the averages over $|0\rangle$, and not $|0\rangle\rangle$, must be taken. Then a linear differential equation in the form of a diffusion equation will be obtained:

$$i\dot{\eta} = W_0\eta + W_2\eta_{xx} \,. \tag{68}$$

The amplitudes of the solutions to (68) decay exponentially with x in direct proportionality to the diffusion constant W_2.

VII. SOLUTIONS

The present equation, Eq. (65), is a special case of a nonlinear Schrödinger equation and is solved following the detailed derivation[40] for a general case. The parameters in Eq. (65) have a physical interpretation which depends on the particular model used. In both cases, however, the nonlinearity parameter Y is proportional to the strength of the cell-heat reservoir coupling: $|\chi|^2$. In the Davydov model the diffusion constant W_2 equals the dipole-dipole potential U and the linear coefficient $W_0 = \epsilon - D(1+B) - 2U - (|\chi_0|^2/\Omega)N$.

All solutions of Eq. (65) can be divided into two groups: (i) static (or time-independent) and (ii) dynamic (or time-dependent). The static solutions follow.

(1) $\eta_1(x) \equiv 0$. It exists when $W_0 \geq 0$ and the cell—heat-bath coupling increases the value of W_0 since Ω_k are negative. This solution represents a disordered, unpolarized phase since the field translation is proportional to the net polarization. When $\eta_1(x) = 0$, there is neither Bose condensation nor a net dielectric polarization.

(2) A solution corresponding to the homogeneous, ordered phase whose amplitude is

$$\eta_2(x,t) = \pm[(-W_0)/T]^{1/2} \tag{69}$$

and it can only exist when $W_0 \leq 0$ which is facilitated by the presence of a sufficiently strong coupling:

$$|\chi|^2 \geq \frac{\omega_0}{N}\Omega_0 \,.$$

This solution represents an ordered, polarized phase existing when Bose condensation takes place. Solutions (1) and (2) were, in fact, the subject of investigations by Fröhlich and they describe the time-independent aspect of the problem. Note that we use the terminology of phase transitions since the field translation η can be treated as a time- and space-dependent order parameter. Moreover, since without the presence of external electric fields breaking the symmetry manifested by the appearance of "$\pm$" in Eq. (69) two ordered phases are allowed, there is an additional solution connecting the two phases. It has the form of a domain wall and is given by

(3) an interface solution,

$$\eta_3(x,t) = \eta_0 \tanh\left[\frac{x}{\sqrt{2}\xi_c(T)}\right] , \tag{70}$$

where $\eta_0 = |\eta_2|$ and $\xi_x(T)$ is the so-called correlation length which equals $\xi_c(T) = -W_2/W_0$. Thus, it is necessary that $W_2 > 0$ and $W_0 < 0$ for this solution to exist.

The dynamic solutions are solitons.

(4) A kink-antikink pair corresponding to the Davydov soliton:

$$\eta_4(x,t) = \exp[i\delta_c(\Delta x_c - v_c t)]\{[(1+A)/4C]\sinh[x_1 \pm 2\sqrt{C}(x-vt)] + [(1-A)/4C]\cosh[x_1 \pm 2\sqrt{C}(x-vt) - D/2C]\}^{-1/2} \,, \tag{71}$$

where δ_c, x_c, and v_c are the carrier width, phase shift, and velocity, respectively, and x_1 is the envelope phase shift. The following symbols have also been introduced:

$$C = \frac{-W_0}{W_2} + \tfrac{1}{2}\left[\frac{v}{W_2}\right]^2 , \tag{72}$$

$$A = -\left[\frac{T}{W_2}\right]^2 \leq 0 \,, \tag{73}$$

$$D = \frac{-T}{W_2} \,. \tag{74}$$

This solution can be interpreted as a solitary wave of polarization-soliton propagating through the system at a constant velocity v without loss of energy. Both directions of motion are allowed and the width of this soliton is $\delta_e = 2\sqrt{C}$ which vanishes as $W_0 \to 0$ or $W_2 \to \infty$.

(5) This solution is a moving order-disorder phase wall given by

$$\eta_5(x,t) = \exp[i\delta_c(\Delta x_c - v_c t)] \times \{(1/2C)\exp[x_2 \pm 2\sqrt{C}(x-vt)] - D/2C\}^{-1/2} \,. \tag{75}$$

It exists only when $A = 0$ (i.e., if $T = 0$ or $W_2 = \infty$) and $C > 0$. This solution separates two neighboring regions, one of which is disordered (solution 1) and the other of which is ordered (solution 2) and therefore exists at the transition point where $W_c = 0$.

Neither the static domain wall (solution 3) nor the dynamic domain wall (solution 5) have been found before and they seem to play important roles in these phenomena. Moreover, the remaining solutions which are divided into two distinct groups appear to describe different aspects of the same phenomenon. The static solutions described first by Fröhlich are manifestations of the Bose condensation in the system and the dynamic solutions are polarization waves propagating across the system as soli-

tons in a lossless manner. Therefore, the two seemingly different models of biological order are not only mathematically equivalent but also physically complementary. We have shown that they can be unified into a general, complete theory.

VIII. CONCLUSIONS

Using a series of Fourier and canonical transformations, we have demonstrated the relationship between the two seemingly independent theories of biological order put forward by Fröhlich and Davydov. Within the bounds of the approximations used, the two models are mathematically equivalent as they yield identical effective Hamiltonians. A model Hamiltonian encompassing both models is constructed which yields an equation of motion for the ground-state expectation value of the creation and annihilation operators involved, called a field translation. Under the conditions for Bose condensation the Fourier transform of the field-translation variable is shown to obey a nonlinear Schrödinger equation (NLSE) whose solutions are well known. The set of NLSE solutions can be classified as static (time independent) or dynamic (time dependent). The first group was the subject of Fröhlich's studies whereas the second was discussed by Davydov. Thus, the two models seem to complement each other physically. We have found two new solutions: a standing interface between two ordered phases whose amplitudes are of opposite sign and a moving interface between an ordered and a disordered phase. It is concluded that the field translation associated with the presence of Bose condensation can be considered as an order parameter in biological systems. In the absence of Bose condensation or when the dispersion function for the cell phonons does not meet certain restrictions, the resultant equation of motion does not admit solitons, but ordinary waves which diffuse and decay.

Based on our findings, we expect both static and dynamic effects to occur simultaneously and they are interpreted as two aspects of the same phenomenon. Thus, Bose condensation of membrane-vibrational modes should be accompanied by the solitonic propagation of a polarization wave. Conversely, the solition transport of bond energy along the peptide chain should be accompanied by Bose condensation of lattice vibrations. We note that the existence of solitons and Bose condensation have been shown to be related[41,42] also elsewhere, which supports our conclusions.

The main difference between the Davydov and Fröhlich models is one of emphasis on different manifestations of the same problem. Fröhlich's model concentrates on time-independent effects (stable states) and leads to conditions for establishing order in the system whereas Davydov's model investigates time-dependent effects and highlights propagation of this order throughout the system. Furthermore, due to the differences in the particulars of the systems under study, the energy constants and coupling coefficients appear to have different strengths and dispersion properties. Notably, Fröhlich assumed the dipoles to vibrate at high frequencies and his approach implies[43] that the dipole-dipole energy is less than kT. Davydov, on the other hand, considers the case when the dipoles are statically aligned and their interaction energy far exceeds kT.[44] Both models, however, arrive at an attractive long-range effective potential which is proportional to r^{-3}. Since the active objects are of different dimensions in these theories (Fröhlich, membranes; Davydov, electrons), it is not surprising to find that the two potentials differ significantly in strength. Paul *et al.*[18] calculated, using the Wu-Austin Hamiltonian, that $E \simeq -2.3\times10^{-36}$ J m^3 for human erythrocytes whereas for the peptide group $E \simeq -2.0\times10^{-60}$ J m^3 using the Davydov expression. It would be necessary to investigate the dispersion properties of the coefficients appearing in the Wu-Austin Hamiltonian, without which it would be difficult to argue that solitons do exist in biological membranes.

We note in closing that Fröhlich[43] himself predicted the significance of electronic excitations in biological cells although he did not relate them explicitly to the model of membrane vibrations. Having related Fröhlich's theory to Davydov's theory of electron transport it seems natural to explore the possibilities of membranes and electrons attaining similar frequencies. Such as analysis could quantify Fröhlich's speculations about the role of free electrons in destroying the growth control mechanisms.[43]

SELECTIVE LONG RANGE DISPERSION FORCES BETWEEN LARGE SYSTEMS

H. FRÖHLICH
Department of Theoretical Physics, University of Liverpool, UK

Received 8 March 1972

Two large molecular systems capable of giant dipole vibrations of frequencies ω_1 and ω_2 respectively may exert selective very strong long range forces upon each. The selectivity refers to frequency resonance ($\omega_1 \approx \omega_2$). Further conditions are (i) the dielectric constant of the medium between them shows strong dispersion in the relevant frequency region or (ii) coherent vibrations are excited by pumping. The latter is always attractive, the former may be either attractive or repulsive.

The interaction between two large systems (e.g. giant molecules) at a distance R, larger than their linear dimensions L arises principally from the interaction between their giant dipole vibrations (= zero wave number polarisation waves). Let ω_1 and ω_2 respectively ($\omega_1 \geqslant \omega_2$) be the frequencies of these vibrations in the separated systems. Then through their interaction at finite distance two frequencies ω_+ , ω_- of the joint system arise,

$$\omega_\pm^2 = \tfrac{1}{2}(\omega_1^2 + \omega_2^2) \pm (\Delta^2 + \beta^4/\epsilon_\pm^2)^{\frac{1}{2}},$$
$$\Delta = \tfrac{1}{2}(\omega_1^2 + \omega_2^2) \qquad (1)$$

where $\epsilon_\pm$ is the longitudinal dielectric constant at frequency $\omega_\pm$ of the medium separating the systems and

$$\beta^2 = e^2 |A| (z_1 z_2)^{\frac{1}{2}} / MR^3. \qquad (2)$$

Here the two systems are considered to contain z_1 and z_2 elastically bound particles of mass M and charge e. $|A|$ is a positive constant of magnitude unity which depends on various angles. The frequencies ω_1 and ω_2 depend on the macroscopic shape of the systems and for simplicity will be assumed non degenerate. Generalisations to more complicated systems are straight forward. Clearly the frequency separation increases with the size of the systems and for large systems may reach considerable values such that in a sispersion region of the intermediate medium ϵ_+ may differ considerably from ϵ_-. The result is a resonance-like interaction energy between the systems which is linear in β^2 (i.e. $\propto 1/R^3$) if $\epsilon_+ \neq \epsilon_-$ but $\omega_1 \approx \omega_2$. For $\epsilon_+ = \epsilon_-$ on the other hand the second order London interaction ($\propto 1/R^6$) is obtained which is not frequency slective.

The interaction energy I is defined as the difference of the free energy F at distance R from its value at $R \to \infty$. Thus in the extreme quantum case (I_q) when $KT/\hbar$ is small compared with ω_-,

$$I_q/kT = \hbar((\omega_+ + \omega_-) - (\omega_1 + \omega_2))/2kT \qquad (3)$$

whereas in the extreme classical case

$$I_c/kT = \log \omega_+ \omega_- / \omega_1 \omega_2. \qquad (4)$$

To discuss the result consider first the case of weak coupling defined as

$$(\Delta^2 + \beta^4/\epsilon_\pm^2)^{\frac{1}{2}} - \Delta \ll \omega_2^2 \qquad (5)$$

Systematic development near resonance then yields

$$I_q/kT = \frac{\hbar}{4kT}\left\{\Delta\left(\frac{1}{\omega_2} - \frac{1}{\omega_1}\right) + \left(\frac{\Delta^2}{\omega_1^2} + \frac{\beta^4}{\omega_1^2\epsilon_+^2}\right)^{\frac{1}{2}} - \left(\frac{\Delta^2}{\omega_2^2} + \frac{\beta^4}{\omega_2^2\epsilon_-^2}\right)^{\frac{1}{2}}\right\} \qquad (6)$$

Hence at resonance, $\omega_1 = \omega_2 = \omega$, $\Delta = 0$,

$$\frac{I_{q\,res}}{kT} = \frac{\hbar\omega}{4kT}\frac{\beta^2}{\omega^2}\left(\frac{1}{\epsilon_+} - \frac{1}{\epsilon_-}\right), \quad \omega_1 = \omega_2. \qquad (7)$$

If $\hbar\omega/4kT$ is large, $I_q/kT > 1$ may well arise although (5) requires $\beta^2/\omega^2\epsilon < 1$. The result in the classical case is similar to (7) except for the factor $\hbar\omega/kT$ so that $I_c < kT$. Outside the resonance region the usual London result $\propto 1/R^6$ obtains; eq. (6) must then be taken to the next order.

If the weak coupling condition (5) is not fulfilled

then according to (1) considerable softening of the mode ω_- may arise. The case $\omega_-^2 < 0$ is, of course, well known from the theory of mode softening in ferroelectrics and will not be considered here. Small but positive ω_-^2 implies that the classical limit only need be considered. According to (4) it may lead to strong attractive interaction but is not sensitive to resonance conditions.

Our main result thus indicates the possibility of strong, frequency selective, long range forces between large systems provided the longitudinal dielectric constant $\epsilon(\omega)$ of the intermediate medium shows appropriate dispersion in the relevant frequency region; the sign of $\partial\epsilon/\partial\omega$ decides whether these forces are attractive or repulsive.

Selective long range forces which are always attractive are obtained if the system is pumped as has been suggested to occur in biological systems through their metabolism [1]. It has been shown then that the lowest frequency in a band of polarisation waves should be very strongly excited. Now at infinite separation of our two systems the frequency of the polarisation waves with zero wave number (responsible for long range interaction) is not in general the lowest one but according to (1), ω_- is depressed at closer approach and this may become the lowest frequency at a distance below a critical one. The interaction then is always negative, (n_- = number of quanta in ω_-)

$$I = (n_- + \tfrac{1}{2})\hbar(\omega_- - \omega_2) \approx$$
$$-\hbar(n_- + \tfrac{1}{2})((\Delta^2 + \beta^4/\epsilon^2)^{\frac{1}{2}} - \Delta)/2\omega_2 \qquad (8)$$

Thus we have found that a system capable of giant dipole vibrations may attract another strongly, and selectively in frequency. The range of this interaction is much larger than that of the more usual forces. At closer distance, however, the behavior of the individual atoms composing the large systems should become more relevant and the highly specific nature of the London forces as demonstrated by Jehle et al. [2] as well as other chemical interaction may become of principal importance. The two aspects are complementary and should be decisive in many aspects of selective and specific interaction of large systems [3,4].

Self-focusing and Ponderomotive Forces of Coherent Electric Waves: A Mechanism for Cytoskeleton Formation and Dynamics

E. DEL GIUDICE[1], S. DOGLIA[2], and M. MILANI[1]

[1] Istituto Nazionale di Fisica Nucleare,
[2] Gruppo Nazionale di Struttura della Materia del C.N.R.,
Istituto di Fisica dell'Università, Via Celoria 16, I-20133 Milano

Coherent electric waves have been predicted to exist in biological systems.(1) We try to link the consequences of their propagation in the cell medium to some peculiar features of cell architecture and organization such as cytoskeleton formation and dynamics.(2) This will give a consistency argument in favour of the existence of coherent electric waves in living systems.(3)

The general ponderomotive force produced by an electric field $\vec{E}$ and a magnetic field $\vec{H}$ acting on a dielectric with polarization $\vec{P}$ and magnetization $\vec{M}$ is given by(4)

$$\vec{f} = \rho\vec{E} + \frac{1}{c}\dot{\vec{j}} \times \vec{H} + (\vec{P}\cdot\nabla)\vec{E} + (\vec{M}\cdot\nabla)\vec{H} + \frac{1}{c}\frac{\partial\vec{P}}{\partial t} \times \vec{H} - \frac{1}{c}\frac{\partial\vec{M}}{\partial t} \times \vec{E} \qquad (1)$$

In a first approach we will drop the terms depending on the magnetization $\vec{M}$ (which is expected to be important only in a specialized class of cells) and we will also omit the linear term arising from the "true" current source $\dot{\vec{j}}$. Therefore

$$\vec{f} = \rho\vec{E} + (\vec{P}\cdot\nabla)\vec{E} + \frac{1}{c}\frac{\partial\vec{P}}{\partial t} \times \vec{H} \qquad (1')$$

In eq. (1') we have the usual linear term $\rho\vec{E}$, the nonlinear term, called the "gradient force" $(\vec{P}\cdot\nabla)\vec{E}$, and the term of "radiation pressure" $\frac{1}{c}\frac{\partial\vec{P}}{\partial t} \times \vec{H}$. Since coherent waves can bring very large values of $\vec{E}$ (of the order of 10^7 V/m), the nonlinear terms of eq. (1') are expected to dominate on the linear one. Consequently, we will drop the first term in the right hand side of eq. (1'). The gradient term can be written as(5)

Coherent Excitations in Biological Systems
Ed. by H. Frõhlich and F. Kremer
© by Springer-Verlag Berlin Heidelberg 1983

$$(\vec{P}\cdot\nabla)\vec{E} = -\ \text{grad}\ p_o(\rho,T) + \frac{1}{8\pi}\ \text{grad}\ E^2\rho\left(\frac{\partial\varepsilon}{\partial\rho}\right)_T + \qquad (2)$$

$$-\frac{1}{8\pi}\ E^2\ \text{grad}\ \varepsilon$$

where ε is the dielectric permittivity of the medium and $p_o(\rho,T)$ is the pressure in the medium in the absence of an external field, at the same volume and temperature T. The pressure gradient term, although relevant in many applications,can be disregarded in a microscopic approach. Moreover, we will use an approximation valid for gaseous media and dilute solutions (as the cytoplasm can be considered in a rough approximation):

$$\rho\frac{\partial\varepsilon}{\partial\rho} \sim (\varepsilon - 1) \qquad (3)$$

After trivial manipulations one gets from eq. (1')

$$\vec{f} = \frac{1}{8\pi}(\varepsilon-1)\nabla E^2 + \frac{1}{c}\frac{\partial\vec{P}}{\partial t} \times \vec{H} \qquad (4)$$

The first term in the right hand side of eq. (4) shows that a high power, strong directional electric wave

$$\vec{E}(\vec{r},t) = \frac{1}{2}\vec{A}(\vec{r},t)\ \exp\left[i(\omega t - \vec{k}\cdot\vec{r})\right] + \text{c.c.}$$

can produce condensation or rarefaction in a medium according to the sign of the coefficient of ∇E^2. This coefficient is a function both of the frequency ω of the beam and of the typical resonance frequencies ω_{ok} of the dielectric. It has been shown[6] that

$$\frac{1}{8\pi}(\varepsilon-1)\nabla E^2 = C\sum_k\left[\frac{\omega_{ok}^2 - \omega^2}{(\omega_{ok}^2 - \omega^2)^2+\Gamma_k^2}\right]\nabla E^2 \qquad (5)$$

where C is some positive constant and Γ_k is the damping of the k-th oscillator. This gradient force is important when the incoming frequency ω approaches ω_o, one of the frequencies of the medium. An attractive (repulsive) force in the direction transverse to the propagation axis of the beam will then be present when $\omega_o > \omega\ (\omega_o < \omega)$.

The gradient force produces then a waveguide in the medium along the intense and directional electric beam, where a condensation of matter takes place. This process eliminates the geometric and diffraction divergences of the beam, leading to a very efficient propagation within the waveguide ("self-focusing").

In order to discuss this kind of propagation, the gradient force can be expressed in terms of the properties of the refractive index of the nonlinear medium[7]. On the basis of the Kerr properties of protein solutions[8], we will consider a "cubic"

medium, i.e. $n = n_o + n_2|A|^2$ ($\varepsilon = \varepsilon_o + \varepsilon_2|A|^2$).

From the Clausius-Mossotti equation for an isotropic medium

$$\frac{n^2-1}{n^2+2} = \frac{4}{3}\pi\rho\alpha \tag{6}$$

where α is the polarizability, we can express the variation Δn (at the lowest order) induced by an electric field $\vec{E}$ as

$$\begin{aligned} \Delta n &= (\Delta n)_\rho + (\Delta n)_\alpha \\ (\Delta n)_\rho &= \frac{1}{2} K_\rho \lambda |A|^2 \\ (\Delta n)_\alpha &= \frac{1}{2} K_\alpha \lambda |A|^2 \\ \lambda &= \frac{2\pi}{n}\frac{c}{\omega} \end{aligned} \tag{7}$$

K_ρ, K_α are the electrostrictive and ac Kerr constants respectively. $(\Delta n)_\rho$ is the variation of the refractive index due to electrostriction; $(\Delta n)_\alpha$ is the variation of the refractive index arising from ac Kerr contribution. It should be noticed[9] that only in the case of non-polar molecules it is possible to approximate the ac Kerr constant K_α with the contribution coming from the induced dipole moments $(K_1)_{dc}$ to the dc Kerr constant; this contribution is always positive whereas the dc Kerr constant K_{dc} can also be negative. For polar molecules with large dipole moments, K_α is in general smaller than the absolute value of the dc Kerr constant. Again we find as it appeared from eq. 2, that the propagation of an electric wave in a nonlinear dielectric is governed by an electrostriction term and by a molecular orientational one(Kerr term). From eqs. (2) and (7) the Kerr contribution appears to depend on ω and can be strongly enhanced when ω approaches a resonant frequency of the medium.

As far as the propagation of the beam is concerned, it can be shown[7] that eq.(7) implies the "self-focusing" of the beam, i.e. the beam shrinks and, after travelling in the medium a critical length

$$R_{nl} = \frac{a}{2}\left(\frac{n_o}{n_2|A|^2}\right)^{\frac{1}{2}}$$

(a being the radius of the cross-section of the beam), gets confined in a thin waveguide ("self-trapping") provided that its power be greater than a critical value

$$P_{cr} = (1.22)^2\lambda^2 c/256\, n_2$$

The above discussion compels us to conclude that coherent electric waves form in the medium a network of waveguides which in turn may attract "selectively" molecules in solution which have appropriate vibrational frequencies. Self-focusing strengthens very much the role of the gradient force by shrinking the beam and steepening its profile. Therefore molecules will experience stronger forces when the conditions

for the beam self-trapping are met. An increase of concentration and an alignment of the solute molecules are then generated around the beam, resulting in a dynamic self-association, which is a requirement for polymerization. It has been recently reported[10] that polymerization can be actually induced by ordering the monomers.

At this point, let us turn to the radiation pressure term in eq.(4). The direction in which this force is exerted depends upon the longitudinal or transversal character of the time dependent electric field : a longitudinal wave produces a force transversal to the direction of propagation whereas in the transversal case the force is directed along the beam axis. As a consequence, in the first case the gradient force will change its magnitude; in the second case, molecules will also be pushed along the beam axis. The interplay between gradient forces and radiation pressure gives rise to an "optical mechanics"as shown by the experiments on laser induced"levitation" performed by Ashkin[11] and on laser isotope separation[12]: biological systems seem to be an excellent lab for such an"optical mecanics".The radiation pressure squeezes then the molecules, selected and attracted by the gradient force, in the waveguide and transports them along it.This squeezing enhances the probability that monomers ordered by the gradient force could polymerize. The contribution of the radiation pressure term to the assembly of the monomers could account for the dynamics of polymerization: the polymer can lose monomers at the end of the self-trapped beam while acquiring them at the opposite end.

The cytoskeleton consists of three different networks of filaments built up with protein (mainly actin and tubulin) polymers. These filaments exhibit a labile character, and their formation and dynamics strictly depend on a number of factors such as cell shape,timing, environment [13,14]. Moreover, a "treadmilling" behaviour has been observed[15]: monomers are assembled at one end of the filament and disassembled at the opposite end, giving rise to a unidirectional flow of matter. These features, insofar unexplained, can thus be accounted for by the ponderomotive forces generated by coherent electric waves propagating in form of filaments in the nonlinear medium.

An evidence for the general character of the proposed model is provided by the experiments on blood clotting[16]; filaments - the so-called contractils - appear when erythrocytes interact among themselves "à la Fröhlich" and an appropriate macromolecule is present in the suspension.

Solitary Excitons in One-Dimensional Molecular Chains

By

A. S. DAVYDOV and N. I. KISLUKHA

The change in time of the state of intramolecular excitation in an one-dimensional molecular chain is investigated, where its deformability is taken into account. It is shown that the excitation which is accompanied by a local deformation of the chain, can move uniformly along the chain, the size of the region under excitation remaining constant. These excitations in one-dimensional molecular chains can be called *particle-like excitons* or *solitary excitons.*

Es werden die zeitlichen Änderungen des intramolekularen Anregungszustandes in einer ein-dimensionalen molekularen Kette untersucht, wobei deren Deformierbarkeit berücksichtigt wird. Es wird gezeigt, daß die Anregung der Kette, die durch eine lokale Deformation begleitet ist, sich gleichförmig längs der Kette bewegen kann, wobei die Größe des angeregten Bereichs konstant bleibt. Diese Anregungen in ein-dimensionalen Molekülketten können *partikel-ähnliche Exzitonen* oder *solitäre Exzitonen* genannt werden.

1. One-Dimensional Molecular Chain

The stationary states of the electron excitation taking crystal lattice deformation into account were considered in [1, 2]. The change of such a state in time is of certain interest. The present paper is devoted to this problem.

Consider a one-dimensional infinite molecular chain. The Hamiltonian of the electron excitation in the Heitler-London approximation has the form (see [3]):

$$H = \sum_n [\varepsilon + D(n)]\, B_n^+ B_n + \sum_{l,n}{}' M_{ln}(r_l - r_n)\, B_n^+ B_n\,, \tag{1}$$

where ε is the excitation energy of an isolated molecule;

$$D(n) = \sum_{l(\neq n)} D_{ln}(r_l - r_n)\,,$$

$D_{ln}(r_l - r_n)$ is the change in the interaction energy between molecules l and n, when the molecule n is excited; $M_{ln}(r_l - r_n)$ are the matrix elements of the resonance interaction; r_n is the coordinate along the chain of the molecule n; B_n^+, B are the creation and annihilation operators of the electronic excitation over the molecule n.

The kinetic energy T of the molecules of the chain is

$$T = \frac{m}{2} \sum_n \left(\frac{\partial r_n}{\partial t}\right)^2, \tag{2}$$

where m is the mass of the molecule.

In the nearest-neighbour approximation the potential energy of the chain is

$$U = \sum_n u(R_n)\,, \tag{3}$$

where $R_n = r_{n+1} - r_n > 0$ are the intermolecular distances;

$$u(R_n) = \frac{C}{R_n^s} - \frac{A}{R_n^q},$$

$C, A, s, q > 0$ are the constants defining the interaction of unexcited molecules; $s > q$.

In the ground state $|0\rangle$ (without intramolecular excitations) the chain possesses periodicity and the intermolecular distances obtained from the condition of a minimum of potential energy (3) are equal to

$$R = \left(\frac{s\,C}{q\,A}\right)^{1/(s-q)}. \tag{4}$$

In the state $|\psi\rangle$ when the intramolecular excitation is present, the intermolecular distances R_n are different from R and the potential energy of the chain changes by the value ΔU, as compared to the energy of the chain in the ground state. In the harmonic approximation

$$\Delta U = \sum_n [u(R_n) - u(R)] \approx w \sum \varrho_n^2, \tag{5}$$

where

$$R_n = R - \varrho_n, \qquad |\varrho_n| < R, \tag{6}$$

$$w = \frac{1}{2}\left[\frac{\partial^2 u}{\partial R_n^2}\right]_{R_n = R}. \tag{7}$$

Taking into account (6), the formula (2) for the kinetic energy of the molecules can be transformed to

$$T = \sum_n \left\{\frac{m}{2}\left[\sum_l \frac{\partial \varrho_{l+n}}{\partial t}\right]^2\right\}. \tag{8}$$

Then the total energy E of the deformation of the chain is written as

$$E = T + \Delta U = \sum_n \left\{\frac{m}{2}\left[\sum_{l=n}^{\infty} \frac{\partial \varrho_l}{\partial t}\right]^2 + w\,\varrho_n^2\right\}. \tag{9}$$

2. The Nearest-Neighbour Approximation

In the nearest-neighbour approximation the operator (1) takes on the form

$$H = \sum_n \{[\varepsilon + D(R_n)]\, B_n^+ B_n + M(R_n)\,[B_n^+ B_{n+1} + B_{n+1}^+ B_n]\}. \tag{10}$$

In (10) we adopt

$$D_{n-1,n}(R_{n-1}) + D_{n+1,n}(R_n) \approx D(R_n),$$

$$M_{n,n+1}(R_n) \approx M_{n+1,n}(R_n) = M(R_n).$$

Let

$$D(R_n) = -\frac{\alpha}{R_n^p}, \tag{11}$$

where $\alpha, p > 0$ are the parameters of theory.

In the case of a dipole–dipole resonance excitation (and only this excitation is considered below)

$$M(R_n) = \frac{b}{R_n^3}. \tag{12}$$

We assume that the dipole moment of transition, $\boldsymbol{d}$ is oriented along the chain. Then in (12) $b = -2d^2$. Suppose that the following inequality is valid for distances close to R:

$$D > M\,, \tag{13}$$

where $D \equiv -D(R) > 0$; $M \equiv -M(R) > 0$. Using (6), (11), and (12), $D(R_n)$ and $M(R_n)$ in (10) can be expanded near the point R. In $D(R_n)$ we keep only the term linear in ϱ_n, and in $M(R_n)$ the zero term, i.e. we set $D(R_n) \approx \approx -(1 + p\,\varrho_n/R)\,D$, $M(R_n) \approx -M$. Then (10) takes the form

$$H = \sum_n \{[\varepsilon + (1 + p\,\varrho_n/R)\,D]\,B_n^+\,B_n - M\,[B_n^+\,B_{n+1} + B_{n+1}^+\,B_n]\}\,. \tag{14}$$

The operator $\mathcal{H}$ of the excitation energy of the chain with its deformation energy taken into account reads

$$\mathcal{H} = H + E\,. \tag{15}$$

The solutions of the Schrödinger equation

$$i\,\hbar\,\frac{\partial}{\partial t}\,|\Psi(t)\rangle = \mathcal{H}\,|\Psi(t)\rangle \tag{16}$$

are looked for in the form

$$|\Psi(t)\rangle = \sum_n a_n(t)\,B_n^+|0\rangle \tag{17}$$

provided

$$\langle\Psi(t)|\Psi\rangle = \sum_n |a_n(t)|^2 = 1\,. \tag{18}$$

The operator (15) is the function of a set of the values of ϱ_n. Moreover, these values are dependent on the state $|\Psi(t)\rangle$.

In the region of the chain where the density of the probability of finding the excitation $|a_n(t)|^2$ is great, one should expect greater deformation of the chain which is defined by the values of ϱ_n. From the condition of a minimum of the total excitation energy $\langle\Psi(t)|\Psi(t)\rangle$ at every fixed moment of time t, and the fact that $\partial\varrho_n/\partial t$ is independent of ϱ_n, we find

$$\varrho_n = \frac{p\,D}{2\,w\,R}\,|a_n(t)|^2\,. \tag{19}$$

Substituting (19) into (14), we obtain

$$H = \sum_n \{[\varepsilon - D]\,B_n^+\,B_n - M\,[B_n^+\,B_{n+1} + B_{n+1}^+\,B_n] - G\,|a_n(t)|^2\,B_n^+\,B_n\}\,, \tag{20}$$

where $G = p^2\,D^2/2\,w\,R^2$ is the parameter of nonlinearity. Further, according to (9) and (19)

$$E = \frac{1}{2}\sum_n \left\{F\left[\sum_{l=n}\frac{\partial}{\partial t}\,|a_l(t)|^2\right]^2 + G\,|a_n(t)|^4\right\}, \tag{21}$$

where

$$F = \frac{m\,G}{2\,w}.$$

Now the equation (16) takes the form

$$\sum_n \left\{i\,\hbar\,\frac{\partial a_n(t)}{\partial t} + e\,a_n(t) - M\,[a_{n+1}(t) + a_{n-1}(t)] - G\,|a_n(t)|^2\,a_n(t)\right\} B_n^+|0\rangle = 0\,, \tag{22}$$

where

$$e = \varepsilon - D + E \,.$$

Using (22) and the fact that the system $B_n^+|0\rangle$ is complete and orthogonal, we obtain the equation for $a_n(t)$

$$i\hbar \frac{\partial a_n(t)}{\partial t} + M\,[a_{n+1}(t) + a_{n-1}(t)] - e\,a_n(t) + G\,|a_n(t)|^2\,a_n(t) = 0\,. \tag{23}$$

In (23) we go over to a long-wave approximation and replace the differences by the derivatives. Thus

$$a_n(t) \to \varphi(\xi, t)\,, \qquad \varphi(n, t) = a_n(t)\,, \tag{24}$$

$$\varphi(\xi + 1, t) + \varphi(\xi - 1, t) \approx 2\,\varphi(\xi, t) + \frac{\partial^2 \varphi(\xi, t)}{\partial \xi^2}\,, \tag{25}$$

where $\xi = r/R$ is the dimensionless coordinate. Then the differential-difference equation (23) transforms to

$$i\hbar \frac{\partial \varphi}{\partial t} + M \frac{\partial^2 \varphi}{\partial \xi^2} - \lambda\,\varphi + G|\varphi|^2\,\varphi = 0\,, \tag{26}$$

where

$$\lambda \equiv \varepsilon - D - 2\,M + \frac{1}{2}\int_{-\infty}^{\infty} \mathrm{d}\xi \left\{ F\left[\int_{\xi}^{\infty} \mathrm{d}\eta \frac{\partial}{\partial t}\,|\varphi(\eta, t)|^2 \right]^2 + G\,|\varphi(\xi, t)|^2 \right\}, \tag{27}$$

3. The Particle-Like Excitation

The normalized solution of the nonlinear equation (26) has the form of a solitary wave

$$\varphi_v(\xi, t) = \frac{\sqrt{\frac{\mu}{2}} \exp\left\{ i \left[\frac{\hbar\, v}{2\,M} (\xi - \xi_0) - \Omega\, t \right] \right\}}{\cosh\left[\mu\,(\xi - \xi_0 - v\,t)\right]}\,, \tag{28}$$

where

$$\mu = \frac{G}{4\,M}\,,$$

$$\hbar\,\Omega = \varepsilon - D - 2\,M - \frac{G^2}{48\,M} + \frac{m^*\,R^2\,v^2}{2}\,, \tag{29}$$

$$m^* = m_0^* + m_{\mathrm{d}}^* = \frac{\hbar^2 + (G\,F/6)}{2\,M\,R^2}\,; \tag{29a}$$

$m_0^* = \hbar^2/2\,M\,R^2$ is the effective mass of the excitation in the chain with rigidly fixed molecules; $m_{\mathrm{d}}^* = m\,G^2/24\,M\,w\,R^2$ is the addition to the effective mass which is caused by a local deformation.

According to (28), the excitation is localized in the neighbourhood $\xi = \xi_0 + v\,t$. Consequently, the parameter defines the velocity $V = v\,R$ of the excitation motion along the chain. To every value of v there corresponds an excitation energy of the chain, $\hbar\,\Omega$. The excitation localized near the point ξ_0 corresponds to the value $v = 0$. Its energy $\varepsilon - D - 2\,M - G^2/48\,M$ is less by the value $G^2/48\,M$ than the excitation energy of the chain with rigidly fixed molecules.

Using (19), we find that in the excitation region the equilibrium distances between molecules decrease by the value

$$\varrho(\xi, t) = \frac{\sqrt{\frac{G}{2w}}\frac{\mu}{2}}{\cosh^2[\mu(\xi - \xi_0 - vt)]}. \tag{30}$$

Thus, an appreciable change in the distances between the molecules, which is proportional to the parameter μ, spreads over the region

$$\Delta\xi = \frac{\pi}{\mu} = \frac{4\pi M}{G} \tag{31}$$

around the point $\xi_0 + vt$. This region travels with constant speed along the chain. The average distance between the molecules in the excitation region is

$$\langle R_n \rangle \approx R - 0.3\mu\sqrt{\frac{G}{2w}}. \tag{32}$$

Therefore, when the inertia and deformability of a chain is taken into account, the motion of the excitation is accompanied by a local distortion of the chain and the velocity V of an excitation decreases, as the effective mass (29a) increases.

Unlike the states of motion of free particles described by wave packets, the excitation state corresponding to the function (28) does not "spread" in the course of time. These excitations in one-dimensional molecular chains can be called *particle-like excitons*, or solitary excitons.

The long-wave approximation used by us requires that the inequality $\Delta\xi > 1$, i.e. $\mu = G/4M < \pi$ is satisfied. On the other hand, for the particle-like excitons the following inequality should be valid:

$$\Delta\xi \ll N \quad \text{i. e.} \quad \mu > \frac{\pi}{N},$$

where N is the total number of molecules in the chain; $N \gg 1$.

At the very small values of the parameter μ ($\mu \ll 1$) the expression (25) can be transformed to the form of a simple harmonic wave

$$\varphi_v(\xi, t) \approx \sqrt{\frac{\mu}{2}} \exp\left\{i\left[\frac{\hbar v}{2M}(\xi - \xi_0) - \Omega t\right]\right\}.$$

Consequently, in this limiting case the excitation is practically nonlocalized.

Excitations such as (28) can arise in the chain under the influence of an external perturbation $\Phi(\xi, t)$ which satisfies the inequality

$$\int \Phi(\xi, t)\, \varphi_v^*(\xi, t)\, d\xi \neq 0.$$

We have not taken into account the processes of relaxation of the arising excitation. Phenomenologically the relaxation processes can be taken into account by replacing the excitation energy (26) by the complex value $\hbar\Omega - i\hbar\gamma$. Then an exponentially decreasing factor $\exp(-\gamma t)$ appears in the function (28) determining the average life-time $(1/\gamma)$ of the excitation.

Solitonic Ionic Currents Along Microtubules

M. V. Satarić, D. Sekulić*, and M. Živanov

Faculty of Technical Sciences, University of Novi Sad, Trg D. Obradovića 6, 21000 Novi Sad, Serbia

Microtubules are very important cytoskeletal structures implicated in different cellular activities. We should mention the cell division and traffic of organelles (mitochondria, vesicles and other cargos) by kinesin and dynein motor proteins. Microtubules are also playing important roles in higher neuronal functions including mechanisms of consciousness and memory. We here investigate the circumstances and the conditions enabling microtubules to act as nonlinear electrical transmission lines for ions flow along their cylinders. We established a model in which each tubulin dimmer protein is an electric element with a capacitive, resistive and negative incrementally resistive property due to polyelectrolyte nature of microtubules in cytosol. The particular attention was paid to the role of nano-pores existing between neighboring dimmers within a MT wall which exhibit properties like ionic channels. These nano-pores are candidates to explain some properties of microtubules resembling to unipolar transistors enabling the rectification and amplification of ionic currents.

Keywords: Cytoskeleton, Microtubule, Polyelectrolyte, Nonlinear Transmission Line, Ionic Waves, Soliton, Nano-Pore.

1. INTRODUCTION

The cytoskeleton consists of three mayor types of thin rod-like filaments that span the cytoplasm: actin-based filaments (i.e., microfilaments), tubulin-based filaments (i.e., microtubules-MTs) and intermediate filaments (e.g., neurofilaments-keratin). There are at list three well-studied mechanical functions of the cytoskeleton *in vivo*, providing the mechanical strength of the cell, segregating the chromosomes and participating in the cellular traffic.[1]

MTs are long and rigid tubulin polymers. They are the key protein filaments that form several μm long hollow cylinders typically $d = 25$ nm in outer diameter, Figure 1, and exhibit dynamically unstable polymerization kinetics.

MTs are formed as ferroelectric polymers whose building block is a protein called tubulin. The hollow cylindrical wall of a MT is made up of parallel chains or protofilaments of tubulin-hetero-dimer. Each dimer, 8 nm in length, is composed of two units, a α-tubulin and a β-tubulin monomer. Each MT is generally made up of 13 protofilaments *in vivo*. Every tubulin monomer of the MT cylinder has a C-terminal helix, H12, followed by a highly acidic amino-acid sequence protruding out of the MT outer surface and called C-terminus tail (TT). The TTs sequences have length $l_{TT} = 4{,}5$ nm when completely outstretched. The TTs are being essential for MT interactions whit MT associated proteins and motor proteins, (kinesin and dynein).[2,3] More details about TTs structures and properties can be found in Ref. [4]. The shape of tubulin dimer with pertaining TTs is presented in Figure 2, including the detailed charge distributions on the tubulin surface calculated by team lead by Tuszynski.[5]

At neutral pH the negative charge on TT causes it to remain extended due to electrostatic repulsion. Under more acidic conditions the negative charges of pertaining amino acids within TT are partially neutralized by counter-ions condensed on them. This effect allows the β-TTs to be compacted by folding, as shown in Figure 3.

This is the largest structural effect in MTs and this fact has the great importance in establishing of our model with respect to the variable effective electrical capacitance of MTs. The detailed charge distribution on the MT surface, calculated in Ref. [5], enabled the determination of an electrostatic potential around a MT. It exhibits non-uniformity along the MT radius with a peak and a trough corresponding to every of 13 protofilaments and the area between them populated with mentioned nano-pores. These findings play an essential role in presented modeling of MT as a "coaxial cable" for intracellular communication.

In as much MTs are mostly negatively charged on their outer surface they are true polyelectrolyte polymers. This is the consequence of the fact that numerous amino acids forming tubulin have many negatively charged residues under physiological conditions, as was already stressed for TTs. Thus the conditions for application of Manning's theory[6] are provided enabling "condensation" of positive

counter-ions near the negative surface of MT landscape. As a result, every MT attracts positive counter-ions in narrow shell (ionic cloud-IC) near its surface, while negative ions of the cytosol are being repelled such that a roughly

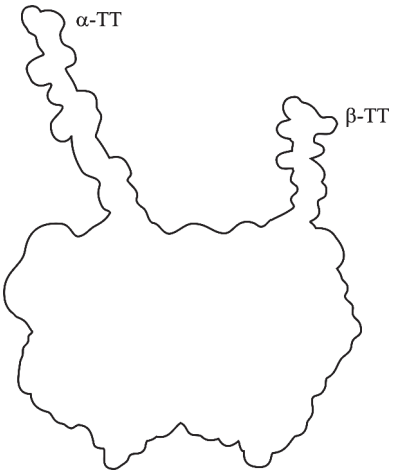

Fig. 3. The shape of TTs, where β-TT is being shrank, thus diminishing its capacity.

cylindrical depletion area around a MT is being created, Figure 4. The thickness of this depleted area is defined by so-called Bjerrum length, which is the distance from the MT surrounding IC at which the Coulomb energy of the screened surface charges equals the thermal energy

$$\frac{e^2}{4\pi\varepsilon_o\varepsilon l_B} = k_B T \tag{1}$$

Here e is the charge of an electron, ε_0 the permittivity of vacuum, ε the relative permittivity of cytosol and k_B is Boltzmann's constant. At a physiological temperature of $T = 310$ K, and taking $\varepsilon = 80$, it is clear from Eq. (1) that we have

$$l_B = 6.7 \times 10^{-10} \text{ m} \tag{2}$$

On the other hand, the thickness of the IC of positive counter-ions is dictated by the surface landscape and by its negative charge distributions. In the case of actin filament, Pollard and Cooper[6] estimated that the radius of IC is of the order of 8 nm, while the filament radius is 2.5 nm, giving IC thickness of 5.5 nm. From the best of our knowledge the evidences for MTs IC thickness are still missing but we anticipate that the corresponding value should be of the order of 2 nm since the surface of MTs is pretty less negative than in actin filament. Significant ionic movements within this bound IC are therefore allowed along the length of the MT provided that it is shielded from the bulk solution by the depletion layer of thickness l_B.

Bearing in mind the IC geometry around the MT we see that effectively MTs may act as biological "electrical wires" which can be modeled as nonlinear inhomogeneous transmission lines that are able to propagate nonlinear dispersive ionic waves. First attempts to elaborate the cytoskeleton as a network of nonlinear polyelectrolyte transmission lines are made by Tusyznski et al.,[7] for actin filaments, and later further elaborated by Sataric et al.[8] Similar approach was applied for MTs in Ref. [4]. Here

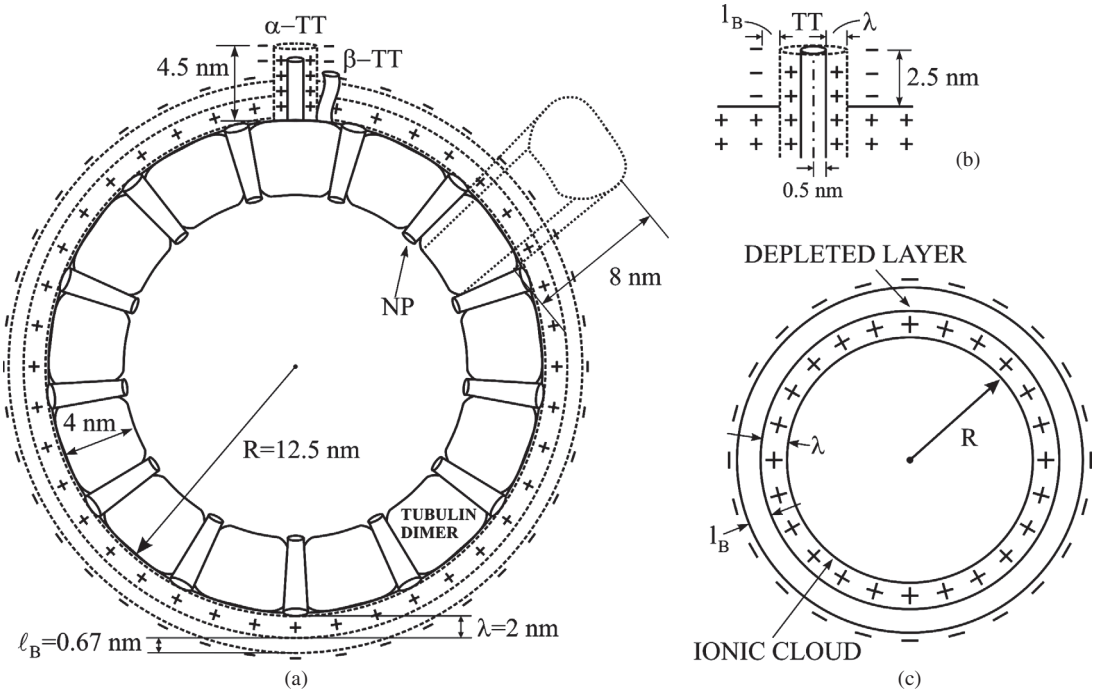

Fig. 4. The geometry of a MT with ionic cloud and depleted layer clearly depicted, including corresponding dimensions: the thickness of IC $\lambda = 2$ nm and Bjerrum length $l_B = 0.67$ nm. The top part of (a) shows α and β TTs.

we further amend the model introduced in Ref. [4] paying particular attention on the role of nano-pores (NPs) embedded in MT wall. In that respect we partially relied on the results published by the group lead by Eisenberg,[9, 10] which emphasize the particular role of calcium ions in dynamics of NPs.

Some fifteen years ago, Lin and Cantiello[11] performed an assay demonstrating that IC waves along a single actin filament were highly nonlinear in nature exhibiting the wave patterns remarkably similar to recorded solitary waveforms from various experimental studies on electrically stimulated nonlinear transmission lines.[12] Recently Tuszynski and Cantiello[13] conducted similar experiment on single MT which even manifested transistor-like amplification of electrical signals. It is our objective in this article to amend our earlier model[3, 4] in order to explain these features of MTs and their possible role in information processing within neurons.

The paper is organized in the following way:

In the Section 2 we reexamined the estimations of elementary capacitance, inductance and resistance components of elementary MT ring and elaborated the role NPs.

The Section 3 is dedicated to the modeling of each MT as a nonlinear C–R–G transmission line and evaluating KdV- like equation and its solution.

Section 4 deals with the influence of viscous dissipation and intrinsic electrical field on the dynamics of ionic solitons along MTs.

The Last section offers the conclusions regarding this interesting physical mechanism in terms of the cell's electrical activity provided by the MTs and their interactions with ions from MT lumen.

2. THE ELEMENTS OF A MT AS AN ELECTRIC TRANSMISSION LINE

The basic assumption is that a MT with condensed counter-ions is separated from the rest of the ions in the bulk solution by a depleted layer which plays the role of a dielectric medium located between MTs and the cytosol solution. This IC is electro-conductive medium responsible for electrical properties of MT. The depleted layer provides that IC and repelled ions represent the "conductive plates" of cylindric capacitor. The ions injected from appropriate cell's compartment are confined to flow parallel with MTs within the IC of the supposed thickness $\lambda = 2$ nm. We here pay particular attention to the case where calcium ions are injected within IC.

2.1. The Capacitance of a MT Elementary Ring

The elementary ring (ER) consists of 13 dimers, Figure 4(a), forming the ring of radius of 12.5 nm and of length $l = 8$ nm. On the basis of the Poisson-Boltzmann equation the detailed derivation given in Ref. [4] yielding the basic capacity of such cylindric ER as follows

$$C_0 = \frac{2\pi\varepsilon_0\varepsilon l}{\ln(1 + (l_B/R))} \tag{3}$$

RESEARCH ARTICLE

where $l = 8 \times 10^{-9}$ m is length of an ER, (length of one tubulin dimer), $\varepsilon_0 = 8.85 \times 10^{-12}$ F/m, $\varepsilon = 80$, $l_B = 0.67 \times 10^{-9}$ m. In contrast to,[4] we here take $R = (d/2 + \lambda) = (12.5 + 2)$ nm leading to elementary capacity:

$$C_0^{(1)} = \frac{6.8 \times 8.85 \times 10^{-12} \times 80 \times 8 \times 10^{-9}}{\ln(1 + (0.67/14.5))} = 0.8 \times 10^{-15} \text{ F} \tag{4}$$

In the same way, we consider an extended TT as a smaller cylinder with the length $l_{TT} = 4.5$ nm and the radius $R_{TT} = 0.5$ nm giving $R = R_{TT} + \lambda = 2.5$ nm. From formula (3) we calculate an additional capacity $C_0^{(2)}$ for $n = 13 \times 2 = 26$ TTs, contained in the same ER, composed of 13 dimers, see Figure 4(a), top position, and Figure 4(b).

The length of each TT capacitor is now $l_{eff} = (4{,}5\text{-}2)$ nm $= 2.5$ nm, since 2 nm are embedded in part of already calculated capacitor $C_0^{(1)}$

$$C_0^{(2)} = \frac{26 \times 6.28 \times 8.85 \times 10^{-12} \times 80 \times 2.5 \times 10^{-9}}{\ln(1 + (0.67/2.5))} = 1 \times 10^{-15} \text{ F} \tag{5}$$

Two above capacities are being connected in parallel, so the total maximal capacity of the ER is now estimated to be

$$C_0 = C_0^{(1)} + C_0^{(2)} = 1.8 \times 10^{-15} \text{ F} \tag{6}$$

It was already mentioned that the increase of negative voltage should increase the concentration of positive counter-ions in IC. These ions additionally condense on the surface of a MT and on its TTs. This brings about β-TTs to shrink diminishing their effective length $l_{eff} = 4.5$ nm, and thus the capacity $C_0^{(2)}$. It is reasonable to assume that this change of capacity is linear with respect to the applied voltage. This circumstance is of fundamental importance for establishing of an adequate model of MTs as nonlinear transmission lines for ionic currents. It will be elaborated in next Section in details.

2.2. The Effective Inductance of an ER in MT

The straightforward calculation performed in Ref. [4] revealed that the order of magnitude of the inductance of an ER in MT is of the order of $L \sim 10^{-15}$ H. This is very small value regarding pertaining reactive resistance. For example, if the frequency ω is of the order of MHz we have $\omega L \sim 10^{-9}$ Ω while capacitive impedance amounts $1/(\omega C) \sim 10^{9}$ Ω. Similar discrepancy holds for the energies of corresponding fields

$$\frac{1}{2} L i^2 \ll \frac{1}{2} C_0 v^2 \tag{7}$$

since i is of the order of nA and v of the order of several mV. Thus, the role of inductance in this model could be safely ignored. This circumstance removes the discrepancy between estimated wave velocity obtained for ionic current along actin filament[14] and the experimental evidences.

2.3. The Ohmic Resistance of an ER in MT

We here safely rely on recently published experimental findings, regarding electro-orientation method, performed by MTs *in vitro*.[15] This assay provided the value of MT conductivity as follows:

$$\sigma = (0.15 \pm 0.01) \frac{S}{m} \tag{8}$$

If we now take that the resistivity within an IC around a MT (with the thickness λ) is roughly homogeneous, the resistance of the ER with length $l = 8 \times 10^{-9}$, and the area $A = 2\ \pi R \lambda$, see Figures 4(a, c), is estimated to be of the order of:

$$R = \frac{1}{\sigma} \frac{l}{2\pi R \lambda} = \frac{8 \times 10^{-9}}{0.15 \times 2\pi \times 12.5 \times 10^{-9} \times 2 \times 10^{-9}} \ \Omega = 0.34 \times 10^{9}\ \Omega \tag{9}$$

2.4. The Nano-Pores in MT

The structural design of the MT is remarkable in terms of its biological functions. By cryoelectron microscopy, the group led by Nogales,[16] performed an assay which clearly revealed that between tubulin dimers within MT wall the conical NPs of about 1.7 nm in diameter exist, Figure 5. These NPs are characterized by the presence of the α-helix, H6, which can move down in MT structure increasing the effective size of the holes enhancing the diffusion of small ligands and ions into the MT lumen and vice versa. It could be expected that this movement may be controlled by physiological conditions.

We believe that NPs in MT are not just tubes that allow diffusion across it, but more sophisticated molecular machines able to respond on the changes in their environment and undergo precisely timed conformational change in order to be selective and to tune electric currents and signals confined within considered IC.

For comparison, it is well known that some ionic channels in cell membrane are being gated by ATP hydrolysis.[17] We could speculate that in the case of NPs in MTs the hydrolysis of GTP ligand binding process could cause the mentioned movement of H6, thus gating them. Such closed NPs are being open after an activation signal (in this case electrical) passes by. We here pay attention

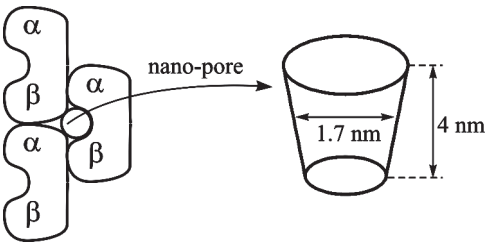

Fig. 5. The sketch of a NP with approximates shape and dimensions, the conical shape follows from MT geometry.

RESEARCH ARTICLE

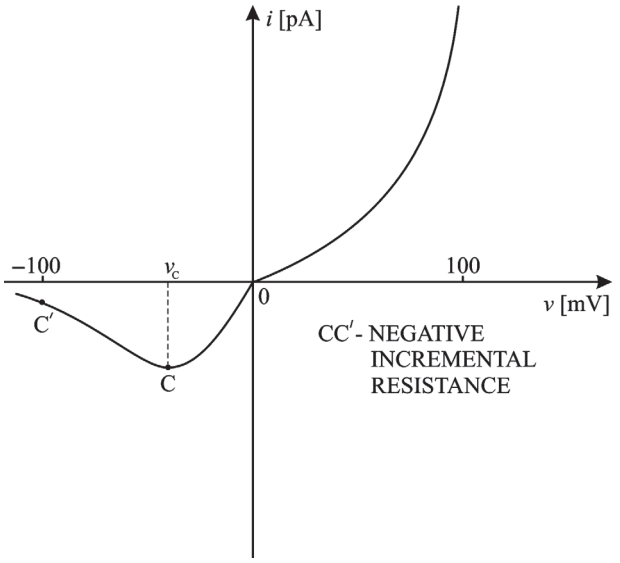

Fig. 6. The qualitative shape of current–voltage characteristics for NPs in the context of Eisenberg's group's work.[9,10] The segment CC′ shows the negative incremental resistance.

on the possible role of calcium ions which are good candidates for being injected from endoplasmic reticulum, and thus transported along MTs.

The group lead by Eisenberg[9,10] examined an artificial single asymmetric conical ionic NP-system whose rectifying properties for ionic current are changed dramatically by addition of a small concentration of calcium ions. They suggest that binding and unbinding of calcium ions to the pore walls produces pumping of potassium ions, by a flashing-rachet mechanism. This simplified case could suggest that we envisage NPs in MT as possible candidates for this kind of calcium-induced voltage gating. Nevertheless NPs in MTs are much more complex because the potential across the NP is a dynamic variable, hence the conductive properties of the pore must vary accordingly.

We could start this segment by the fact that voltage–current functions for mentioned artificial NPs with calcium-gating exhibit negative incremental resistance for a specific domain of sufficient negative voltage across NPs, Figure 6, section C–C′.[9,10] The threshold voltage v_c depends on calcium concentration and on overall characteristics of NPs. But we will later include the effects of nonlinear dynamical variations of NPs conductivity within MT.

3. THE MODEL OF MT AS A NONLINEAR TRANSMISSION LINE

On the basis of above estimations for the resistive components of the ER of a MT we are now in the position to establish the corresponding model. We consider a long transmission line (or ladder networks) composed of lumped sections equal to ERs. A typical section scheme is shown in Figure 7.

The longitudinal current is represented by the series of negligible inductance L_n and ohmic resistance R_n for one ER, as being estimated in previous section. The nonlinear capacity charged with Q_n is in parallel with total conductance of all NPs, G_n contained in an ER of the length $l = 8$ nm. This is because we consider the bulk cytosol and MT lumen as grounded. Applying Kirchoff's low to ladder of ERs, envisaged to represent coupled electrical circuits, we have

$$i_n - i_{n+1} = \frac{\partial Q_n}{\partial t} + G_n v_n \tag{10}$$

$$v_{n-1} - v_n = R_n i_n \tag{11}$$

We already stressed that the ER's capacitance C_0 must change with an increasing concentration of counter-ions due to the shrinking of flexible β-TTs. This implies that the charge on this capacitor diminishes with increased voltage in a nonlinear way as follows:

$$Q_n = C_0(1 - bv_n)v_n \tag{12}$$

where b is expected to be small enough ($bv_n \ll 1$) since the change of the area of a β-TT is small compared with total

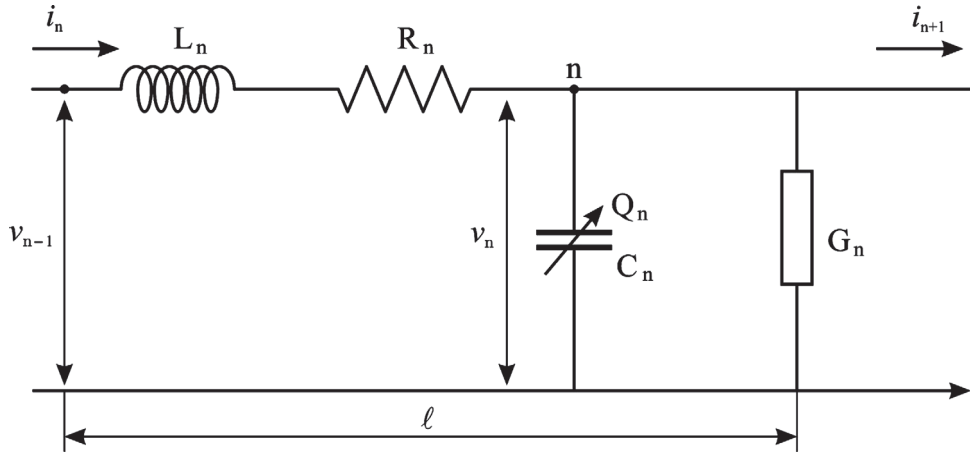

Fig. 7. An effective circuit diagram for the n-th ER with characteristic elements for Kirchoff's laws.

outer surface of the corresponding tubulin dimmer plus surface of α-TT. Now, we pay attention on the role of NPs in the context of negative incremental resistance (conductance) discovered by Eisenberg's group.[9, 10] We upgraded this idea by choosing the conductance of NPs to have the form dependent of voltage

$$G_n = -G_0\left(1-\beta\frac{dv_n}{dt}\right) \tag{13}$$

thus bringing an additional nonlinearity of system.

Replacing (12) and (13) in Eq. (10), one gets

$$i_n - i_{n+1} = -G_0 v_n + C_0\frac{\partial v_n}{\partial t} + \beta G_0 v_n\frac{\partial v_n}{\partial t} - 2bC_0 v_n\frac{\partial v_n}{\partial t} \tag{14}$$

$$v_{n-1} - v_n = R_n i_n \tag{15}$$

We now introduce the characteristic impedance of our system

$$Z = \frac{1}{C_0\omega} \tag{16}$$

and establish new function $u(x, t)$, unifying voltage and current as follows

$$u_n = Z^{1/2} i_n = Z^{-1/2} v_n \tag{17}$$

Bearing in mind that voltage v_n and current i_n change gradually from ER_n to its neighbors, we can safely expand u_n in a continuum approximation using a Taylor serie in terms of a small spatial parameter l (the length of a dimmer):

$$u_{n\pm1} = u \pm l\left(\frac{\partial u}{\partial x}\right) + \frac{l^2}{2!}\left(\frac{\partial^2 u}{\partial x^2}\right) \pm \frac{l^3}{3!}\left(\frac{\partial^3 u}{\partial x^3}\right) + \frac{l^4}{4!}\left(\frac{\partial^4 u}{\partial x^4}\right) \pm \ldots \tag{18}$$

By using Eqs. (16–18), system of Eqs. (14) and (15) now reads

$$\frac{\partial u}{\partial x} + \frac{l}{2}\frac{\partial^2 u}{\partial x^2} + \frac{l^2}{6}\frac{\partial^3 u}{\partial x^3} + \frac{l^3}{24}\frac{\partial^4 u}{\partial x^4} + \frac{l^4}{120}\frac{\partial^5 u}{\partial x^5} - G_0 Z u + \frac{ZC_0}{l}\frac{\partial u}{\partial t} + \frac{\beta Z^{3/2} G_0}{l} u\frac{\partial u}{\partial t} - \frac{2bZ^{3/2}C_0}{l} u\frac{\partial u}{\partial t} = 0 \tag{19}$$

$$\frac{\partial u}{\partial x} - \frac{l}{2}\frac{\partial^2 u}{\partial x^2} + \frac{l^2}{6}\frac{\partial^3 u}{\partial x^3} - \frac{l^3}{24}\frac{\partial^4 u}{\partial x^4} + \frac{l^4}{120}\frac{\partial^5 u}{\partial x^5} - \frac{RZ^{-1}}{l} = 0$$

Adding last two equations and neglecting terms beyond the order of l^5, we get

$$2\frac{\partial u}{\partial x} + \frac{l^2}{3}\frac{\partial^3 u}{\partial x^3} + \frac{1}{l}\left(RZ^{-1} - G_0 Z\right)u + \frac{ZC_0}{l}\frac{\partial u}{\partial t} + \left(\frac{\beta Z^{3/2} G_0}{l} - \frac{2bZ^{3/2}C_0}{l}\right)u\frac{\partial u}{\partial t} = 0 \tag{20}$$

We proceed by imposing the condition that third term in above equation should be zero

$$(RZ^{-1} - G_0 Z) = 0 \tag{21}$$

This condition enables that the ohmic loss could be balanced by fresh ions injected from NPs since these act as ionic pumps in suitable voltage regime.

It is now the important step to go over to dimensionless variables. In that respect, we introduce the characteristic scales of time and length. The characteristic time of charging ER-capacitor C_0 is $\tau = RC_0$. Taking the values of Eqs. (6) and (9), we have

$$\tau = 0.34\times10^{9}\times1.8\times10^{-15}\ \text{s} = 0.6\times10^{-6}\ \text{s} \tag{22}$$

The characteristic velocity of spreading the ionic wave is $v_0 = l/\tau$, which yields

$$v_0 = \frac{8\times10^{-9}}{0.6\times10^{-6}} = 13.3\ \frac{\text{mm}}{\text{s}} \tag{23}$$

Now we will use the standard travelling-wave form for unified function $u(x, t)$:

$$u(x,t) = u\left(\frac{x}{l} - v\frac{t}{l}\right) = u\left(\frac{x}{l} - \frac{v}{v_0}v_0\frac{t}{l}\right) = u\left(\frac{x}{l} - s\frac{t}{\tau}\right);\quad s = \frac{v}{v_0} \tag{24}$$

Introducing joined space-time dimensionless variable

$$\xi = \frac{x}{l} - s\frac{t}{\tau} \tag{25}$$

we have

$$\frac{\partial u}{\partial x} = \frac{1}{l}\frac{du}{d\xi};\quad \frac{\partial^3 u}{\partial x^3} = \frac{1}{l^3}\frac{d^3 u}{d\xi^3};\quad \frac{\partial u}{\partial t} = -\frac{s}{\tau}\frac{du}{d\xi} \tag{26}$$

It brings Eq. (20) into the form of ordinary differential equation, as follows

$$\frac{d^3 u}{d\xi^3} - 3\left(\frac{ZC_0 s}{\tau} - 2\right)\frac{du}{d\xi} + 3\frac{(2Z^{3/2}bC_0 - Z^{3/2}\beta G_0)s}{\tau} u\frac{du}{d\xi} = 0 \tag{27}$$

If we go back to the definition $u = Z^{1/2} i$, and then introduce the dimensionless current $W = i/i_0$, with i_0 being the peak value, we have

$$u = Z^{1/2} i_0 W = Z^{1/2} i \tag{28}$$

Inserting Eq. (28) into (27) yields

$$\frac{d^3 W}{d\xi^3} - 3\left(\frac{ZC_0 s}{\tau} - 2\right)\frac{dW}{d\xi} + 3\frac{i_0 s}{\tau}(2Z^2 bC_0 - Z^2\beta G_0)W\frac{dW}{d\xi} = 0 \tag{29}$$

Introducing the abbreviations

$$A = 3\left(\frac{ZC_0 s}{\tau} - 2\right); \quad B = 3\frac{i_0 s}{\tau} Z^2 (2bC_0 - \beta G_0) \quad (30)$$

we have

$$\frac{d^3W}{d\xi^3} - A\frac{dW}{d\xi} + BW\frac{dW}{d\xi} = 0 \quad (31)$$

After two successive integrations with the appropriate boundary conditions as follows

$$W_\infty = \left(\frac{dW}{d\xi}\right)_\infty = 0$$

one gets

$$\frac{dW}{d\xi} = \left(\frac{B}{3}\right)^{1/2} (DW^2 - 2W^3)^{1/2}; \quad D = \frac{3A}{B} \quad (32)$$

By introducing the new variable y

$$W = \frac{1}{2} D \cos h^2(y) \quad (33)$$

we finally obtain

$$W = \left[\frac{3(s\sigma - 2)}{s\sigma i_0 Z(2b - \beta(G_0/C_0))}\right] \times \sec h^2\left\{\frac{1}{2}\left[\frac{3}{2}(s\sigma - 2)\right]^{1/2}\left(\frac{x}{l} - s\frac{t}{\tau}\right)\right\} \quad (34)$$

with

$$\sigma = \frac{ZC_0}{T} \quad (35)$$

Let us estimate the dimensionless parameter σ. Starting from $Z = 1/C_0\omega$ we get $\sigma = 1/\tau\omega$. If we choose the moderate frequency of range $\omega = 10^4$ s^{-1}, which is based on the fact that the characteristic oscillations of ionic currents in Ref. [13] are of the order of kHz. Combining it with Eq. (22), it readily follows

$$\sigma = \frac{1}{6 \times 10^{-7} \times 10^4} = 1.67 \times 10^2 \quad (36a)$$

Accordingly the pertinent impedance reads

$$Z = \frac{1}{C_0\omega} = 5.56 \times 10^{10}\ \Omega \quad (36b)$$

Taking from the definition $i = i_0 W$, the IC current now has the form:

$$i(x,t) = \left[\frac{3(s\sigma - 2)}{s\sigma Z(2b - \beta(G_0/C_0))}\right] \sec h^2\left\{\frac{1}{2}\left[\frac{3}{2}(s\sigma - 2)\right]^{1/2}\left(\frac{x}{l} - s\frac{t}{\tau}\right)\right\} \quad (37)$$

This solution we will call ionic cloud soliton (ICS). It is apparent that down-limit of it velocity follows from the necessary condition

$$s\sigma - 2 > 0 \quad (38)$$

yielding

$$s \geq 1.2 \times 10^{-2} \quad (39)$$

Relying on Eq. (23) we now have the inequality for the speed of ICS

$$v > 0.16\ \frac{\text{mm}}{\text{s}} \quad (40)$$

Interestingly that the upper limit of ICS speed also exists on the basis of condition that its minimal width d can not be smaller of the length of one ER:

$$d = \frac{l}{1/2[(3/2)(s\sigma - 2)]^{1/2}} \geq l; \quad s\sigma \leq \frac{14}{3} \quad (41)$$

It gives

$$s \leq 2.8 \times 10^{-2} \text{ or } v \leq 0.34\ \frac{\text{mm}}{\text{s}} \quad (42)$$

Thus we get a pretty narrow window of possible solitonic speeds

$$(0.16 \leq v \leq 0.34)\ \frac{\text{mm}}{\text{s}} \quad (43)$$

In the other hand, using the balance condition, Eq. (21) we may estimate the negative conductance of NPs contained in an ER:

$$G_0 = \frac{R}{Z^2} = \frac{3.4 \times 10^8 \Omega}{5.6^2 \times 10^{20} \Omega^2} = 1{,}1 \times 10^{-13}\ \text{Si} \quad (44)$$

The order of magnitude of corresponding current is

$$i_{\text{NP}}^{(13)} = vG_0 = 0.1\ \text{V} \times 1{,}1 \times 10^{-13}\ \text{Si} = 1,1 \times 10^{-14}\ \text{A} \quad (45)$$

If the conductance nonlinearity parameter (βG_0) is much smaller than capacitance one, (bC_0) the ICS has very small amplitude of the order of 0.3 pA. But in the case where the conductance nonlinearity is getting competitive with capacitance nonlinearity, the ICS amplitude increases accordingly.

Thus, if we take $\sigma s = 2.5$, and assuming small margin of nonlinearities as follows

$$2b - \beta\frac{G_0}{C_0} = 0.1$$

which with $Z = 5.56 \times 10^{10}\ \Omega$, Eq. (37), yields:

$$i_0 = 27\ \text{pA} \quad (46)$$

If we compare it with experimental evidence from,[13] where the collected currents were in the range (2–6) nA, we could infer that dozens of ICS constituting the train-like pulses are involved in measured currents along MT.

Interestingly, the nonlinearities in NP conductance and TTs capacity have the opposite signs. This is the consequence of the fact that pumping of positive ions (potassium) by NPs from MT lumen causes diminishing of TTs capacity, and vice versa. The opposite signs of two nonlinearities lead to increase of amplitude of ICS, but do not affect its width and speed. We stress here that this bell-shaped ICS qualitatively differs from the localized wave obtain in Ref. [4] which was anti-kink-like.

We have shown a couple of numerical illustrations of ICS for different values of $s\sigma$ as represented in Figure 8.

We here emphasize that ICSs of our model exhibit the typical properties of KdV solitons in fluid dynamics. Their velocities are bellow the characteristic velocity v_o and increasing the velocity leads to increase of their amplitude and decrease of corresponding width (higher localisation).

Eventually, we could estimate the charge carried by one ICS with $s\sigma = 3$. Starting from $Q_n = C_0(1 - bv_n)v_n$ and using continuum approximation, the total charge is

$$Q = \frac{C_0}{l}\int_{-\infty}^{+\infty}(v - bv^2)\,dx; \quad v(x,t) = Z \cdot i(x,t) \tag{47}$$

or explicitly:

$$Q = \frac{C_0}{l}\left[i_o Z\right]\int_{-\infty}^{+\infty}\operatorname{sec h}^2\left\{\frac{1}{2}\left[\frac{3}{2}\times 1\right]^{1/2}\left(\frac{x}{l} - s\frac{t}{\tau}\right)\right\}dx$$
$$-\beta\frac{C_0}{l}[i_0 Z]^2\int_{-\infty}^{+\infty}\operatorname{sec h}^4\left\{\frac{1}{2}\left[\frac{3}{2}\times 1\right]^{1/2}\left(\frac{x}{l} - s\frac{t}{\tau}\right)\right\}dx$$

The second addend could be safely ignored, as very small. Using Eq. (47) with already known parameters C_0, Z and $i_0 = 27$ pA, yields

$$Q = 2.7\times 10^{-15}\ \text{C} = 1.7\times 10^4\ \text{e} \tag{48}$$

One could also assess the energy carried by an ICS. The basic assumption is that the energy loss due to the ohmic resistance is being compensated through fresh supply of ions by NPs. Under such circumstances it is clear that the energy contained in ER capacitors should be preserved. This energy amounts:

$$E = \frac{Q^2}{2C_0} = \frac{(2.7\times 10^{-15}\ \text{C})^2}{2\times 1.8\times 10^{-15}\ \text{F}}$$
$$= 2\times 10^{-15}\ \text{J} = 1.7\times 10^4\ \text{eV} \tag{49}$$

Taking the charge of $Q = 1.7\times 10^4$ e, Eq. (3.39), to be attributed to monovalent ions, the energy per single ion involved in ICS is of the order of 0.8 eV which is one thirty times greater of thermal energy (25 meV).

4. THE INFLUNCE OF VISCOUS DISSIPATION AND INTRINSIC ELECTRIC FIELDS ON THE DYNAMICS OF ICSs ALONG MTs

In the absence of dissipation the ICS, Eq. (46), is expected to move at a constant speed s. But, since ICS behaves like

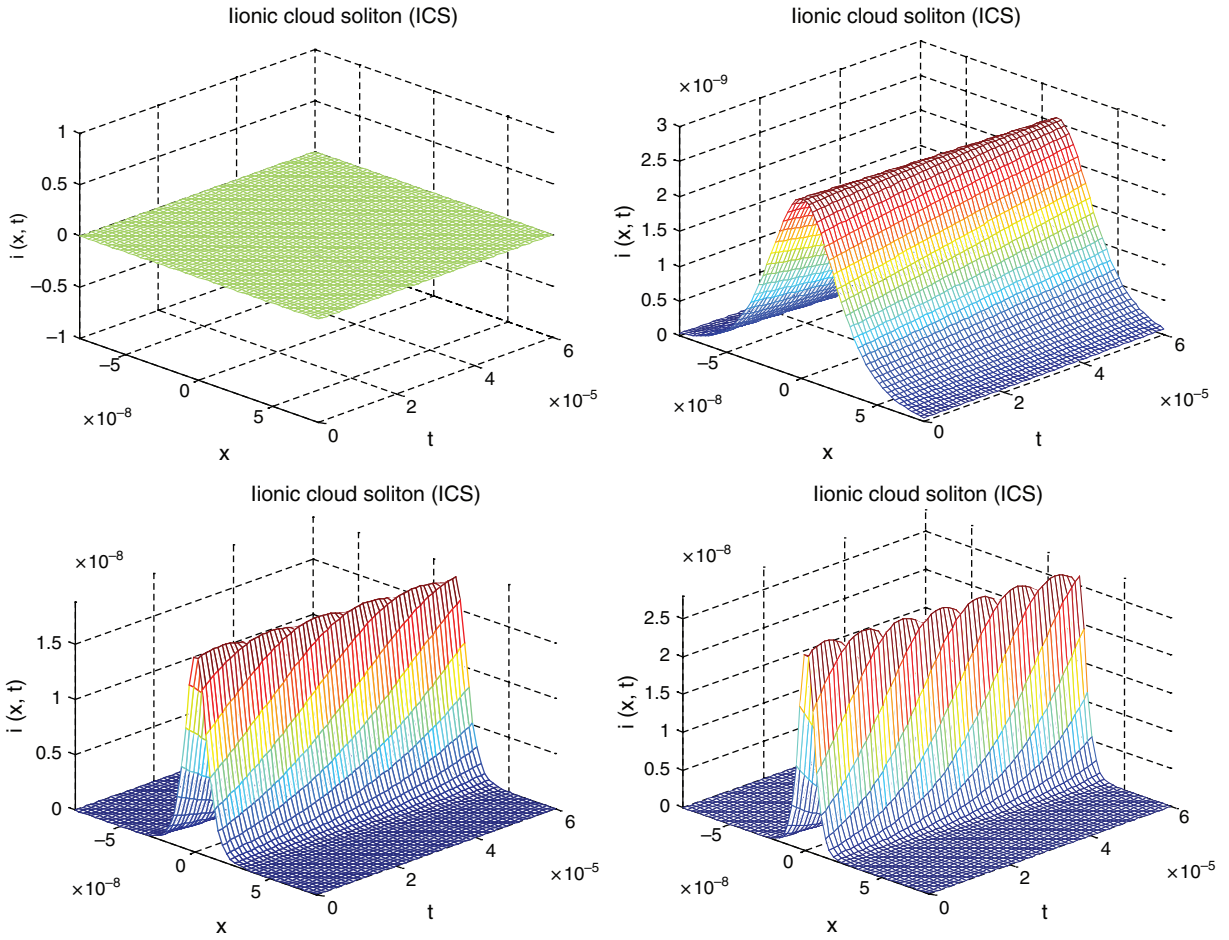

Fig. 8. Numerical solutions: (a) for $s\sigma = 2$ (the smearing limit), (b) for $s\sigma = 2.1$, (c) for $s\sigma = 3$ and (d) for $s\sigma = 4$.

RESEARCH ARTICLE

a "particle" in a viscous fluid, it is evident that the role of viscous cytosol is to decrease its speed.

The rate of deceleration could be calculated on the basis of Energy method.[18, 19] This rate appears to follow exponential decay tending to the down-limit ($s\sigma = 2$), Eq. (38), when ICS is being totally smeared out.

In the other hand, since ICS is being subjected under the action of intrinsic electrical field of MT[20, 21] it should be accelerated.

The most interesting case is when these two opposite tendencies are mutually balanced. The viscous damping is proportional to the speed of an ICS:

$$F_{\text{vis}} = -kv \tag{50}$$

where k depends on dynamical viscosity of cytosol and on the geometry of ICS, while the force of electric field simply reads

$$F_{\text{if}} = Q \cdot E_i \tag{51}$$

with E_i being the strength of intrinsic electrical field along MT.

Equations (50) and (51) we can calculate the value of parameter k on the basis of estimated $E_i = 10^4$ V,[21] and taking $v = 0.2$ mm/s, and Q from Eq. (48), we get

$$k = \frac{Q \cdot E_i}{v} = \frac{2.7 \times 10^{-15} \times 10^4}{0.2 \times 10^{-3}} = 1.35 \times 10^{-7} \ \frac{\text{kg}}{\text{s}} \tag{52}$$

Obviously the strength of intrinsic electric field could be an important mechanism for tuning dynamics of ICS.

5. CONCLUSION AND DISCUSSION

We here farther improved the former model[3, 4] for ionic currents propagating in narrow layer along MTs. This model is established in terms of polyelectrolyte concept applied to the molecular structure and geometry of MT, and taking into account its interaction with solvent ions. As the consequence, the MT cylinder with flexible TTs, surrounded by counter-ions from cytosol, is considered as an electrical transmission line, with R, C and G elements estimated on the basis of approximate MT geometry and other experimental evidences available. The essentially important nonlinearity of model pertains to its capacitance arising from structure and dynamics of β-TTs and from dynamic conductance of NPs.

We here paid the particular attention to the possible role of NPs acting as ionic pumps thus creating the negative incremental resistance in the considered circuit.

As a result, the nonlinear second order differential equation for ionic current along MT was evaluated. The travelling-wave solution of Eq. (48) is localized ICS which exhibits the features of celebrated Korteveg de Wries soliton from fluid dynamics. It is important to emphasize the qualitative difference of this bell-shaped ICS compared with anti-kink solution obtained in former approach.[4] It appears that the role of NPs exerts some kind of self-focusing effect on IC increasing its amplitude.

Interestingly, this ICSs have pretty narrow window of possible velocities with the order of magnitude being a fraction of (mm/s), based on the assessed capacity and ohmic resistance of an ER of such transmission line.

We estimated the order of magnitude of pertaining current along a single MT, together with the charge of ICS and its energy. These parameters have pretty reasonable values, being comparable with still scarce experimental data.

Let us especially pay attention on the interesting experimental assay performed by the group led by Tuszynski.[13] The measured values for the ionic current along the single MT were in the range (2–6) nA. Moreover they stated that the electrical amplification by MTs is equivalent to their ability to act as the bimolecular living transistors. In that respect the NP current of pumped ions, Eq. (45), in our model is expected to play the control role as well as the base current does play in bipolar transistor.

It is worth to mention the experimental results regarding intracellular calcium dynamics.[22] Calcium ions released from endoplasmic reticulum could be candidate for propagation along MT in the context of present model. The calcium puffs launched from above compartment could have enough energy (proper velocity) to form ICS. This localized propagation of ions is being controllable by cellular electric fields and goes faster than the pure diffusion through cytosol. Experimental speed of diffusive calcium waves, according to Ref. [22], is of the order of 12 (μm/s), which is one order of magnitude bellow the ICS window, Eq. (43).

We finally considered biophysically realistic circumstances where the damping effects are being balanced by energy supply provided by existing cell's intrinsic electrical fields.

Our results could encourage experimentalists to conduct more subtle assays in an attempt to ellucidate this important aspect of cellular activities.

Collective Properties of Biological Systems

Solitons and Coherent Electric Waves in a Quantum Field Theoretical Approach

Emilio Del Giudice, Silvia Doglia, Marziale Milani, and Giuseppe Vitiello

ABSTRACT: We present a dynamical scheme for biological systems. We use methods and techniques of quantum field theory since our analysis is at a microscopic molecular level. Davydov solitons on biomolecular chains and coherent electric dipole waves are described as collective dynamical modes. Electric polarization waves predicted by Fröhlich are identified with the Goldstone massless modes of the theory with spontaneous breakdown of the dipole-rotational symmetry. Self-organization, dissipativity, and stability of biological systems appear as observable manifestations of the microscopic quantum dynamics.

1. Introduction

Biological systems are collective systems indeed. They seem to be satisfactorily described when the list of their components is supplemented by the prescription of their location inside the system and the timing of their operation. Biologists refer to such a timing as a "cell clock"; what is now

required is the engine responsible for such a dynamical ordering. Dynamical mechanisms that could give account for collective behavior have been proposed in the frame of different approaches.

H. Fröhlich[1] has introduced, in a framework of far-from-equilibrium processes, coherent electric polarization waves as the physical agent able to control the working of distant and separate parts of the system, making them cooperative. On the other hand, it has been shown that biomolecules are able to host on their own chains, in a conservative framework, highly nonlinear subdynamics which give rise to deep structural and conformational changes.

Very interesting subdynamics have been investigated by A. S. Davydov,[2,3] who has shown that metabolic reactions can result in strictly confined "bumps" traveling along biomolecular chains and carrying energy in an efficient way a long distance away from the point of release.

Our aim is to provide a systematic approach to the dynamics of a biological system[4,5] by using the widely accepted tool for exploring the collective properties of a system made from a large number of elementary microscopic components, namely, quantum field theory (QFT). We choose quantum field theory instead of classical field theory since quantum theory has proved to be the most adequate tool for describing atoms, molecules, and their interactions, and we wish actually to carry out an investigation of the biological system at a molecular level. Moreover, we choose quantum field theory instead of quantum mechanics because we are not interested in singling out just a few degrees of freedom of the system; on the contrary we would like to get a comprehensive description of the dynamics of the whole system (collective behavior).

The QFT approach could be sketched as follows. In a preliminary stage the microscopic components of the system are enumerated; the state of minimum energy is called the ground state or the vacuum. It is possible that more than one ground state exists for the same system, each of them being characterized by different macroscopic properties. In such a case different regimes or phases will correspond to different vacua. Subsequently, the microscopic components are linked to field operators whose dynamical evolution is obtained through equations of motion derived from a Lagrangian. The usual prescription is to choose this Lagrangian as symmetric as possible in order to get the simplest equations of motion while that part of the dynamics which is less symmetric is taken into account via the vacuum.

Where the vacuum does not exhibit the same invariance of the Lagrangian, one says that a spontaneous breakdown of the symmetry occurs. General theorems have been derived which elucidate the dynamical consequences on the whole system of the interplay between a symmetric Lagrangian and a nonsymmetric vacuum. The Goldstone theorem[6] is a

very important one; it states that massless modes (usually called Goldstone bosons) appear when the Lagrangian is invariant, while the vacuum is noninvariant under a certain group of transformations. Notice that the invariance or noninvariance of the Lagrangian and of the vacuum under a transformation compels us to take into account the whole of the system degrees of freedom so that the Goldstone modes are really collective modes. A massless mode actually describes a long-range interaction among the system components and such an interaction establishes a correlation (i.e., order) among the components. The noninvariance of the vacuum under a certain transformation thus implies that this vacuum is an ordered state, in which absorption and emission of quanta of the Goldstone field, undergoing the transformation of noninvariance, take place. The mathematical structure of the theorem makes evident that the above-mentioned boson quanta exist in a condensed form and their condensation onto the ground state corresponds to a sort of "printing" of the symmetry pattern on the vacuum.

It is interesting to compare the collective properties arising from a microscopic theory with the macroscopic predictions obtained at a thermodynamic level in the framework of different approaches. The ordering of biological systems by coherent electric waves as proposed by Fröhlich could be understood, for instance, as the phenomenological manifestation of the breakdown of some symmetry at a microscopic level.[4,5,7] In this case the fact that the condensation, i.e. the emission and absorption, of Goldstone boson quanta does not require any energy expense is the microscopic counterpart of the thermodynamic dissipativity condition, which is a necessary condition[1] for the appearance of these waves. Dissipativity is a very general and important feature of living systems as far-from-equilibrium systems.[8] If we consider the Goldstone modes not as particles but as waves, the condensation of quanta producing an ordered state would lead us to take into account coherent waves. Coherent electric polarization waves require then, in the above framework, a vacuum with a nonzero value for the relevant field, namely, for the polarization field. As a matter of fact, water around biomolecules exhibits a nonzero polarization, i.e., an electret.[9,10]* Zero frequency modes have been also observed, which point to the existence of massless modes.[11]

Nonlinear dynamical effects on one-dimensional systems such as biomolecular chains, e.g., Davydov solitons, can also be analyzed in terms of boson condensation.[12–14] In the Fröhlich wave case, the condensation

* We define the electret state of a dielectric material, in agreement with the definition of Refs. 9 and 10, as a metastable state characterized by a stored polarization. Its decay time must be assumed long with respect to the characteristic time of experiments performed on the material.

induced by a symmetry breakdown occurs on large regions homogeneously, whereas in one-dimensional molecular systems one has quite localized condensations producing solitons. QFT can provide a unified description of such physically different situations. It is also interesting to note that an analysis by means of boson condensation can be performed in a variety of systems in many-body physics.[12] Thus a QFT approach has the appealing feature of extending methods and mathematics currently used in condensed matter physics to living matter.

In the following sections we present such a unified treatment. First we sketch qualitatively the interplay between Davydov and Fröhlich mechanisms (Section 2). Then we present an account of both of them and we discuss the transition from one regime to the other (Section 3). Finally we discuss the phenomenological implications of the theoretical scheme and the available supporting experimental evidence (Section 4).

2. *Solitons, Electrets, and Fröhlich Waves*

A very appealing schematization features a biological system as a set of electric dipoles, a dielectric with peculiar properties. Both water molecules—which account for a large amount of the global weight—and the macromolecules having a role in the biochemical machinery (DNA, RNA, proteins, and so on) have relevant dipole values or exhibit atomic subgroups with large dipole values. The starting point of the Fröhlich approach, for instance, is just to treat living matter as a dielectric, where the correlations among different parts are established by electric polarization waves. On the other hand the dynamics of a one-dimensional set of dipoles gives rise to vibrational solitons on biomolecular chains as proposed by Davydov.

Let us first discuss these two mechanisms separately. Biological systems are considered by Fröhlich as three-dimensional sets of dipoles. It is well known that the basic dipole–dipole interaction is rotationally invariant, so that we expect that the Lagrangian describing the whole system—whatever its detailed mathematical form is—be rotationally invariant too. On the other hand an electret (not a ferroelectret) has been detected for almost all the biomolecules.[9,10] Furthermore, this electret does not belong to the bare molecular structure but to its "dressing," the surrounding hydration water. Some sort of molecular dynamics produces a nonzero electric polarization in the surroundings, thus breaking the rotational symmetry of the dipole dynamics. It is possible consequently to introduce the formalism and theorems concerning spontaneously broken symmetries and their dynamical rearrangement (see Section 3).[15] In a first rough treatment one could use the Goldstone theorem, which predicts the

appearance of massless bosons. A more adequate treatment would consider the electric field as a gauge field; a massive electric quantum excitation would then appear. It is known that the mass of a quantum of a field is inversely proportional to its propagation range; consequently, while a rigorously massless mode would correspond to an infinite propagation range (infinite size of the system), a nonzero mass corresponds to the observed finite range correlations (finite size of the system). A further improvement would concern the introduction of finite temperature effects which will allow thermal excitations. The problem will then arise of the interaction of coherent electric waves with thermal effects.

Let us now consider the one-dimensional dynamics occurring on the macromolecular chains. Davydov has shown[2,3,16] that a vibrational soliton—namely, a localized excitation strictly bound to a localized deformation—occurs on one-dimensional chains made by weakly bound monomers under two conditions:

i. the initial excitation is localized, i.e., energy is supplied to the system at small sized sites;
ii. the coupling between monomers exhibits a positive anharmonicity.

Under the above conditions solitons are created and travel quite slowly on the chain exhibiting a remarkable stability when their lifetime is compared with the one of the original excitation. Solitons have been therefore proposed as the long-range carriers of the energy produced by metabolic reactions and stored on the molecules.[17] For this reason they were used in a model of muscle contraction by Davydov.

Apart from the storage of energy, many additional and partially unexplored consequences arise on the biomolecules because of solitons. Conformational and structural changes may occur as well as changes in the vibrational frequency patterns. The binding of hydration water molecules to biomolecules is also affected. Davydov has recently pointed out[18] that a soliton on the α-helix of a protein behaves as a mobile trap for loosely bound electrons, giving rise to an electrosoliton which has the features of a supercurrent. In other words, once a vibrational soliton is produced when a certain amount of energy is supplied, an electric current is obtained without further expense of energy. It is reasonable to assume that such a supercurrent, via its associated fields, might induce a preferred direction (an orientation) among water molecules surrounding the biomolecule. Actually, it is a fact[9] that the activation energy that one must supply to a biomolecule in order that an electret may appear around it is just of the same order of magnitude (0.2–0.4 eV) as the energy required for the production of a soliton on an α-helix protein through the ATP hydrolysis.

The above-discussed mechanisms are particular ones. It is possible to integrate them in a provisional, unified scheme giving a partial qualitative

picture of cell operation.[19] The metabolic reaction, governed by nutrition and membrane activity, produces localized excitations at selected points of selected molecules (DNA). Such excitations propagate in soliton form along the chains storing energy on them; the rate of accumulation is controlled by the difference between the number of solitons produced per unit time (metabolic reaction rate) and the number of solitons decaying in unit time. This rate is linked to the chain elasticity, a time-dependent parameter. We have described what we call the energy charge phase of the cell cycle. Simultaneously, a water electret is created around the molecule because of the soliton accumulation. When the electret reaches a threshold corresponding to the breakdown of the rotational symmetry of the dipole set (representing a finite-sized cell), then a different dynamical regime is switched on, where electric polarization waves must appear according to the previous discussion on the dynamical rearrangement of symmetry. These waves, propagating in the system, are instrumental in its biochemical organization, as discussed elsewhere.[19,20]

3. *Boson Condensation and Collective Modes*

Quantum field theory provides a two-level description for a system:

a. the dynamical level, where basic microscopic fields, say $\psi(x)$, are introduced, which are called the Heisenberg fields and obey the dynamic equations

$$\Lambda(\partial)\,\psi(x) = J[\psi(x)] \tag{3.1}$$

b. the phenomenological level, where observable quantities are expressed in terms of physical fields, say $\phi(x)$, which are called also asymptotic or quasiparticle fields and satisfy free field equations

$$K(\partial)\,\phi(x) = 0 \tag{3.2}$$

In Eqs. (3.1) and (3.2), $\Lambda(\partial)$ and $K(\partial)$ are kinetic differential operators, x stands for $(\mathbf{x}, t)$, and $J[\psi(x)]$ is a nonlinear functional of $\psi(x)$.

As a next step, the set of the physical states, or Fock space, of the system is introduced. It is denoted by $\{|0\rangle\}$ and contains all the states obtained by repeated application of the "quasiparticle" creation operators on the ground state, or "vacuum," $|0\rangle$. The "quasiparticle" creation operators are functions of the fields $\phi(x)$.

At the first level of description the "forces" acting among the system components appear through the functional $J[\psi(x)]$, while, at the second level, the fields are considered free, because only fairly independent quan-

tities are observable. In a scattering process, for instance, the particles are observed only before and after the collision. In a complex system either the whole compound system or the correlations among the constituents—namely, the free particles acting as messengers (phonons and so on)—are observed. These "free" phenomenological fields are of course the output of the inner dynamics described at the first level and such relationship is provided by the "dynamical map"[12,15]:

$$\langle a|\ \psi(x)\ |b\rangle = \langle a|\ \Psi[\phi(x)]\ |b\rangle \tag{3.3}$$

Equation (3.3) is the bridge between the deep underworld where the "forces" are at work and the apparent world where observations are performed. In Eq. (3.3) $|a\rangle$ and $|b\rangle$ are wave-packet states, which belong to the Fock space $\{|0\rangle\}$ and $\Psi[\phi(x)]$ is a functional of (normally ordered) products of the $\phi(x)$ fields.

Let us now investigate how a symmetry at the dynamical level would affect the phenomenological description. Consider a transformation which leaves Eq. (3.1) invariant, namely, let g be an element of the symmetry group of Eq. (3.1):

$$\psi'(x) = g\psi(x) \tag{3.4}$$

$$\Lambda(\partial)\,\psi'(x) = J[\psi'(x)] \tag{3.5}$$

The dynamical map (3.3) would then select a field $\phi'(x)$ corresponding to $\psi'(x)$, defining a transformation h which would give $\phi'(x)$ as a function of the field $\phi(x)$ corresponding to the original $\psi(x)$ via the dynamical map

$$\langle a|\ g\psi(x)\ |b\rangle = \langle a|\ \Psi[h\phi(x)]\ |b\rangle \tag{3.6}$$

Usually the functional $\Psi[\phi(x)]$ is highly nonlinear, so that h is expected to be different from g. However, since g leaves Eq. (3.1) invariant (i.e., it corresponds to a physical process which requires no expense of energy), h leaves in turn Eq. (3.2) invariant

$$\phi'(x) = h\phi(x) \tag{3.7}$$

$$K(\partial)\,\phi'(x) = 0 \tag{3.8}$$

If the transformations g form a group G, then the transformations h form a group H, too.

We are interested in the situation $H \neq G$, namely, when the dynamical map (3.6) rearranges the symmetry transformations so that the system acquires a symmetry at the phenomenological level, which is quite different from the one at the microscopic dynamical level. In this case we say that a dynamical rearrangement of the symmetry occurs.

We are going to explore the consequences of the dynamical rearrangement of the symmetry in the two cases of the Davydov vibrational solitons on macromolecules and of the Fröhlich electric waves in the whole biological system. In the first case we deal with an explicit form of the equations, so that a complete treatment is possible, while in the second case we limit ourselves to the consideration of the dynamical rearrangement of the symmetry and of the consequent appearance of massless modes.

Let us consider first the soliton dynamics on the biomolecular chains.

3.1. Davydov Soliton Regime

A biomolecular chain can be schematized as a one-dimensional chain of weakly bound monomers of mass M, whose electric dipole moment is aligned along the chain. Consequently the internal dipole quantum number, giving the spatial orientation of the dipole, can be taken as frozen; the electric dipole, which would be described by a spinor in the usual three dimensions, is described in this one-dimensional case by a scalar.

In a first approximation the molecule length is assumed infinite and corrections due to the finite length are introduced as a second step. The intramolecular excitation brought by an external supply of energy (e.g., the output of a chemical reaction) is described by a complex Heisenberg boson field $\psi(\xi, t)$, solution of a nonlinear Schrödinger equation[2,3,16]:

$$\left(i\hbar\frac{\partial}{\partial t} - \Lambda + J\frac{\partial^2}{\partial \xi^2}\right)\psi(\xi, t) = -G\psi^+(\xi, t)\,\psi(\xi, t)\,\psi(\xi, t) \tag{3.9}$$

The right-hand side of Eq. (3.9) is understood to be normally ordered. Λ is a constant energy term which may depend on the free exciton energy, on the static interaction energy, and on the deformation energy. J is the resonance interaction energy between neighboring monomers. The quasiparticle free equation (3.2) becomes in this case

$$\left(i\hbar\frac{\partial}{\partial t} - \Lambda + J\frac{\partial^2}{\partial \xi^2}\right)\phi(\xi, t) = 0 \tag{3.10}$$

The operator $\phi(\xi, t)$ is the free exciton field. As a first step we are going to show that the c-number Davydov soliton[2,3,16]

$$\chi_c(\xi, t) = \left(\frac{\mu}{2}\right)^{1/2} \frac{\exp i\left[\dfrac{\hbar v}{2J}(\xi - \xi_0) - E_v\dfrac{t}{\hbar}\right]}{\cosh \mu(\xi - \xi_0 - vt)} \tag{3.11}$$

$$\int |\chi_c(\xi, t)|^2\, d\xi = 1 \tag{3.12}$$

is just a convenient vacuum expectation value for $\psi(\xi, t)$ in the "classical" limit. In Eq. (3.11) $\hbar$ is the Planck constant and

$$E_v = \Lambda + \frac{\hbar v^2}{4J} - J\mu^2, \qquad \mu = \frac{G}{4J} \tag{3.13}$$

Let us assume a transformation B such that

$$\psi(\xi, t) \to \psi'(\xi, t) = B\psi(\xi, t) \tag{3.14}$$

$$\chi_c(\xi, t) = \langle 0|\, \psi'(\xi, t)|0\rangle\,|_{\hbar=0} = \langle 0|\, B\psi(\xi, t)\,|0\rangle\,|_{\hbar=0} \tag{3.15}$$

which leaves Eq. (3.9) invariant. The dynamical map (3.3) then becomes

$$\langle 0|\, B\psi(\xi, t)\,|0\rangle = \langle 0|\, \psi[\beta\phi(\xi, t)]\,|0\rangle \tag{3.16}$$

which defines β as an invariant transformation for Eq. (3.10). Let us require also that β be a canonical transformation, namely, β preserves the canonical commutation relations

$$\begin{aligned}
&[\phi(\xi, t), \dot{\phi}(\xi', t)] = [\phi'(\xi, t), \dot{\phi}'(\xi', t)] = i\delta(\xi - \xi') \\
&[\phi(\xi, t), \phi(\xi', t)] = [\phi'(\xi, t), \phi'(\xi', t)] = 0 \\
&[\phi(\xi, t), \phi(\xi', t)] = [\phi'(\xi, t), \phi'(\xi', t)] = 0
\end{aligned} \tag{3.17}$$

where

$$\phi'(\xi, t) = \beta\phi(\xi, t) \tag{3.18}$$

We consider now the general class of canonical transformations

$$\phi'(\xi, t) = \beta\phi(\xi, t) = \phi(\xi, t) + f(\xi, t) \tag{3.19}$$

where the field $\phi(\xi, t)$ is translated by a c-number function $f(\xi, t)$. The transformation (3.19) would leave Eq. (3.10) invariant, provided that $f(\xi, t)$ is a (c-number) solution of the same equation, namely,

$$f(\xi, t) = ce^{-\mu(\xi - vt)} \exp\left[i\left(\frac{\hbar v}{2J}\xi - \frac{E_v t}{\hbar}\right)\right] \tag{3.20}$$

Let us show that the transformation (3.19) on the fields ϕ, which corresponds to the "translation" (3.20), induces through the dynamical map just the transformation (3.14) on the fields ψ, so that Eq. (3.15) is satisfied. The generator of (3.19) in the $v = 0$ frame of reference is

$$D = -\int_{-\infty}^{\infty} d\xi[g(\xi, t)\,\dot{\phi}(\xi, t) - \dot{g}(\xi, t)\,\phi(\xi, t)] \tag{3.21}$$

where

$$g(\xi, t) \doteq \theta(\xi)\, f_0(\xi, t)$$
$$f_0(\xi, t) = f(\xi, t)\,|_{v=0} \tag{3.22}$$

$\theta(\xi)$ is the usual step function: $\theta(\xi) = 0$ for $\xi < 0$ and $\theta(\xi) = 1$ for $\xi > 0$. It is possible to read Eq. (3.19) as

$$\phi'(\xi, t) = \beta\phi(\xi, t) = \lim_{g \to f_0} e^{-iD}\phi(\xi, t)\, e^{iD} \qquad \text{at} \quad v = 0 \tag{3.23}$$

and

$$\langle 0|\, e^{-iD}\phi(\xi, t)\, e^{iD}\, |0\rangle\,|_{g=f_0} = \langle f_0|\, \phi(\xi, t)\, |f_0\rangle = f_0(\xi, t) \tag{3.24}$$

The state $|f_0\rangle$ is defined as

$$|f_0\rangle \equiv e^{iD}\, |0\rangle\,|_{g=f_0}, \qquad \langle f_0\,|\,f_0\rangle = 1 \tag{3.25}$$

We introduce now the annihilation operator $a_{\bar{k}}$ of a quantum of the field $\phi(\xi, t)$ whose momentum is $\bar{k}$; let us also consider the c-number function $\alpha(\bar{k})$, the Fourier transform of a function which coincides with $f_0(\xi, t)$ in a suitable ξ domain; then

$$a_{\bar{k}}\, |f_0\rangle = \alpha(\bar{k})\, |f_0\rangle \tag{3.26}$$

i.e., $|f_0\rangle$ is a coherent state for $\phi(\xi, t)$, namely, any functional of ϕ acts on $|f_0\rangle$ as a c-number.

The dynamical map (3.3) then becomes

$$\langle f_0|\, \psi(\xi, t)\, |f_0\rangle = \Psi[f_0(\xi, t)] \tag{3.27}$$

$$\langle f_0|\, J[\psi(\xi, t)]\, |f_0\rangle = J[\Psi[f_0(\xi, t)]] \tag{3.28}$$

A boost to the original frame of reference and the substitution of Eqs. (3.27) and (3.28) into Eq. (3.9) produce at last

$$\left(i\hbar\frac{\partial}{\partial t} - \Lambda + J\frac{\partial^2}{\partial\xi^2}\right)\psi[f] = -G\,|\psi[f]|^2\,\psi[f] \tag{3.29}$$

Equation (3.29) is a c-number equation which coincides with the one proposed by Davydov [see Eq. (2.10) of Ref. 2]. The solution of (3.29) is, then, just the soliton (3.11)

$$\Psi[f(\xi, t)] = \chi_c(\xi, t) \tag{3.30}$$

which allows us to determine the constant c in Eq. (3.20):

$$c = (2\mu)^{1/2} e^{\mu\xi_0} \exp\left(-i\frac{\hbar v}{2J}\xi_0\right) \tag{3.31}$$

In conclusion from the above formalism we can deduce that the Davydov soliton is the macroscopic envelope of the localized boson condensation of the excitation quanta $\phi(\xi, t)$ induced by the β transformation (3.19).[12–14] The vanishing of the coefficient G of the nonlinear term of Eq. (3.29), via Eq. (3.13), implies the disappearance of the soliton, which then looks like a necessary consequence of the nonlinearities of the dynamics.

As a further step, we are going now to show how the QFT approach could recover all the relevant Davydov results starting from a restricted set of assumptions.[4]

We started actually from the nonlinear Schrödinger equation (3.9) governing the $\psi(\xi, t)$ field only. A deformation (phonon) field has not, so far, been independently introduced. But the density probability ρ^f of ψ in the soliton state $|f\rangle$

$$\rho^f(\xi, t) = \gamma \langle f | \psi^+(\xi, t)\psi(\xi, t) | f \rangle = \gamma |\chi_c(\xi, t)|^2 \tag{3.32}$$

or [see Eq. (3.11)]

$$\rho^f(\xi, t) = \gamma \frac{\mu}{2} \frac{1}{\cosh^2 \mu(\xi - \xi_0 - vt)} \tag{3.33}$$

is a solution of the (phonon) equation

$$\left(\frac{\partial^2}{\partial t^2} - v^2 \frac{\partial^2}{\partial \xi^2}\right) \rho^f(\xi, t) = 0 \tag{3.34}$$

The phonon equation is then a direct consequence of the self-interacting intramolecular excitation field ψ, which is the only independent physical object. As a matter of fact, the ψ-excitation field dynamics induces conformational changes in the chain lattice which are described by a phonon field.

It is useful to recast Eq. (3.34) in the more familiar form of the Davydov Eq. (2.56) of Ref. 2. Let us define

$$\begin{aligned} v_{ac} &= \left(\frac{W}{M}\right)^{1/2} \\ v^2 &= v_{ac}^2 - v_{ac}^2(1 - s^2) \\ s &= \frac{v}{v_{ac}} \ll 1 \end{aligned} \tag{3.35}$$

where w is the chain elasticity coefficient and v_{ac} is the sound velocity on the chain in absence of solitons. Equation (3.34) is consequently transformed into

$$\left(\frac{\partial^2}{\partial t^2} - v_{ac}^2 \frac{\partial^2}{\partial \xi^2}\right) \beta^f(\xi, t) - \frac{2K}{M} \frac{\partial}{\partial \xi} |\chi_c(\xi, t)|^2 = 0 \tag{3.36}$$

where

$$K = 1/2w(1 - s^2)\,\gamma \tag{3.37}$$

$$-\frac{\partial}{\partial \xi} \beta^f(\xi, t) = \rho^f(\xi, t) \tag{3.38}$$

Equation (3.36) is just the Davydov equation (2.56) of Ref. 2. Moreover Eq. (3.29) can be transformed as follows:

$$\left[i\hbar \frac{\partial}{\partial t} - \Lambda + J \frac{\partial^2}{\partial \xi^2} - 2K \frac{\partial \beta^f(\xi, t)}{\partial \xi} \right] \chi_c(\xi, t) = 0 \tag{3.39}$$

where

$$\mu = \frac{K^2}{w(1 - s^2)\,J} \tag{3.40}$$

Equation (3.39) coincides with Eq. (2.5a) of Ref. 2. We conclude that the present QFT approach is equivalent to the Davydov analysis. All the results of the latter theory can be recovered in the QFT framework, such as, for instance, the soliton stability, the soliton–photon interaction and the attraction of electrons by the self-generating potential wells leading to quasisuperconducting properties of the molecular chains, hosting solitons. The chains considered above were assumed to be infinitely long; let us now drop this assumption. This change affects mainly the stability of the soliton. The soliton is stable when the local deformation $\beta^f(\xi, t)$ [or $\rho^f(\xi, t)$] is stable and vice versa [see Eqs. (3.36) and (3.39)]. The conditions for the stability of β^f have been investigated in Ref. 14. For the sake of conciseness, we do not report here such an analysis (see also Ref. 4), but we give the conclusion. In a finite chain the soliton state has a nonzero transition amplitude with any state of n free excitation quanta, so that its lifetime has to be finite. The longer the chain, the longer the lifetime.

Very important features of solitons, such as their rate of creation and decay, their density on the chain, the effects of external perturbations (for instance, changes of the soliton density and decay rate induced by variations of the physical and chemical structure of the chain) are yet a matter of investigation.

All the above analysis shows that an incoherent energy supply can be transformed into a coherent but localized form (the soliton) through the

inner nonlinear dynamics occurring on the molecules constituting the biological system. The next step is the dynamical appearance of self-organization in the system without further expense of energy; energy stored in soliton form during the "charge" or Davydov regime is completely released outward during the "discharge" or Fröhlich regine.

3.2. Fröhlich Regime

It has been experimentally found that water surrounding biomolecules can be brought in an electret state by low electric fields at low frequency.

We have said in Section 2 that the electret activation energy is of the same order of magnitude as the energy required for the production of a soliton on a biomolecule. The numerical coincidence suggests that the soliton might induce the observed electret while traveling on the chain. How it could happen is at present under investigation; we limit ourselves here to suggesting that the soliton could be a trigger for the water polarization. As a consequence the dipole quantum number carried by the dipole excitation ψ field would no longer be frozen since the water electret has transformed the previously one-dimensional system into a three-dimensional one. Let us describe the dipole quantum number by the spinor:

$$\psi(x) = \begin{pmatrix} \psi\uparrow(x) \\ \psi\downarrow(x) \end{pmatrix} \tag{3.41}$$

where $x \equiv (\vec{x}, t)$. The Lagrangian $\mathscr{L}$ of the whole biological system is very complicated, but it is safe to assume its invariance under the rotation of the dipole degree of freedom of the doublet field (3.4). More technically, we assume its invariance under the $SU(2)$ group of transformations

$$\psi(x) \to \psi'(x) = e^{i\theta_i \sigma_i} \psi(x), \qquad i = 1, 2, 3 \tag{3.42}$$

θ_i are real parameters and σ_i are the Pauli matrices. Let us now get as much information as possible by using symmetry arguments only.

The path integral formalism of QFT appears to be the most suitable one. We introduce[20,21,22] the generating functional

$$\begin{aligned} W[J, j, n] = \frac{1}{N} \int [d\psi][d\psi^+] \exp \Big\{ i \int d^4x \\ \times [\mathscr{L}[\psi(x)] + J^+(x)\,\psi(x) + \psi^+(x)\,J(x) \\ + j^+(x)\,D_\psi^{(-)}(x) + D_\psi^+(x)\,j(x) + D_\psi^{(3)}(x)\,n(x) - i \in D_\psi^3(x)] \Big\} \end{aligned} \tag{3.43}$$

$D_\psi^{(i)}(x)(i=+,-,3)$ is the dipole density operator, whose explicit form is not needed here, but whose transformation law under $SU(2)$ group is

$$D_\psi^{(i)} \to D_\psi^{(i)}(x) - \lambda_j \varepsilon_{ijk} D_\psi^{(k)}(x) \qquad (i,j,k=1,2,3) \tag{3.44}$$

Notice that $D_\psi^{(\pm)}(x) = D_\psi^{(1)}(x) \pm i D_\psi^{(2)}(x)$ The number N in Eq. (3.43) is

$$N = \int [d\psi][d\psi^+] \exp\{i\, d^4x [\mathscr{L}[\psi(x)] - i\varepsilon D_\psi^{(3)}(x)]\} \tag{3.45}$$

The fields ψ and ψ^+ and the sources J and J^+ anticommute, while j and j^+ commute. The ε term in (3.43) takes care, as usual, of the vacuum non-vanishing polarization:

$$\langle 0|\, D_\psi^{(3)}(x)\, |0\rangle = P \neq 0 \tag{3.46}$$

The parameter ε has to be put to zero only *after* all the mathematical manipulations have been performed. Equation (3.46) is referred to as the spontaneous breakdown of the $SU(2)$ dipole rotational symmetry.

The ground state does not share the Lagrangian full invariance, but it is invariant only under rotations around the third axis (i.e., the direction of the electret). This group of residual invariance transformations is a subgroup of the original $SU(2)$ symmetry group. The nonvanishing electric polarization (3.46) is the trigger of the Fröhlich regime.

In Refs. 20, 21, 22 a detailed mathematical treatment is given which illustrates the consequences of the condition (3.46) on the formalism derived from the generating functional (3.43). Here we sketch only the main points and the conclusions. The first point is the validity, in the absence of long-range fields (gauge fields), of the Goldstone theorem. Two massless boson modes $P(x)$ and $P^+(x)$ must appear under the condition (3.46). The set of "phenomenological" fields [namely, the solution of Eq. (3.2)] in our case is then the field $\phi(x)$ of the free excitation quanta and the Goldstone fields $P(x)$ and $P^+(x)$:

$$\Lambda(\partial)\, \phi(x) = 0 \tag{3.47}$$

$$\left[i\frac{\partial}{\partial t} + \omega(\partial) \right] P(x) = 0 \tag{3.48}$$

The form of the differential operators $\Lambda(\partial)$ and $\omega(\partial)$ depends on the details of the dynamics and cannot be given here. Of course, more excitation fields can be added, but here we are interested *in* the Goldstone modes only. In particular we leave for further research the effects of the finite temperature, which imply the consideration of thermal excitations.

Let us concentrate on the Goldstone modes. They are the necessary

consequence, through the Goldstone theorem, of the nonvanishing vacuum polarization (water electret). The interaction of these modes with the "matter" field ϕ is embodied in the scattering matrix S:

$$S(\phi, \phi^+, P, P^+) = \langle :\exp[-iA(\phi, \phi^+, P, P^+)]: \rangle \tag{3.49}$$

while the dynamical map (3.3) is expressed in a path integral formalism as

$$SD^{(i)}(x, \phi, \phi^+, P, P^+) = \langle D_\psi^{(i)}(x) : \exp[-iA(\phi, \phi^+, P, P^+)]: \rangle \tag{3.50}$$

and

$$\begin{aligned} A(\phi, \phi^+, P, P^+) = \int d^4x [&\rho^{-1/2} P(x)\, K(\vec{\partial})\, D_\psi^{(-)}(x) \\ &+ \rho^{-1/2} D_\psi^{(+)}(x)\, K(-\overleftarrow{\partial})\, P^+(x) \\ &+ z^{-1/2} \phi^+(x)\, \Lambda(\vec{\partial})\, \psi(x) \\ &+ z^{-1/2} \psi^+(x)\, \Lambda(-\overleftarrow{\partial})\, \phi(x)] \end{aligned} \tag{3.51}$$

ρ and z are the wave function renormalization constants, $\vec{\partial}$ and $\overleftarrow{\partial}$ denote space-time derivatives operating on the right and left side, respectively, and

$$K(\partial) = -\left[i\frac{\partial}{\partial t} + \omega(\partial) \right] \tag{3.52}$$

By standard techniques it is possible to get the rules of transformation of the fields ϕ and $P(P^+)$ when the field $\psi(x)$ undergoes an $SU(2)$ transformation (3.42):

(a) case $\theta_2 = \theta_3 = 0$:

$$\begin{aligned} &\phi(x) \to \phi'(x) = \phi(x) \\ &P(x) \to P'(x) = P(x) + i\theta_1 \left(\frac{P}{2}\right)^{1/2} \\ &P^+(x) \to P'^+(x) = P^+(x) - i\theta_1 \left(\frac{P}{2}\right)^{1/2} \end{aligned} \tag{3.53}$$

(b) case $\theta_1 = \theta_3 = 0$:

$$\begin{aligned} &\phi(x) \to \phi'(x) = \phi(x) \\ &P(x) \to P'(x) = P(x) - \theta_2 \left(\frac{P}{2}\right)^{1/2} \\ &P^+(x) \to P'^+(x) = P^+(x) - \theta_2 \left(\frac{P}{2}\right)^{1/2} \end{aligned} \tag{3.54}$$

(c) case $\theta_1 = \theta_2 = 0$:

$$\begin{aligned} \phi(x) &\to \phi'(x) = e^{(1/2)i\theta_3\sigma_3}\phi(x) \\ P(x) &\to P'(x) = e^{-(1/2)i\theta_3}P(x) \\ P^+(x) &\to P'^+(x) = e^{+(1/2)i\theta_3}P^+(x) \end{aligned} \tag{3.55}$$

The generators of the above three transformations are, respectively, in the space of physical states,

$$\begin{aligned} D^{(1)} &= \left(\frac{P}{2}\right)^{1/2} \int d^3x [P(x) f(x) + P^+(x) f^*(x)] \\ D^{(2)} &= -i\left(\frac{P}{2}\right)^{1/2} \int d^3x [P(x) f(x) - P^+(x) f^*(x)] \\ D^{(3)} &= \int d^3x \left[\phi^+(x)\frac{\sigma_3}{2}\phi(x) - P^+(x) P(x)\right] \end{aligned} \tag{3.56}$$

The function $f(x)$ is a square-integrable c-number solution of the free field equation (3.48):

$$K(\partial) f(x) = 0 \tag{3.57}$$

and makes the integrals (3.56) convergent. The condition (3.57) makes also the generators (3.56) time independent, so that the corresponding transformations can be physically implemented without any expense of energy.

In other words the transformations (3.53)–(3.55) generated by the operators (3.56) are invariant transformations of the free-field "phenomenological" equations (3.47) and (3.48) for any choice of $f(x)$. Notice that the $P(x)$ field "translations" in Eqs. (3.53) and (3.54) are understood as the limit for $f(x) \to 1$ of the transformation generated by $D^{(1)}$ and $D^{(2)}$, namely,

$$P(x) \to P'(x) = \lim_{f(x)\to 1} \left[P(x) + i\theta_1 f(x)\left(\frac{P}{2}\right)^{1/2}\right] \tag{3.58}$$

The transformations (3.53)–(3.55) do not belong to the original $SU(2)$ group of symmetry [see Eq. (3.42)] but to the so-called $E(2)$ group—the group of the transformations of the Euclidean two-dimensional space into itself. The $E(2)$ group is the group "contraction" of $SU(2)$. We have shown explicitly that the group of symmetry at the level of observable quantities is

different from the group of symmetry at the level of the basic fields. This difference vanishes when the vacuum net polarization P vanishes.

Let us show now that the vacuum electric polarization is induced by a coherent homogeneous condensation of the massless dipole-wave quanta $P(x)$ in the vacuum $|0\rangle$, which is controlled in turn by the field "translation" (3.53) and (3.54). We get indeed, by using Eq. (3.56),

$$\langle 0|\, e^{-iD^{(2)}} e^{-iD^{(1)}} P^{+}(x)\, P(x)\, e^{iD^{(1)}} e^{iD^{(2)}} |0\rangle = P\,|f(x)|^2 \xrightarrow[f\to 1]{} P \tag{3.59}$$

We define

$$|f\rangle = e^{iD^{(1)}} e^{iD^{(2)}} |0\rangle \tag{3.60}$$

Then Eq. (3.59) becomes

$$\langle f|\, P^{+}(x)\, P(x)\, |f\rangle = P\,|f(x)|^2 \xrightarrow[f\to 1]{} P \tag{3.61}$$

By introducing the annihilation operator $P_{\bar{K}}$ of a quantum of the field $P(x)$ with momentum $\bar{K}$ and taking the Fourier amplitude $f_{\bar{K}}$ of $f(x)$, we get

$$P_{\bar{K}}\, |f\rangle = P^{1/2} f_{\bar{K}}\, |f\rangle \tag{3.62}$$

which shows that $|f\rangle$ is a coherent state for the $P(x)$ field. In conclusion, a coherent homogeneous (i.e., not space dependent) condensation of dipole-wave quanta $P(x)$ is responsible for the ordered state of polarization. No expense of energy is required since $D^{(1)}$ and $D^{(2)}$ are time independent. We can then identify the dipole-wave Goldstone fields $P(x)$ and $P^{+}(x)$ with the coherent electric polarization waves predicted by Fröhlich.

A relevant feature of this theory is the so-called "low-energy theorem," analogous to corresponding theorems which hold in ferromagnetism and in particle physics. The invariance of the "phenomenological" field equations under the transformations (3.53)–(3.55) requires a corresponding invariance of the S matrix. In the case of an infinite volume [namely, $f(x) \equiv 1$], this requirement is shown to imply

$$S(\phi(x), \phi^{+}(x), P(x), P^{+}(x)) = S(\phi(x), \phi^{+}(x), \partial P(x), \partial P^{+}(x)) \tag{3.63}$$

The S matrix, then, would be independent of $P(x)$ in the zero-momentum limit; in the infinite volume case, the Fröhlich regime would be stable against external perturbations exciting soft (zero momentum) modes.

In realistic systems, however, the volume is finite and surface effects become important. For a finite volume V it has been shown[4] that

$$\begin{aligned}\langle 0|\, D_{\Psi}^{(3)}(x)\,|0\rangle &= \lim_{\varepsilon\to 0} i\varepsilon \int_{-1/\eta}^{1/\eta} d^3x \int \frac{d^3p}{2\pi} e^{i\vec{p}\cdot\vec{x}}\rho(p) \\ &\quad \times \left(\frac{1}{\omega(p)-i\varepsilon a}-\frac{1}{\omega(p)+i\varepsilon a}\right) \\ &= \lim_{\varepsilon\to 0} i\varepsilon \int d^3p\, \delta_\eta(p)\,\rho(p)\left(\frac{1}{\omega(p)-i\varepsilon a}-\frac{1}{\omega(p)+i\varepsilon a}\right) \\ &= \lim_{\varepsilon\to 0} i\varepsilon\rho(\eta)\left(\frac{1}{\omega(p=\eta)+i\varepsilon a}-\frac{1}{\omega(p=\eta)-i\varepsilon a}\right) \qquad \text{at } \eta\sim 0\end{aligned} \tag{3.64}$$

where $\eta = V^{-1/3}$, $\delta_\eta(p)$ approaches $\delta(p)$ as $\eta\to 0$ and the following relation has been used:

$$\lim_{\eta\to 0}\int d^3p\,\delta_\eta(p)\,f(p) = f(0) = \lim_{\eta\to 0}\int d^3p\,\delta(p-\eta)\,f(p)$$

The function $\omega(p)$ is the energy of a dipole-wave quantum of momentum p; for $V\to\infty$ $(\eta\to 0)$ $\omega(p=0)=0$. Then, as $V\to\infty$, or, alternatively "far from the boundaries" of the system, $\omega(p=\eta)\to 0$ and Eq. (3.64) reduce to Eq. (3.46) [notice that $\rho(0)=p/2$]. Near the boundaries (η different from zero), $\omega(p=\eta)$ behaves as an "effective mass" of the quantum of the $P(x)$ field.

Consequently the range of the correlation mediated by $P(x)$ and the domain of the coherence will extend over a distance η^{-1}. Finite (but long) range correlation forces are then expected in realistic (finite volume) systems. A similar conclusion can be drawn from Eq. (3.58) when an appropriate cut-off function $f_\eta(x)$ is introduced. In conclusion a relation between the size of the system and the not exactly zero mass of the P-field quantum is obtained. As announced in Section 2 a more correct treatment, which considers the electric field as a gauge field, would lead to a dynamically constructed (nonzero) mass of the quanta, producing thus a finite volume for the biological system.

Let us now look at the form the low-energy theorem assumes for $\eta\neq 0$. The field equation becomes

$$K_\eta(\partial)\,P(x) = 0 \tag{3.65}$$

The operator $K_\eta(\partial)$ depends upon the effective mass. Then the transformation rule of $P(x)$ changes to

$$P(x) \to P(x) + f_\eta(x)\,\text{const} \tag{3.66}$$

where $f_\eta(x)$ is prescribed to be a c-number solution of Eq. (3.65). In Eq. (3.63) $\partial P(x)$ must be replaced by $K_\eta(\partial)\,P(x)$ in order to have an S matrix invariant under the $E(2)$ group transformations. Thus an energy threshold, equal to the effective mass of the quantum, appears, through $K_\eta(\partial)$, in the S matrix. The consequence is that external perturbations whose energy is below threshold cannot perturb the system. Since the effective mass increases as $1/\eta$, the smaller the system the higher the threshold. The existence of an energy threshold matches a corresponding feature of the Fröhlich theory.

4. *Phenomenological Evidence*

In the above dynamical scheme a crucial role is played by solitons, water electrets, and coherent electric waves. In this section we present some experimental findings which provide evidence for the existence of such collective modes in biological systems.

4.1. *Solitons on Macromolecules*

Support for solitons on different kinds of molecules has been accumulated in these last years; α-helix proteins have been extensively investigated.[3] It has been recognized that the hydrogen-bond filaments along α-helix chains support a pathway for solitons in the nonlinear dynamics of the chains. It has been shown that a simple positive anharmonicity in the interaction among nearest-neighbour monomers is the required nonlinearity in the chain dynamics (C=O bonds in α-helix).[27,28]

A measure of the dipole–dipole interaction energy between two adjacent monomers and of the anharmonicity of the chain can be obtained by an inspection of the bandwidth of the absorption band of the monomer excitation, that forms the exciton. For α-helix proteins in which inhomogeneous broadening has been eliminated by ordering processes of the samples, the bandwidth of the C=O absorption at 1660 cm^{-1} [29] gives evidence of the excitonlike collectivization of the vibrational C=O excitation along the chain. This is a prerequisite for the existence of Davydov solitons on the chain.[2]

In recent years, it has been suggested that Davydov solitons could actually occur on a number of one-dimensional chains of biological

interest. Raman experiments on green algae *Chlorella P.*[30] suggested the possible formation of Davydov solitons on carotenoid chains.[31] Infrared absorption studies of acetanilide, a model system for one-dimensional chains of H bonds, have been recently interpreted in terms of Davydov-like solitons, involving hydrogen-bonded amide groups.[28,32] Of particular interest is the possible existence of solitons on nucleic acids.[19,33–35] Whether Davydov solitons could actually occur on DNA, has been examined.[19] The stretching vibration of the P–O bond in the phosphodiester backbone of the double helix, being directed along the axis of the chain, satisfies the symmetry and polarity requirements for a collectivization of the excitation along the chain. However, only DNA in B-form displays the proper anharmonicity for the formation of a vibrational P–O exciton. This can be seen from the width of the P–O Raman bond at 830 cm^{-1} [36,37] For DNA in A-form the band of the P–O stretching is shifted at 807 cm^{-1} and narrowed in a sharper line, showing that the P–O excitation remains localized on individual P–O groups and does not spread along the chain in exciton form. A prerequisite for the appearance of Davydov solitons on DNA is then fulfilled only for B helix structures. Different biological functions are associated to B (resting) and A (active) DNA; a soliton dynamics could have a major role in DNA structural and functional transitions. Indeed, B → A,[35] B → Z[34] transitions as well as the opening of DNA helices[33] have been described in terms of soliton dynamics.

4.2. Water in Biological Systems

Water in biological systems exhibits peculiar properties. Only a percentage of total water appears in the form of usual liquid water.[38,39] A relevant part is made up of water molecules which are bound to different sites of macromolecules in the form of hydration water, while a sizable amount, although not fixed to any definite molecular site, is strongly affected by macromolecular fields; this kind of water has been termed "vicinal" water.[39] "Vicinal" water has been extensively investigated in the last decade and it exhibits noticeable properties.[40] It does not have a unique freezing temperature but an interval ranging from -70 to $-50°C$; it is a very bad solvent for electrolytes, but nonelectrolytes have the same solubility properties in it as in usual water. Its viscosity is enhanced and its NMR response is anomalous. The whole of these physical properties point to the existence of some dynamic correlation among its constituents.

It is interesting to notice that most of the "vicinal" water surrounds the elements of the cell cytoskeleton.[39] It is not unlikely that the coherent electric waves discussed in this paper are responsible for such a correlation.[20] Bound water also exhibits some kind of collective behavior;

actually it has been shown that bound water produces electrets around many macromolecules. Activation energies of about 0.3–0.4 eV have been detected and relaxation times up to 10^5 s have been measured, suggesting the existence of zero-frequency modes of oscillation.[9,10] A zero-frequency mode, i.e., in our theoretical framework a massless mode, appears when dynamical rearrangements of symmetry are at work. Since the electret activation energy is of the same order of magnitude as the energy required for a Davydov soliton, we think that the electret is the result, via a spontaneous symmetry breakdown, of the soliton regime occurring on biomolecules.

It is worthwhile noticing that hysteresis has been observed in all cases[9,10]; in our model then the electret would appear different in subsequent cycles (alternance of Davydov and Fröhlich regimes) during the cell lifetime, giving rise to a nonstationary evolution instead of a periodic one (on a time scale comparable with the lifetime of the biological system under consideration).

4.3. Coherent Electric Waves in Living Matter

Up to now, different kinds of evidence can be quoted, which support the Fröhlich proposal of electric waves in living matter. First of all, we mention those resonance experiments where external electromagnetic waves of selected frequencies interact with biological targets inducing macroscopic nonthermal consequences. There is a growing literature[41–43] about microwave interaction with different types of cells. It has been observed that at given frequencies the effects occur only when a threshold is overcome and are independent from different intensities of irradiation.

A similar phenomenon, as far as the biological effects are concerned, has been observed in the visible region for a long time,[44] but only recently has satisfactory phenomenological evidence been achieved.[45] In this case, astonishingly, there is only one frequency in the visible domain (at 632.8 nm, the wavelength of He–Ne lasers) which is the same for different types of cells (for instance *E. coli* and He–La). Moreover, active cells emit electric and electromagnetic radiation on a very large frequency spectrum. Measurements have been performed at frequencies lower than 100 GHz[46,47] and in the optical range.[48] This last type of emission, which could be of coherent type, has been attributed to the dynamics of DNA in the cell.

Further evidence for coherent electric waves comes from Raman experiments on living cells.[49] These experiments show a time-dependent pattern of lines in IR and IR regions. The connections between Raman spectroscopic data and the underlying (spatial and temporal) order in living matter is discussed elsewhere.[50–52]

A different kind of support for Fröhlich ideas has been brought by experiments on rouleaux formation in erythrocyte suspensions.[53] These experiments show that selective long-range interactions appear among metabolically active red blood cells. The connection between the experimental outcome and Fröhlich theory has been recently discussed.[20,54]

In conclusion, phenomenological evidence supports the main elements of our QFT approach. We feel that the task of getting a satisfactory dynamical description of living systems is not out of reach.

Solitons and Energy Transfer Along Protein Molecules

A. S. DAVYDOV

The Institute of Theoretical Physics, Academy of Sciences of the Ukrainian S.S.R., Kiev, U.S.S.R.

(*Received* 2 *July* 1976, *and in revised form* 10 *August* 1976)

It is shown that the energy released in the hydrolysis of ATP molecules can be transferred in the form of vibration solitons along α-helical protein molecules. The vibration solitons are collective excitations travelling along a chain of successively arranged peptide groups and corresponding to amide I vibrations. The exceptional stability of solitons in one-dimensional structures can account for the small probability of their energy transforming into that of disordered heat motion.

1. Introduction

Many biological phenomena are known to be associated with spatial energy transfer along protein molecules. To elucidate the mechanism for this energy transfer at the molecular level is one of the most urgent problems in bioenergetics.

It is now established that the energy (about 0·43 eV or 10 kcal/mol) released in the hydrolysis of adenosine triphosphate molecules (ATP) is the universal energy unit used in all biological phenomena. This energy is only 20 times greater than the average energy of heat motion at physiologic temperatures. It is insufficient to excite the electronic states of molecules. Therefore the importance of vibration excitations (with an energy less than 0·4 eV) of separate groups of atoms in protein molecules has been repeatedly indicated.

The opponents of this viewpoint have frequently mentioned the fact that the lifetime (with respect to transformation into heat) of such excitations is very small (of the order of 10^{-12}–10^{-13} s). At the same time it is usually forgotten that when the molecular system is organized in a certain manner the lifetime of excitations of some of its degrees of freedom can increase by many orders. For example, in condensed luminescent molecular systems (in particular, in crystalline anthracene) the electronic excitations of a system of conjugated π-electrons give off almost all their energy by radiation during the time (10^{-8}–10^{-9} s) exceeding considerably the time of thermal relaxation.

In addition to the fact that the energy released in the hydrolysis of ATP molecules is insufficient to excite electronic states, the excitation of the latter is also disadvantageous because their lifetime relative to radiation is considerably smaller than the corresponding lifetime of vibration states. For example, the lifetime (relative to radiation) of valence vibrations C=O (amide I with an energy of 0·21 eV) in peptide groups of proteins is equal to about 0·01 s. It exceeds the lifetime of electronic excitations of the same group ($\sim$ 4·4 eV of energy) by a factor of $(4{\cdot}4/0{\cdot}21)^4 = 1{\cdot}9 \times 10^5$.

In alpha-helical protein molecules the peptide groups (H—N—C=O) are situated along the molecule in three chains. In each of these chains the neighbouring peptide groups are held together by hydrogen bonding between atomic H and O. Just these bonds provide for a relatively rigid structure of the α-helix.

Amide I vibrations are quite characteristic, i.e. they are weakly connected with other normal vibrations of protein molecules. This fact is confirmed by a very small difference in the amide I vibration frequencies in proteins of different kinds.

The collective excitations of a chain of successively arranged peptide groups which correspond to amide I vibrations are described by "solitary waves"—the vibration solitons. They have a particle-like character, propagate rapidly along the chain and have big lifespan, because they interact with other degrees of freedom of the molecule much more weakly than separate amide I vibrations.

The solitons were first observed as solitary, rapidly moving water loops in narrow channels filled with water. The "tsunami" covering huge distances in the oceans is also identified with solitons by some people. Numerous investigations (Hasegawa & Tappert, 1973; Scott, Chu & McLaughlin, 1973; Toda, 1975) showed that a remarkable property of the solitons described by the same non-linear equation as vibration solitons is their exceptional stability for outer disturbances.

The formation of stable excitations such as vibration solitons in the α-helical portions of protein molecules guarantees the high efficiency of the transfer of energy, released in the hydrolysis of ATP molecules, by protein. The exceptional stability of solitons in one-dimensional structures can account for the small probability of their energy transforming into that of disordered heat motion.

2. Solitons in One-Dimensional Chains

The dipole–dipole interaction between the adjacent peptide groups situated along a hydrogen-bonded chain in the α-helical protein molecules is an order of magnitude higher than a similar interaction between the

nearest groups of neighbouring chains. Therefore the excitations of the three chains may thus be considered independently. For the sake of simplicity we shall further investigate the excited states of only one of these chains.

Consider an infinite chain of weakly bound peptide group with mass M situated along axis x at distance R. Assume that the internal excitations of peptide groups are characterized by an energy ε (equal to 0·21 eV) and an electric dipole moment d directed along the chain. To investigate the collective excitations of this chain we shall use the results obtained by the author and Kislukha (1976).

Let x_n be a co-ordinate characterizing the position of the nth group and B^+ the creation operator for an amide I vibration excitation.

The excited state of such a chain is defined by the wave function

$$\psi(t) = \sum_n a_n(t) B_n^+ |0\rangle \tag{1}$$

with the normalized condition

$$\langle\psi(t)|\psi(t)\rangle = \sum_n |a_n(t)|^2 = 1. \tag{2}$$

Here $|0\rangle$ is the function of the ground state. The function (1) must satisfy the Schrodinger equation

$$i\hbar \frac{\partial \psi}{\partial t} = H\psi.$$

Since the effective mass M of the peptide group is large, we treat their motion classically, and the amide I vibration excitations terms of quantum mechanics.

The Hamiltonian of the chain (provided the interaction between adjacent groups only is taken into account) can then be written as

$$H = T + U + \sum_n [(\varepsilon - D_n) B_n^+ B_n - J(B_{n+1}^+ B_n + B_{n+1} B_n^+)] \tag{3}$$

where the function $-D_n$ characterizes the change in the static interaction (the energy of the hydrogen bond) of the nth group with neighbouring groups when it is excited. Making allowance for the interaction with nearest neighbours we have

$$D_n = \mathscr{D}_n(|x_{n+1} - x_n|) + \mathscr{D}_n(|x_{n-1} - x_n|) \approx \left(1 + \frac{\beta}{R}\rho_n\right) D$$

where

$$\rho_n = R - |x_n - x_{n-1}|$$

is the decrease in equilibrium distances between peptide groups; $D = 2\mathscr{D}(R)$ and β are the positive parameters of a theory. $J = 2d^2/R^3$ is the operator

of the resonance interaction determining the transition of an excitation from one group to another;

$$T+U=\tfrac{1}{2}\sum_n\left[M\left(\frac{\partial x_n}{\partial t}\right)^2+w\rho_n^2\right]$$

are the kinetic and the potential energies of the displacement of peptide groups; w is the elasticity constant of the chain.

The set of functions $a_n(t)$ and $\rho_n(t)$ determine the distribution of excitations of peptide groups in the chain and the relative changes in the equilibrium distances between them. They obey the set of equations

$$i\hbar\frac{\partial a_n}{\partial t}=\left[\varepsilon+T+U-\left(1+\frac{\beta}{R}\rho_n\right)D\right]a_n-J(a_{n+1}-a_{n-1}), \tag{4}$$

$$\frac{\partial^2\rho_n}{\partial t^2}=-\frac{w}{M}(2\rho_n-\rho_{n+1}-\rho_{n-1})+\frac{\beta D}{MR}(2|a_n|^2-|a_{n+1}|^2-|a_{n-1}|^2). \tag{5}$$

Equations (4) and (5) define the collective excitations and deformations of the chain.

We are interested only in excitations distributed over some region of the chain. Therefore we can apply the continual model. At this approximation we can replace discrete functions $a_n(t)$ and $\rho_n(t)$ by the continuous functions $a(\xi, t)$ and $\rho(\xi, t)$ of the dimensionless co-ordinate $\xi = x/R$. Using the expression

$$f(\xi\pm1, t)\approx\left(1\pm\frac{\partial}{\partial\xi}+\frac{1}{2}\frac{\partial^2}{\partial\xi^2}\right)f(\xi, t),$$

we can transform equations (4) and (5) to

$$\left\{i\hbar\frac{\partial}{\partial t}-\left[\lambda-\frac{\beta D}{R}\rho(\xi, t)\right]+J\frac{\partial^2}{\partial\xi^2}\right\}a(\xi, t)=0, \tag{6}$$

$$\left[\frac{\partial^2}{\partial t^2}-v_a^2\frac{\partial^2}{\partial\xi^2}\right]\rho(\xi, t)+\frac{\beta D}{MR}\frac{\partial^2}{\partial\xi^2}|a(\xi, t)|^2=0, \tag{7}$$

where

$$\lambda\equiv\varepsilon+T+U-D-2J,$$

$$T+U\equiv\frac{M}{2}\int_{-\infty}^{\infty}d\xi\left[\left(\int_{-\infty}^{\xi}d\eta\frac{\partial}{\partial t}\rho(\eta, t)\right)^2+v_a^2|a(\xi, t)|^4\right], \tag{8}$$

$v_a^2\equiv w/M$, therefore $V_a=v_aR$ is the longitudinal sound velocity in the chain.

We shall look for solution of the set of equations (6) and (7) in the form of excitations propagating along the chain with velocity $V=vR$. For this

we set

$$\rho(\xi, t) = \rho(\xi - vt), \qquad a(\xi, t) = \Phi(\xi - vt) \exp\left[i\theta(\xi, t)\right].$$

We then obtain from equation (7)

$$\rho(\xi, t) = \frac{\beta D |a(\xi, t)|^2}{MR(v_a^2 - v^2)}. \tag{9}$$

Substituting this value in equations (6) and (8) we transform them to

$$\left\{ i\hbar \frac{\partial}{\partial t} - \lambda + J \frac{\partial^2}{\partial \xi^2} + G_v |a(\xi, t)|^2 \right\} a(\xi, t) = 0, \tag{10}$$

$$T + U = \frac{G_v}{2(v_a^2 - v^2)} \int_{-\infty}^{\infty} d\xi \left[\left(\int_{-\infty}^{\xi} d\eta \frac{\partial}{\partial t} |a(\eta, t)|^2 \right)^2 + v_a^2 |a(\xi, t)|^4 \right], \tag{11}$$

where

$$G_v = \frac{G_0}{1 - (V/V_a)^2}, \qquad G_0 = \frac{\beta^2 D^2}{wR^2}. \tag{12}$$

The exact normalized solution of the non-linear Schrodinger equation (10) is called soliton. It has the form

$$a_v(\xi, t) = \frac{\sqrt{\mu_v/2} \exp\left\{ i \left[\frac{\hbar v}{2J} (\xi - \xi_0) - \Omega_v t \right] \right\}}{\cosh\left[\mu_v(\xi - \xi_0 - v)\right]}, \tag{13}$$

where

$$\mu_v = G_v/4J; \tag{14}$$

ξ_0 is the arbitrary constant due to the translational invariance of equations (6) and (7). Each value $V = vR$ corresponds to the soliton energy

$$E_V \equiv \hbar\Omega_V = \hbar\Omega_0 + \frac{\hbar^2 V^2}{2JR^2} + \frac{G_0^2(z^2 + \frac{3}{2}z^4 - \frac{1}{2}z^6)}{24J(1 - z^2)^3}, \tag{15}$$

where $z \equiv V/V_a$ and

$$\hbar\Omega_0 = \varepsilon - D - 2J - G_0^2/48J \tag{16}$$

is the internal energy of the soliton.

It follows from the expression (15) that when the soliton velocity approaches the longitudinal sound velocity V_a the soliton energy tends to infinity. At all finite values of the soliton energy its velocity is therefore always less than V_a. The soliton energy thus cannot transform into the energy of longitudinal sound waves. This is one of the reasons of the great stability of the solitons.

At small velocities of the soliton when $V \ll V_a$ is valid, the soliton energy (15) transforms to a simple expression

$$E_V = \hbar\Omega_0 + \tfrac{1}{2}m^*V^2, \tag{17}$$

where

$$m^* = \frac{1}{2J}\left[\frac{\hbar^2}{R^2} + \frac{G_0^2}{12V_a^2}\right] \tag{18}$$

is effective mass of the soliton. In the same approximation the parameter

$$\mu_v \approx \frac{G_0}{4J}[1+(V/V_a)^2] \approx \frac{G_0}{4J} = \mu_0$$

is not dependent upon the soliton velocity.

Substituting equation (13) into equation (9) we find the distribution of the change in relative distances between the peptide groups. At small velocities of the soliton we shall get

$$\rho(\xi, t) = \frac{\sqrt{G_0^3/w}}{8J}\,\mathrm{sech}^2\,[\mu_0(\xi - \xi_0 - vt)]. \tag{19}$$

According to equation (19), the maximal relative changes in distances between peptide groups at $\xi = \xi_0 + vt$ moves along the chain with the velocity $V = vR$. The deformation moving along the chain is accompanied by the internal excitation of the peptide groups. The region of the chain embraced by the excitation and deformation is defined by

$$R\Delta\xi \approx \frac{\pi R}{\mu} = \frac{4\pi JwR^3}{\beta^2 D^2}. \tag{20}$$

3. Excitons in One-Dimensional Chains

In an absolutely rigid chain $w = \infty$, so that the non-linearity parameter (12) is equal to zero and equation (10) reduces to linear Schrodinger equation which has solutions in the form of plane waves. In this case an excitation is uniformly distributed along the whole chain. The excitations of this type is called excitons. The internal energy of the exciton is

$$E_0 = \varepsilon - D - 2J. \tag{21}$$

The effective mass of the exciton is

$$m_0^* = \hbar^2/2R^2J\,. \tag{22}$$

At the final value w the non-linear equation (10) has also solution in the form

of plane wave (exciton)

$$a(\xi, t) = A \exp\{i[k\xi R - \omega(k)t]\} \tag{23}$$

which characterizes the uniform distribution of an exciton along the whole chain. To each wave (23) there corresponds the energy

$$\hbar\omega(k) = E_0 + \hbar^2 k^2/2m_0^*.$$

The internal energy exciton E_0 and an effective mass m_0^* are determined by expressions (21) and (22). Therefore the internal energy of the exciton exceeds the internal energy (16) of the soliton by the value $G_0^2/48J$. Thus the excitations (23) in one-dimensional molecular systems are unstable.

In order to satisfy the normalization condition (2), we must set up in a chain of infinite length a wave packet with values of k in some narrow interval $k_0 - \Delta k \leqslant k \leqslant k_0 + \Delta k$, using the solution (23). The excitation described by such a wave packet propagates with the group velocity $V_g = \hbar k_0/m_0^*$. In this state the energy and the momentum of the exciton have not well-defined values. The region of the chain embraced by the excitation increases, because these wave packets are known to "spread". If the excitation was initially localized on segment $(\Delta x)_0 = 2\pi/\Delta k$ this segment increases eventually, so that in the time t

$$(\Delta x)_t \approx \sqrt{(\Delta x)_0^2 + \hbar^2 t^2/[m_0^*(\Delta x)_0]^2}.$$

4. The Stability of Solitons

A remarkable property of the vibration solitons at small velocities is that the distribution of excitation and deformation characterized by the function (19) remains completely unchanged in motion. The value of the maximum, the shape and the width (20) are independent of the velocity (energy) of a soliton and are defined only by the properties of the chain, i.e. the quantities J, G_0, R. When the soliton slows down, its velocity changes, leaving the shape and the size of the excitation region unchanged. The stability property of solitons enables us to regard them as particle-like formations.

The stability of solitons is connected with the competition of two processes: the spreading of excitation region, determined by the resonance interaction J, and the tendency towards excitation localization which is due to the non-linear terms of equation (10) proportional to the parameter (12). In protein molecules the formation of solitons corresponding to the vibration amide I is favoured by the one-dimensional arrangement of peptide groups, the relative softness of hydrogen bonds between peptide groups (the small w) and the orientation of electric dipole moments of vibrations along the chain. Only if the electric dipole moments in the excitation region are arranged

in this manner the distances between peptide group decrease, thus promoting excitation localization. In very rigid chains the ratio G_0/J is very small and the formation of solitons is impossible.

Solitons can be formed only under a strong coupling of the internal vibration with a local deformation of the chain. This coupling is proportional to the non-linearity parameter $G_0 = \beta^2 D^2/wR^2$. This parameter is big enough in comparatively soft chains of the peptide groups in protein molecules.

The condition of the formation solitons in α-helical protein molecules resembles the condition of the super conductivity formation in a metal. The superconductivity state due to the interaction of the electrons of a metal with phonons (the shifts of ions). Good conductors (silver, copper, gold) do not turn into a superconductive state. Superconductive states arise only in the metals which have a strong enough electron–phonon interaction. The strong electron–phonon interaction leading to a large resistivity in the normal state of metal makes the formation a superconducting state without any resistivity.

The above-considered solitons transfer with a very great efficiency the energy of excitation between different portions of the protein molecule. The energy transfer is accompanied by the deformation moving along the protein molecule. These solitons have a longitudinal polarization, since the electric dipole moment is directed along the chain.

The formation of solitons can occur only under the action of local excitations. These types of excitations also include the chemical energy released in the hydrolysis of ATP molecules which often attach themselves to certain portions of protein molecules (for example, to the heads of myosin molecules in the muscles). The vibration solitons cannot be excited by the infrared radiation of suitable frequency ($\sim 1660\ \text{cm}^{-1}$), since the wave length of this radiation is very large ($\sim 6 \times 10^4$ Å), and the photon localization is impossible with an accuracy higher than the wave length of radiation.

The concept of solitons which occur in myosin molecules was used by the present author† (Davydov, 1973, 1974, 1975) to elucidate the contraction mechanism of transversely striated muscles at the molecular level. Only the kinetic energy of solitons is actively used in muscle contraction, since the sliding of thin filaments relative to thick ones in the sarcomeres is due to the movement of solitons in myosin molecules contained in thick filaments.

† In these papers it was assumed that the distortion of the chain follows in an inert manner the movement of excitation. The notion of inert motion of peptide groups is valid only if the soliton velocity is much less than the longitudinal sound velocity in chain of the peptide groups.

Solitons in a Nonlinear Inhomogeneous Transmission Line

Tsuneo YAGI*

Department of Electrical Engineering, Ikutoku Technical University, 1030-Shimoogino, Atsugi-shi, Kanagawa 243-02

(Received October 15, 1980)

Nondestructive propagation of solitons is described in a nonlinear, electrical transmission line having loss and inhomogeneity. According to its nonlinear property expressed in terms of the [P+1]-th power, the transmission line demands a certain balance between the magnitude of loss or activity and inhomogeneity to preserve a unique soliton form of $\mathrm{sech}^{2/P}$ with exponentially varying amplitude. The adiabatic amplification effect for waves propagating in the line is considered by estimating their conserved quantities. The theoretical anticipation is confirmed by several numerical calculations. It is also shown that, for $P \geq 4$, it seems that solitons never travel stably in the real nonlinear transmission line.

§1. Introduction

In this decade, various transmission line models for solitons and related phenomena have been discussed in many articles.[1,2] The recent advance is, in particular, some discovery of the transmission line models which can be shown to have the exact N-interacting soliton solution. For the first time Hirota and Suzuki[3] showed that a certain nonlinear network is an electrical model analog to the well known Toda's exponential lattice[4] in dynamics. Later, other different networks which could be treated analytically were investigated by Hirota and Satsuma,[5] and others.[6-8] However, as a solvable model, each section of such ladder networks has to contain both nonlinear inductor and capacitor which indicate peculiar characteristics of nonlinear mathematical functions.

In parallel with above theoretical investigations another conventional approach has been performed to get a good description of nonlinear phenomena in the realistic nonlinear transmission lines. Noguchi[9] applied the perturbation method[10] to analyze an electrical ladder network of the low-pass filter, and found to explain the comparatively low frequency nonlinear waves such as video solitons in the line. According to this perturbation method, the low frequency waves in the lossless transmission line with [P+1]-th power nonlinearity can be well approximated in the P-th nonlinear K-dV equation.[9,11] In other words, the low frequency nonlinear waves are described by the fundamentals of both linearized dispersion relation and nonlinear property of the transmission line.

The main aim of this article is to extend this method to a case of lossy and inhomogeneous nonlinear transmission lines, and to discuss some interesting consequences. We can find several studies on this problem, *e.g.*, a lossless but linearly inhomogeneous case,[12] a randomly inhomogeneous case,[13] and a nonlinear transmission line with small dissipations.[14] In these examples, however, the describing equations could not have any analytical solutions as puls-like waves, and so experimental or numerical treatments were used in their estimations.

We restrict to an exactly solvable case of a lossy and inhomogeneous transmission line with [P+1]-th power nonlinearity. In the next section, we introduce a model of the nonlinear transmission line, and derive an approximate equation which describes the comparatively low frequency nonlinear waves. We also discuss on the particular case of the approximate equation calles the P-th nonlinear K-dV equation with loss and inhomogeneity. Section 3 is the most interesting one in which

* Deceased. Correspondence to Dr. Kiyoshi Sakai, c/o Professor Noguchi, Department of Electrical Engineering, Faculty of Engineering, Keio University, Yokohama.

we consider about the properties of soliton solutions, and use numerical calculations to compare with the corresponding theoretical results. Section 4 is devoted to more careful discussions on the mechanism of the amplification or damping of video solitons. The last section is a conclusion.

§2. Derivation of a Modified Type of the K-dV Equation

We consider an infinitely long transmission line (or ladder networks) composed of lumped sections; a typical section is shown in Fig. 1. If $\Phi_n(i_n)$ is the nonlinear flux per unit length Δ at stage n, the flux of the section is $\Delta\Phi_n(i_n)$ webers. Similarly the resistance of the section is ΔR_n ohms, the nonlinear charge is $\Delta Q_n(v_n)$ coulombs, the leakage conductance is ΔG_n mohs.

The fundamental equations derived from Fig. 1 are

$$i_n - i_{n+1} = \Delta G_n v_n + \Delta \frac{\partial Q_n}{\partial t}, \tag{1}$$

$$v_{n-1} - v_n = \Delta R_n i_n + \Delta \frac{\partial \Phi_n}{\partial t}. \tag{2}$$

We express each parameters of the line as follows:

$$\Phi_n = L_0[1 - \Gamma_L(n, t) - \alpha_L i_n^{\mathrm{P}}/(\mathrm{P}+1)]i_n, \tag{3}$$

$$Q_n = C_0[1 - \Gamma_C(n, t) - \alpha_C v_n^{\mathrm{P}}/(\mathrm{P}+1)]v_n, \tag{4}$$

$$R_n = R_0[1 - \Gamma_R(n, t)], \tag{5}$$

$$G_n = G_0[1 - \Gamma_G(n, t)], \tag{6}$$

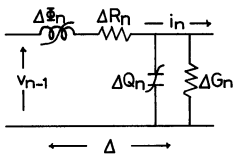

Fig. 1. A nonlinear transmission line, (a unit section).

$$\Gamma_L/\Gamma_{L_0} = \Gamma_C/\Gamma_{C_0} = \Gamma_R/\Gamma_{R_0} = \Gamma_G/\Gamma_{G_0} = \Gamma(n, t). \tag{7}$$

Where $\Gamma(n, t)$ describes an inhomogeneity of the line. We assume that $\Gamma(n, t)$ is a slowly varying function with respect both n and t and so,

$$\begin{aligned}\Gamma(n, t) &= \Gamma(n\Delta - (L_0C_0)^{-1/2}t) = \Gamma(\xi) \\ &= \Gamma(\xi_0 + (\xi - \xi_0)) \\ &\simeq \Gamma(\xi_0) + (\xi - \xi_0)\left.\frac{\partial \Gamma}{\partial \xi}\right|_{\xi=\xi_0},\end{aligned} \tag{8}$$

and the magnitudes of dissipations (R_0/G_0) are assumed to be both small. The nonlinear inhomogeneous transmission line shown here slightly differs from the previous line[15] which has the frequency dispersion even in the limit of distributed network $(\Delta \to 0)$. In the examination of the present transmission line we must remember that the line is constructed from lumped parameters $(\Delta = 1)$. So we consider the continuum approximation of eqs. (1) and (2). This is a reasonable approximation for the long wavelength (or low frequency) waves comparing with the length of a section of the line. By using

$$f_{n\pm1}(t) = \left[f(x, t) \pm \Delta \frac{\partial f}{\partial x} + \frac{\Delta^2}{2}\frac{\partial^2 f}{\partial x^2} \pm \frac{\Delta^3}{6}\frac{\partial^3 f}{\partial x^3} + \frac{\Delta^4}{24}\frac{\partial^4 f}{\partial x^4} \pm \cdots \right]_{x=n\Delta}, \tag{9}$$

rewriting i_n, v_n, i_{n+1} and v_{n-1} in eqs. (1) and (2), we obtain a set of nonlinear partial differential equation for $v(x, t)$ and $i(x, t)$. From the Ohm's law, if we can assume

$$v \simeq \left[\frac{\partial \Phi}{\partial i}\Big/\frac{\partial Q}{\partial v}\right]^{1/2} i \simeq \left(\frac{L_0}{C_0}\right)^{1/2} i = Zi, \tag{10}$$

and introduce $u(x, t)$ as the right progressing waves;

$$u = Z^{1/2} i = Z^{-1/2} v, \tag{11}$$

the next two equations are derived as,

$$\frac{\partial u}{\partial x} + \frac{\Delta}{2}\frac{\partial^2 u}{\partial x^2} + \frac{\Delta^2}{6}\frac{\partial^3 u}{\partial x^3} + \frac{\Delta^3}{24}\frac{\partial^4 u}{\partial x^4} + \frac{\Delta^4}{120}\frac{\partial^5 u}{\partial x^5} + \cdots + RZu + Z\frac{\partial Q(Z^{1/2}u)}{\partial t} = 0, \tag{12}$$

$$\frac{\partial u}{\partial x} - \frac{\Delta}{2}\frac{\partial^2 u}{\partial x^2} + \frac{\Delta^2}{6}\frac{\partial^3 u}{\partial x^3} - \frac{\Delta^3}{24}\frac{\partial^4 u}{\partial x^4} + \frac{\Delta^4}{120}\frac{\partial^5 u}{\partial x^5} - \cdots + GZ^{-1}u + Z^{-1}\frac{\partial \Phi(Z^{-1/2}u)}{\partial t} = 0. \tag{13}$$

Adding eqs. (12) and (13), and neglecting small terms,

$$2\frac{\partial u}{\partial x}+\frac{\Delta^2}{3}\frac{\partial^3 u}{\partial x^3}+(GZ+RZ^{-1})u+Z\frac{\partial Q}{\partial t}+Z^{-1}\frac{\partial \Phi}{\partial t}=0. \tag{14}$$

In eq. (14), we introduce a coordinate system moving to the right with the velocity of an infinitesimally small amplitude wave along the line,

$$\xi=x-(L_0C_0)^{-1/2}t, \quad \tau=(L_0C_0)^{-1/2}t, \tag{15}$$

and using the simple relation; $\partial/\partial\tau \simeq -\partial/\partial\xi$, we get the following modified type of the P-th nonlinear K-dV equation having loss and nonuniformity terms,

$$\frac{\partial u}{\partial \tau}+\alpha u^{\mathrm{P}}\frac{\partial u}{\partial \xi}+\beta\frac{\partial^3 u}{\partial \xi^3}+\gamma\frac{\partial u}{\partial \xi}+\delta u=0, \tag{16}$$

where

$$\alpha=\alpha_C Z^{\mathrm{P}/2}+\alpha_L Z^{-\mathrm{P}/2}, \quad \beta=\frac{\Delta^2}{6}=\frac{1}{6},$$

$$\gamma=\Gamma_C+\Gamma_L=(\gamma_{C_0}+\gamma_{L_0})\Gamma(\xi)=\gamma_0\Gamma(\xi), \quad \delta=\gamma_0+(GZ+RZ^{-1})/2. \tag{17}$$

The above eq. (16) with eqs. (17) seems to describe well the comparatively long wavelength waves in the line. Hereafter, we examine a simpler case of which the previous assumption (10) is completely valid;

$$\gamma_{C_0}=\gamma_{L_0}=\gamma_0/2, \quad \alpha_L Z^{-\mathrm{P}/2}=\alpha_C Z^{\mathrm{P}/2}=\alpha_0/2, \quad \text{and} \quad G=R=d_0/(Z+Z^{-1})=\text{const.} \tag{18}$$

The coefficients of eq. (16), eqs. (17) are then,

$$\alpha=\alpha_0, \quad \beta=1/6, \quad \gamma=\gamma_0(\xi-\xi_0), \quad \text{and} \quad \delta=\gamma_0+d_0/2. \tag{19}$$

Besides the above critical case, even in the below cases,

$$|\alpha_C Z^{\mathrm{P}/2}-\alpha_L Z^{-\mathrm{P}/2}|, \quad |\gamma_{C_0}-\gamma_{L_0}|, \quad |\gamma_{G_0}Z+\gamma_{R_0}Z^{-1}|=O(\varepsilon), \tag{20}$$

the assumption (10) and so eq. (16) with eqs. (17) may still hold sufficiently well.[15]

Here, we introduce the following dependent variable transformations;

$$U(\zeta,\theta)=\exp(2\gamma_0\tau/\mathrm{P})u(\xi,\tau),$$
$$\theta=\exp(-3\gamma_0\tau)/(-3\gamma_0),$$
$$\zeta=\exp(-\gamma_0\tau)(\xi-\xi_0), \tag{21}$$

and rewrite eq. (16) to the P-th nonlinear K-dV equation with an additional term,

$$\frac{\partial U}{\partial \theta}+\alpha U^{\mathrm{P}}\frac{\partial U}{\partial \zeta}+\beta\frac{\partial^3 U}{\partial \zeta^3}+\sigma\theta^{-1}U=0, \tag{22}$$

where $\sigma=2/3\mathrm{P}-\delta/3\gamma_0$. Figure 2 indicates the conditions in which the last term of eq. (22) disappears ($\sigma=0$) for the various nonlinear property P of the line. In such cases, eq. (22) reduces to the usual P-th nonlinear K-dV equation which has the single soliton solution to each natural number P. We discuss in detail on the property of these soliton solutions in the next section.

In the final of this section, we denote some other solvable case without the condition $\sigma=0$. If $\sigma=1$ ($\sigma=2$), eq. (22) reduces to the P-th nonlinear spherical (cylindrical) K-dV equation. For P=1, such spherical (cylindrical) soliton like pulses have been already found as ion-acoustic plasma waves.[16,17] It is interesting that the behavior of three dimensional

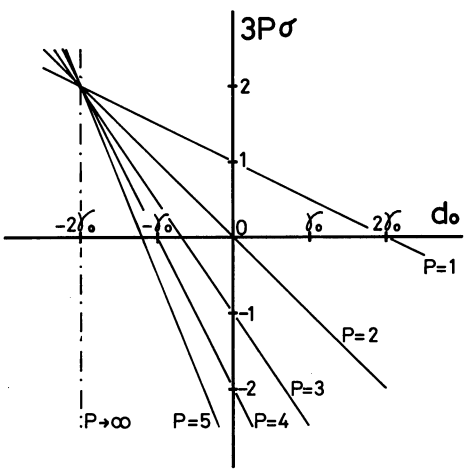

Fig. 2. Schematic description of conditions $\sigma=0$.

nonlinear waves can be simulated in the one-dimensional nonlinear transmission line with loss and nonuniformity.

In general, by introducing the transformation;[18]

$$U' = U \exp\left(\sigma \int \theta^{-1}\, d\theta\right), \tag{23}$$

and substituting to eq. (22), then

$$\frac{\partial U'}{\partial \theta} + \alpha'(\theta) U'^{P} \frac{\partial U'}{\partial \zeta} + \beta \frac{\partial^3 U'}{\partial \zeta^3} = 0, \tag{24}$$

where

$$\alpha'(\theta) = \alpha \exp\left(-P\alpha \int \theta^{-1}\, d\theta\right).$$

The asymptotic solutions of the above variable-coefficient K-dV equation (24) for P=1 and 2 have been discussed in detail,[19,20] so we can obtain a little more information on the solutions of eq. (24), and so of eq. (16).

§3. Properties of Solitons

In this section, we show the single soliton solution of the P-th nonlinear K-dV equation with loss and nonuniformity terms (16). The single soliton solution is derived from that of the usual K-dV equation (22), through the explicit transformations (21), under the condition of

$$\sigma = 2/3P - \delta/3\gamma_0 = 0, \tag{25}$$

as

$$u(\xi, \tau) = u_s(\tau)\, \mathrm{sech}^{2/P} \times \left[W_s^{-1}(\tau) \left\{ \xi - \xi_0 (1 - e^{\gamma_0 \tau}) + \frac{V_s(\tau)}{3\gamma_0} (1 - e^{3\gamma_0 \tau}) \right\} \right], \tag{26}$$

where

$$u_s(\tau) = u_0 \exp(-2\gamma_0 \tau / P),$$
$$V_s(\tau) = 2\alpha u_s(\tau)^P / (P+1)(P+2),$$
$$W_s(\tau) = [P^2 V_s(\tau) / 4\beta]^{-1/2}.$$

The amplitude dependent velocity of the single soliton (26) is

$$\frac{d\xi}{d\tau} = -\frac{\partial \phi}{\partial \tau} \Big/ \frac{\partial \phi}{\partial \xi} \gamma_0 (\xi - \xi_0) + V_s(\tau) \exp(-2\gamma_0 \tau), \tag{27}$$

where $\phi(\xi, \tau)$ is the phase of $\mathrm{sech}^{2/P}[\phi]$ in eq. (26). This velocity becomes a constant value $V_s(\tau)|_{\gamma_0 - 0}$ to each natural number P. For any P, if $\gamma_0 > 0$ ($\gamma_0 < 0$), then the single soliton comes to broaden (compress) its own width during the propagation, since the front (tail) part of the body moves faster than tail (front). In Fig. 3, 4, and 5, we show typical results of numerical simulation of eq. (16) for P=1, 2, and 3, respectively. We used the single soliton-form (26) as the initial wave profile, and other experimental conditions were denoted in the corresponding figure captions. As is already shown in eq. (25), to preserve a unique soliton form without emitting any oscillatory waves, the following relations must be satisfied between the magnitudes of inhomogeneity and loss or activity;

$$\gamma_0 = (GZ + RZ^{-1})/2 \quad \text{for } P=1,$$
$$GZ + RZ^{-1} = 0 \text{ and any } \gamma_0 \quad \text{for } P=2,$$
$$\gamma_0 = -(GZ + RZ^{-1})/(2 - 4/P) \quad \text{for } P \geq 3.$$

It is evaluated that, for the cases of $P \geq 2$, the amplitudes of solitons are grown ($\gamma_0 < 0$) by the inhomogeneity even in the transmission

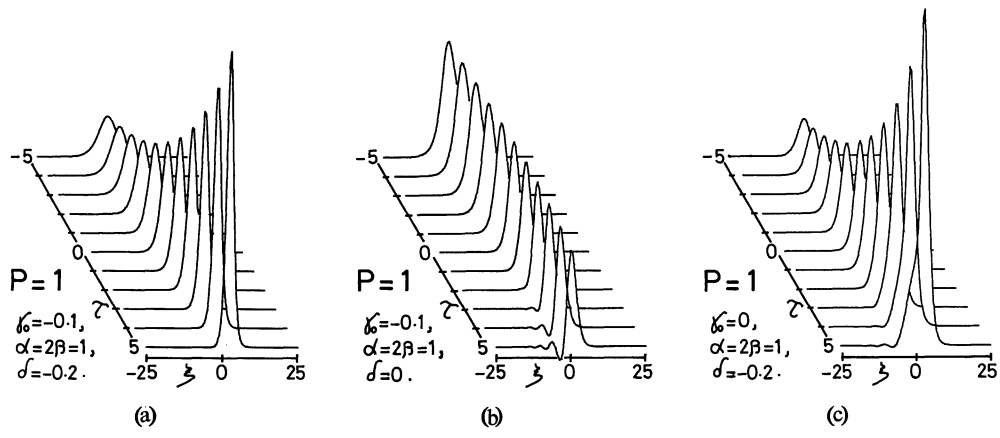

Fig. 3. Amplification and damping of one-soliton for P=1; (a) $\sigma=0$, ($\gamma_0=-0.1$, $\delta=-0.2$), (b) $\sigma\neq 0$, ($\gamma_0=-0.1$, $\delta=0$), (c) $\sigma\neq 0$, ($\gamma_0=0$, $\delta=-0.2$).

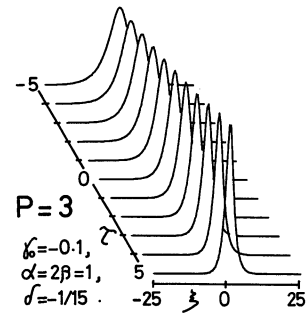

Fig. 5. Amplification and damping of one-soliton for P=3.

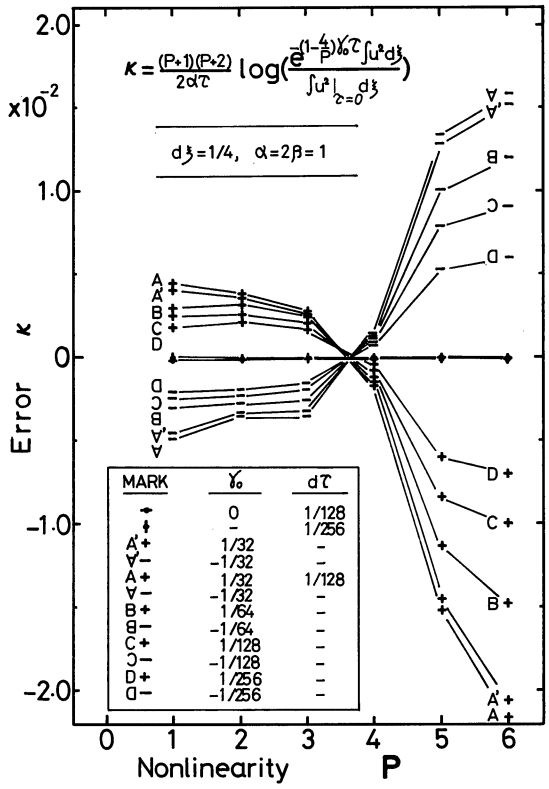

Fig. 6. An estimation of the errors due to instability of one-soliton.

line having real dissipations.

We examine such adiabatic amplification effect by a gradual inhomogeneity of parameters. As will be shown in the next section, the P-th nonlinear K-dV equation possesses at least three polynomial conserved quantities. The instantaneous energy of waves propagating in the line is proportional to u^2, because of the assumption (11). By using the result (eq. (32)) of the next section, the total energy of the single soliton (26) is derived in the moving frame as,

$$E_P(\tau)=\int_{-\infty}^{\infty}\left(\frac{u^2}{2}\right)d\xi=\int\frac{1}{2}u_s^2\,\mathrm{sech}^{4/P}[\phi]d\xi$$
$$=\frac{A_P}{2}u_s^2W_s, \tag{28}$$

where

$$A_P=\int_{-\infty}^{\infty}\mathrm{sech}^{4/P}\xi'\,d\xi', \quad A_1=4/3,$$
$$A_2=2, \quad A_3\simeq 2.587, \quad \text{and} \quad A_4=\pi.$$

The amplitude u_0 and time dependences of the above total energy E_p are calculated as,

$$E_P(\tau)\propto u_0^{2-P}\exp[(1-4/P)\gamma_0\tau]. \tag{29}$$

We note that, for P>4, eq. (29) shows the total energy of soliton comes to depend negatively on its amplitude, and the time dependence of the energy also changes. The total energy of the single soliton comes to decrease with the passage of time even for $\gamma_0<0$ against the growth of the amplitude of soliton. For P=4, the energy of the soliton becomes a constant value with respect to both amplitude and time. Consequently, it seems that such anomalous dependences of the total energy for the occasions of P≥4, (i.e., $\partial E_p/\partial u_0\leq 0$) never permit the corresponding single soliton to propagate stably in the nonlinear transmission line. We conclude this section by showing a brief confirmation on the above conjecture in Fig. 6. The figure indicates that the obvious difference between two groups, P≤3 and P>4 in the range of stable propagation of the single solitons.

§4. Adiabatic Amplification and Conserved Quantities

It is well known that the usual K-dV equation and the modified K-dV equation (in this paper,

they correspond to the cases P=1 and 2 of eq. (22) with $\sigma=0$, respectively) have the N-soliton solutions[21,22] which denote the time and space evolution of N-multiple interacting solitons. So, we can easily obtain the N-soliton solutions of eq. (16) by using already known N-soliton for P=1 and 2 through our transformations (21).

The N-soliton solutions $U(\zeta, \theta)$ for P=1 and 2 are described as follows:[21-24]

$$U^{\mathrm{P}}=\frac{2\beta(\mathrm{P}+1)(\mathrm{P}+2)}{\alpha \mathrm{P}^2}\frac{\partial^2}{\partial\zeta^2}[\log w], \quad w=\det|H|,$$

$$H_{ij}=\delta_{ij}+\left[\frac{2(k_ik_j)^{1/2}}{k_i+k_j}\right]\exp\left(\frac{\zeta_i+\zeta_j}{2}\right),$$

$$\zeta_m=k_m\zeta-\beta k_m^3\theta-\theta_m, \quad m=1, 2, 3, \cdots, N, \quad (30)$$

where δ_{ij} is the Kronecker's delta and θ_m constants. It should be noted again that the description (30) is valid only for P=1 and 2. As an example, in Fig. 7, we show the configuration of 3-interacting solitons for P=2. Although, we can see the effect of amplification or damping in Fig. 7, from the condition (25), in this case the nonlinear transmission line may not have any activities nor losses. Such adiabatic (or generally, parametric) amplification or damping is understood by estimating the following conserved quantities

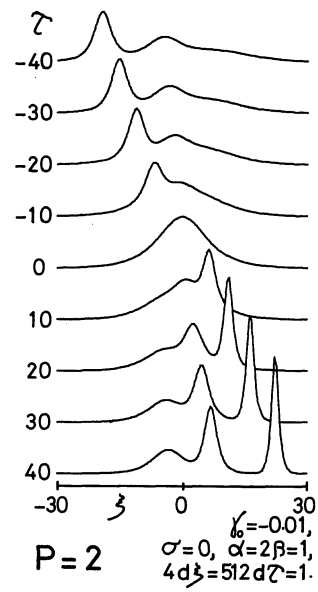

Fig. 7. Three interacting solitons for P=2, ($\sigma=0$).

(or constants) of motion. To any natural number P, the first three conserved quantities are obtained as:

$$I_1=\int_{-\infty}^{\infty} U\,\mathrm{d}\zeta=\mathrm{e}^{(2/\mathrm{P}-1)\gamma_0\tau}\int u\,\mathrm{d}\xi, \quad (31)$$

$$I_2=\int_{-\infty}^{\infty}\frac{U^2}{2}\,\mathrm{d}\zeta=\mathrm{e}^{(4/\mathrm{P}-1)\gamma_0\tau}\int\frac{u^2}{2}\,\mathrm{d}\xi, \quad (32)$$

$$I_3=\int_{-\infty}^{\infty}\frac{1}{\mathrm{P}+1}\left[U^{\mathrm{P}+2}-\frac{(\mathrm{P}+1)(\mathrm{P}+2)\beta}{2\alpha}\left(\frac{\partial U}{\partial\zeta}\right)^2\right]\mathrm{d}\zeta$$

$$=\mathrm{e}^{(4/\mathrm{P}+1)\gamma_0\tau}\int\frac{1}{\mathrm{P}+1}\left[u^{\mathrm{P}+2}-\frac{(\mathrm{P}+1)(\mathrm{P}+2)\beta}{2\alpha}\left(\frac{\partial u}{\partial\xi}\right)^2\right]\mathrm{d}\xi. \quad (33)$$

These quantities are considered to hold as the conservation of momentum, energy, and another higher order constant of motion for each P. Only for P=1 and 2, further higher order (infinite) conserved quantities have been derived.[23,24]

We show the next higher order constant of motion as an example of the use of the transformetions (21),

$$I_4=\int_{-\infty}^{\infty}\frac{1}{2(\mathrm{P}+1)}\left[U^{2(\mathrm{P}+1)}-\frac{2(\mathrm{P}+1)(2\mathrm{P}+1)\beta}{\alpha}U^{\mathrm{P}}\left(\frac{\partial U}{\partial\zeta}\right)^2+\frac{6(\mathrm{P}+1)(2\mathrm{P}+1)\beta^2}{5\alpha^2}\left(\frac{\partial^2 U}{\partial\zeta^2}\right)^2\right]\mathrm{d}\zeta$$

$$=\mathrm{e}^{(4/\mathrm{P}+3)\gamma_0\tau}\int\frac{1}{2(\mathrm{P}+1)}\left[u^{2(\mathrm{P}+1)}-\frac{2(\mathrm{P}+1)(2\mathrm{P}+1)\beta}{\alpha}u^{\mathrm{P}}\left(\frac{\partial u}{\partial\xi}\right)^2+\frac{6(\mathrm{P}+1)(2\mathrm{P}+1)\beta^2}{5\alpha^2}\left(\frac{\partial^2 u}{\partial\xi^2}\right)^2\right]\mathrm{d}\xi, \quad (34)$$

for P=1 and 2. Since the interaction of 3-solitons for P=2 is known to be described by the fifth conserved quantity itself, the existence of the corresponding integral, which depends only on time as $\exp(-7\gamma_0\tau)$, is indirectly indicated by the fact that famous particle-like interaction of solitons can still hold as shown in Fig. 7.

§5. Concluding Remarks

In this paper, it is shown that the P-th power nonlinear transmission lines with a certain

loss and inhomogeneity can still support the single solitons to each natural number P, and especially to P=1 and 2, even the exact N-multi interacting solitons. We have obtained a generalization of the result of the previous report[15] in which a special case as eq. (20) in this article had been treated. The theoretical conditions of balancing between the magnitudes of loss and inhomogeneity to each nonlinearity P show that the nondestructive amplification or damping of solitons without radiations may seem to be done in the P-th power nonlinear transmission lines with loss or activity and inhomogeneity.

Although the stability analysis on the propagating single solitons shown in the last half of section 3 is considered not to be completed, a numerical result briefly indicates that, in the transmission line with P-th ($P \geq 4$) nonlinearity, we can not only amplify nor reduce the amplitude of soliton nondestructively but even see the stable propagation of the single soliton. The similar method for the stability analysis of the single soliton have been already reported by several authors,[25,26] and we can see their results for the K-dV equation and a different nonlinear evolution equation bears very well resemblance to ours.

It is not difficult to extend our result for the nonlinearity P=1 to a shallow water waves,[27] a nonlinear lattice waves,[28] and a few types of nonlinear plasma waves.[29] The Alfven waves[30] in a nonuniform plasma may be also described by our modified type of the K-dV equation (16) with the nonlinearity P=2.

As well as the amplification or damping of solitons, it is also interesting to consider nonlinear periodical waves such as the cnoidal waves in inhomogeneous media. The well known recurrence phenomenon brought up by Fermi, Pasta, and Ulam[31] has been also observed in nonlinear transmission lines having quadratic (P=1)[32,33] and cubic (P=2)[32] nonlinearity. In conjunction with the problem of thermalization, the recurrence like phenomenon in the nonlinear inhomogeneous media is considered to be worth studying.

As a final remark, to realize the nondestructive amplification or damping of amplitude of solitons in the transmission line having the nonlinearity P=2, we can use a coupling between high and low frequency waves propagating together in the line. The method and result will be appeared in the next paper.

Solitons in One-Dimensional Molecular Chains

By

A. S. DAVYDOV (a) and N. I. KISLUKHA (b)

A theory of collective excitations in one-dimensional chains of weakly bound molecules which correspond to intramolecular excitations is developed. It is shown that these excitations are described by solitary waves (solitons) propagating (without "smearing") along the chain together with local deformation. The theory is developed without applying the assumption of inertialess motion of molecules. It is shown that the ultimate velocity of solitons is the velocity of sound waves corresponding to longitudinal vibrations of molecules. The problem of soliton stability is discussed.

Es wird eine Theorie kollektiver Anregungen in eindimensionalen Ketten von schwach gebundenen Molekülen entwickelt, die intramolekularen Anregungen entsprechen. Es wird gezeigt, daß diese Anregungen beschrieben werden durch solitäre Wellen (Solitonen), die sich (ohne „Verschmierung") in Richtung der Kette ausbreiten, zusammen mit einer lokalen Deformation. Die Theorie wird ohne die Annahme einer trägheitslosen Bewegung der Moleküle entwickelt. Es wird gezeigt, daß die Grenzgeschwindigkeit der Solitonen die Geschwindigkeit von Schallwellen ist, die den longitudinalen Schwingungen der Moleküle entsprechen. Das Problem der Solitonenstabilität wird diskutiert.

1. Introduction

A special type of collective excitations which has been discussed by the authors in [1] and called particle-like excitations or solitary excitons is possible in one-dimensional molecular chains which consist of periodically repeated molecules (or groups of strongly bound atoms) interacting by relatively weak forces. In what follows these excitations will be referred to as solitons. Particular cases of these systems are α-helical protein molecules in which the peptide groups made up of four atoms (HNCO) bound by chemical forces are arranged along the molecule in the form of three chains. In each chain the neighbouring peptide groups are linked by hydrogen bonds which provide for a rigid structure of α-helix.

The collective excitations of a one-dimensional molecular chain which correspond to intramolecular electronic or vibrational excitations with an electric moment directed along the chain are of a very specific nature different from ordinary excitons in three-dimensional crystals. In protein molecules these excitations include excitations (based on valent Amide I vibrations) with an energy of 0.21 eV and an electric dipole moment of 0.3 Debye directed along the axis of the molecule.

The solitons (solitary excitons) considered in [1] are excitations localized in some region of a chain; they are connected with varying distance between the molecules and propagate with a certain velocity along the chain. The theories of electronic excitations and vibrational amide I excitations of α-helical protein

molecules, developed in [1] and [2], respectively, assumed that the distortion of the chain follows in an inertialess manner the motion of the excitation. This assumption imposes some restrictions on the excitation velocity. In the present paper we develop a theory avoiding the concept of the inertialess motion of the molecules. We show that the ultimate velocity of a soliton in a molecular chain is the velocity of sound waves corresponding to molecular vibrations along the chain. The problem of the soliton stability is also discussed.

2. The Basic Equations and Their Solution in the Form of Solitons

Consider an infinite chain of weakly bound molecules (or groups of atoms) with mass M, which are at distance R. We also assume that the internal excitations of molecules (electronic or vibrational ones) in the chain are characterized by an energy ε and an electric dipole moment $\boldsymbol{d}$ directed along the chain. When the molecule becomes excited the forces of its interaction with neighbouring molecules are changed, this resulting in a change in the equilibrium distances between the molecules. Besides, since the molecules are identical, there arise some additional resonance interactions causing the excitation transfer from one of the molecules to another. The internal excitations of the molecules and their motion about equilibrium positions are inseparably linked.

In a one-dimensional chain it is sufficient to take into account only the interaction between the neighbouring molecules. In this approximation the collective excitations of the chain which correspond to an intramolecular excitation with an energy ε may be described by the Hamiltonian

$$H = T + U + \sum_n [(\varepsilon - D_n) B_n^+ B_n - J(B_{n+1}^+ B_n + B_{n+1} B_n^+)] , \qquad (1)$$

here the subscript n labels the molecules occupying the positions x_n in the chain; B_n^+, B_n are the creation and the annihilation operators of an intramolecular excitation. They satisfy the commutation relations

$$[B_n, B_m^+] = \delta_{nm} , \qquad [B_n, B_m] = 0 .$$

The function $-D_n$ characterizes the change in the static interaction of the n-th molecule with the neighbouring molecules when it is excited. If ϱ_n is defined by the expression

$$x_n - x_{n-1} = R - \varrho_n , \qquad (2)$$

then (allowing for the interaction with the nearest neighbours)

$$D_n = \mathcal{D}_n(|x_{n+1} - x_n|) + \mathcal{D}(|x_{n-1} - x_n|) \approx \left(1 + \frac{\beta}{R} \varrho_n\right) D , \qquad (3)$$

where $D \equiv 2\mathcal{D}(R)$ and β are the positive parameters of the theory. The resonance interaction determining the transition of an intramolecular excitation from one molecule to another is characterized by the quantity $-J$ which is defined by the electric dipole moment using the equality

$$J = 2\boldsymbol{d}^2 R^{-3} . \qquad (4)$$

The first two terms in (1) correspond to the potential and the kinetic energy of the longitudinal displacements of molecules. The potential energy is chosen in the harmonic approximation:

$$U = \tfrac{1}{2} w \sum_n \varrho_n^2 . \qquad (5)$$

When the equation $\dot{x}_n = -\sum_{-\infty<l\leq n} \dot{\varrho}_l$ (5a) is taken into account the kinetic energy can be written as

$$T = \tfrac{1}{2} M \sum_n \dot{x}_n^2 = \tfrac{1}{2} M \sum_n \Big(\sum_{-\infty<l\leq n} \dot{\varrho}_l \Big)^2 . \tag{6}$$

Dotted symbols in (6) and in subsequent expressions mean a derivative with respect to time.

The collective excitations of interest are described by the wave function

$$|\psi\rangle = \sum_n a(t)\, B_n^+ |0\rangle . \tag{7}$$

The coefficients $a_n(t)$ satisfy the condition

$$\sum_n |a_n(t)|^2 = 1 \tag{7a}$$

and characterize the distribution of excitation along the chain of molecules. These coefficients satisfy a set of equations which can be obtained from the Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} |\psi\rangle = H\, |\psi\rangle . \tag{8}$$

Using the explicit form of the operator H and (8), we obtain the equation

$$\sum_n \left\{ i\hbar \frac{\partial a_n}{\partial t} - \left[\varepsilon + T + U - \left(1 + \frac{\beta}{R} \varrho_n \right) D \right] a_n - J(a_{n+1} + a_{n-1}) \right\} B_n^+ |0\rangle = 0 .$$

Since the functions $B^+ |0\rangle$ corresponding to different values of n are orthogonal, we can use this equation to obtain the following set of equations:

$$i\hbar \frac{\partial a_n}{\partial t} = \left[\varepsilon + T + U - \left(1 + \frac{\beta}{R} \varrho_n \right) D \right] a_n - J(a_{n+1} + a_{n-1}) . \tag{9}$$

It is now convenient to introduce the functional of the variables ϱ_n, $\dot{\varrho}_n$ and a_n

$$F \equiv \langle \psi |\, H\, |\psi\rangle =$$
$$= \sum_n \left\{ \left[\varepsilon + T + U - \left(1 + \frac{\beta}{R} \varrho_n \right) D \right] a_n^* a_n - J a_n^* (a_{n+1} + a_{n-1}) \right\} . \tag{10}$$

Following Toda [3], we associate the displacements with canonically conjugated variables

$$s_n = \frac{\partial T}{\partial \dot{\varrho}_n} = -M \sum_{l\geq n} \dot{x}_l .$$

This expression yields the equation

$$\dot{x}_n = \frac{1}{M} (s_n - s_{n-1}) ,$$

which enables the kinetic energy of the molecular motion to be expressed in terms of the variables

$$T = \frac{1}{2M} \sum_n (s_n - s_{n-1})^2 . \tag{11}$$

Thus at fixed values of the coefficients $a_n(t)$ the function F is the Hamiltonian function with respect to the molecular displacements ϱ_n and their

canonical conjugates s_n. We can therefore write the Hamilton equations

$$\dot{\varrho}_n = \frac{\partial F}{\partial s_n} = \frac{1}{M}(2s_n - s_{n+1} - s_{n-1}),$$

$$\dot{s}_n = -\frac{\partial F}{\partial \varrho_n} = -w\varrho_n + \frac{\beta D}{R}|a_n(t)|^2 .$$

Eliminating s_n from these equations we find

$$\ddot{\varrho}_n = -\frac{w}{M}(2\varrho_n - \varrho_{n+1} - \varrho_{n-1}) + \frac{\beta D}{MR}(2|a_n|^2 - |a_{n+1}|^2 - |a_{n-1}|^2) . \quad (12)$$

The set of equations (9) and (12) defines the collective excitations of a chain. If we are interested only in excitations distributed over some region of a chain, we can apply the continuum model. Let us introduce a dimensionless variable $\xi = x/R$ and continuous functions $\varrho(\xi, t)$ and $a(\xi, t)$ such that

$$\varrho(n, t) = \varrho_n(t) , \qquad a(n, t) = a_n(t) .$$

Using the expressions

$$\varrho(\xi \pm 1, t) \approx \varrho(\xi) \pm \frac{\partial \varrho(\xi, t)}{\partial \xi} + \frac{1}{2}\frac{\partial^2 \varrho(\xi, t)}{\partial \xi^2},$$

$$a(\xi \pm 1, t) \approx a(\xi) \pm \frac{\partial a(\xi, t)}{\partial \xi} + \frac{1}{2}\frac{\partial^2 a(\xi, t)}{\partial \xi^2},$$

$$|a(\xi \pm 1, t)|^2 \approx |a(\xi, t)|^2 \pm \frac{\partial}{\partial \xi}|a(\xi, t)|^2 + \frac{1}{2}\frac{\partial^2}{\partial \xi^2}|a(\xi, t)|^2,$$

we can transform (9) and (12) to

$$i\hbar \frac{\partial a(\xi, t)}{\partial t} - \left[\lambda - \frac{\beta D}{R}\varrho(\xi, t)\right] a(\xi, t) + J\frac{\partial^2 a(\xi, t)}{\partial \xi^2} = 0 , \quad (13)$$

$$\frac{\partial^2 \varrho(\xi, t)}{\partial t^2} - v_a^2 \frac{\partial^2 \varrho(\xi, t)}{\partial \xi^2} + \frac{\beta D}{MR}\frac{\partial^2}{\partial \xi^2}|a(\xi, t)|^2 = 0 , \quad (14)$$

where

$$\lambda \equiv \varepsilon + T + U - D - 2J , \quad (15)$$

$$T + U = \frac{M}{2}\int_{-\infty}^{\infty} d\xi \left[\left(\int_{-\infty}^{\xi} d\eta \frac{\partial}{\partial t}|\varrho(\eta, t)|^2\right)^2 + v_a^2 |a(\xi, t)|^4\right], \quad (16)$$

$v_a = \sqrt{w/R}$, $v_a R = V_a$ is the longitudinal sound velocity in the chain.

We shall look for solutions of the set of (13), (14) in the form of excitations propagating along the chain with the velocity $V = vR$. In other words, we set

$$\varrho(\xi, t) = \varrho(\xi - vt) , \qquad a(\xi, t) = \Phi(\xi - vt)\, e^{i\theta(\xi, t)} . \quad (17)$$

We then obtain from (14)

$$\varrho(\xi, t) = \frac{\beta D |a(\xi, t)|^2}{MR(v_a^2 - v^2)} . \quad (18)$$

Substituting the right-hand side of (18) into (13) and (16), one obtains

$$i\hbar \frac{\partial a(\xi, t)}{\partial t} - \lambda a(\xi, t) + J \frac{\partial^2 a(\xi, t)}{\partial \xi^2} + G_\nu |a(\xi, t)|^2 a(\xi, t) = 0 , \tag{19}$$

$$T + U = \frac{G_\nu}{2(\nu_a^2 - \nu^2)} \int_{-\infty}^{\infty} \mathrm{d}\xi \left[\left(\int_{-\infty}^{\xi} \mathrm{d}\eta \frac{\partial}{\partial t} |a(\eta, t)|^2 \right)^2 + \nu_a^2 |a(\xi, t)|^4 \right], \tag{20}$$

$$G_\nu \equiv \frac{\beta^2 D^2}{M R^2 (\nu_a^2 - \nu^2)} = \frac{G_0}{1 - V^2/V_a^2}, \tag{21}$$

$$G_0 \equiv \beta^2 D^2 / M V_a^2 . \tag{22}$$

The exact solution of the nonlinear equation (19), normalized by

$$\int_{-\infty}^{\infty} |a(\xi, t)|^2 \, \mathrm{d}\xi = 1$$

has the form

$$a_\nu(\xi, t) = \frac{\sqrt{\frac{\mu_\nu}{2}} \exp\left\{ i \left[\frac{\hbar \nu}{2J} (\xi - \xi_0) - \Omega_\nu t \right] \right\}}{\cosh\left[\mu_\nu (\xi - \xi_0 - \nu t) \right]}, \tag{23}$$

where ξ_0 is an arbitrary constant due to the translational invariance of (13) and (14). The other quantities contained in (23) are defined by

$$\mu_\nu = G_\nu / 4J , \tag{24}$$

$$\hbar \Omega_\nu = \lambda + (\hbar^2 \nu^2 - \tfrac{1}{4} G_\nu^2)/4J . \tag{25}$$

When (23) is taken into account the expression (20) takes the form

$$T + U = \frac{G_\nu^2 (\nu^2 + \nu_a^2)}{24J(\nu_a^2 - \nu^2)} .$$

Substituting this into (15), we obtain the final expression for the energy of a soliton described by the function (23), when the velocity of its motion along the chain is fixed $V = \nu R$

$$\hbar \Omega_\nu = \hbar \Omega_0 + \frac{\hbar^2 V^2}{4JR^2} + \frac{G_0^2 (Z^2 + \frac{3}{2} Z^4 - \frac{1}{2} Z^6)}{24J(1 - Z^2)^3}, \tag{26}$$

where

$$Z \equiv V/V_a , \qquad \hbar \Omega_0 = \varepsilon - D - 2J - G_0^2/48J \tag{27}$$

is the internal energy of the soliton.

It follows from the expression (26) that when the soliton velocity approaches the longitudinal sound velocity V_a, the soliton energy tends to infinity. At all finite values of the soliton energy its velocity is therefore less than V_a. The soliton energy thus cannot be transformed into the energy of the longitudinal waves.

At small velocities of the soliton ($V \ll V_a$) the soliton energy (26) takes the form

$$\hbar \Omega_\nu = \hbar \Omega_0 + \frac{\hbar^2 V^2}{2R^2 J} + \frac{G_0^2 V^2}{24 V_a^2 J} \left[1 - \frac{9}{2} (V/V_a)^2 + \cdots \right].$$

In the same approximation the parameter

$$\mu_v \approx \frac{G_0}{4J}[1 + (V/V_a)^2] \approx \frac{G_0}{4J} = \mu_0 \tag{28}$$

depends but very weakly upon the soliton velocity.

Substituting (23) into (18) we find the distribution of the changes in the relative distances between the molecules

$$\varrho(\xi, t) = \frac{\sqrt{G_0^3/w}}{8J(1 - V^2/V_a^2)^2} \operatorname{sech}[\mu_v(\xi - \xi_0 - vt)] . \tag{29}$$

According to (29), the maximal deviation

$$\varrho_{\max} = \frac{\sqrt{G_0^3/w}}{8J(1 - V^2/V_a^2)^2} \tag{30}$$

obtained at $\xi = \xi_0 + vt$ moves along the chain with the velocity $V = vR$. The deformation moving along the chain is accompanied by the internal excitation. The region of the chain embraced by the internal excitation and the deformation is defined by

$$R\,\Delta\xi \approx \frac{\pi R}{\mu_v} = 4\pi J R/G_v . \tag{31}$$

The applicability condition of the continuum approximation is associated with the validity of the inequality $\Delta\xi = 4\pi J/G_v \gg 1$.

3. The Stability of Solitons

A remarkable property of solitons is that once the velocity is fixed the distribution of excitation and deformation described by the functions (23) and (29) remains unchanged during the soliton motion. At $V \ll V_a$ we have $G_v \approx G_0$, so that the size and shape of the soliton are both independent of its velocity, i.e. the soliton slows down without changing its shape.

In order to study the stability of solitons we consider the expression (10) at zero velocity ($v = 0$). In this case $a(\xi, t)$ represents a state with a simple time dependence, i.e.

$$a(\xi, t) = \Phi(\xi) \exp(-i\Omega_0 t) . \tag{32}$$

Using the continuum approximation in (10) and taking (32) into account, we obtain

$$F_0\{\Phi\} = \varepsilon - D - 2J - \int_{-\infty}^{\infty} \Phi(\xi)\left[J\frac{\partial^2\Phi(\xi)}{\partial\xi^2} + \frac{1}{2}G_0\Phi^3(\xi)\right] d\xi . \tag{33}$$

The expression (33) can be regarded as a functional of $\Phi(\xi)$; its absolute minimum defines the soliton energy at zero velocity, i.e.

$$(\hbar\Omega)_{\min} = \min F_0\{\Phi\} . \tag{33a}$$

If $\Phi(\xi)$ is taken to be a normalized function depending on a single parameter μ

$$\Phi(\xi) = \sqrt{\mu/2} \operatorname{sech}[\mu(\xi - \xi_0)] , \tag{34}$$

we obtain

$$F_0(\mu) = \varepsilon - D - 2J + \tfrac{1}{3}\left[J\mu^2 - \tfrac{1}{2}G_0\mu\right]. \tag{35}$$

The minimum (35) corresponds to the value $\mu_0 = G_0/4J$, and the energy

$$(\hbar\Omega)_{\min} = \varepsilon - D - 2J - G_0^2/48J \tag{36}$$

is exactly the same as that given by (27). The functions different from (34), or the values $\mu \neq \mu_0$ correspond to higher energies. In particular, the value of the functional (35) at $\mu = 0$ corresponds to nonlocalized excitations — the excitons. Their energy (at zero velocity) is equal to $\varepsilon - D - 2J$ thus exceeding the soliton energy by the value $G_0^2/48J$. These excitations are unstable in one-dimensional molecular systems.

If the electric dipole moment d is directed perpendicular to the chain, the parameter J which characterizes the resonance interaction will have a negative value ($\approx -d^2/R^3$). In this case the functional (35) has no minimum, the continuum approximation is not valid and there are no stable excitations such as the soliton. The excitation tends to be completely localized on a single molecule.

In conclusion we investigate the stability of the solitons for external disturbances. As a disturbance we consider a sound wave

$$A\cos\omega\,(t - \xi/v_a) \tag{37}$$

assuming the frequency ω to be low enough so that the sound wavelength exceeds considerably the size of an exciton,

$$\frac{2\pi v_a R}{\omega} \gg R\,\Delta\xi = 4\pi J R/G_0\,. \tag{38}$$

As mentioned above, at finite values of the soliton energy its velocity is much less than that of longitudinal sound waves. Therefore when investigating the soliton–longitudinal sound wave interaction the solitons may be regarded as unmoving.

To take into account the role of the exciton–sound wave interaction we investigate the solutions of (13) and (14) using

$$\varrho(\xi, t) = \varrho_0(\xi) + A\cos\omega(t - \xi/v_a)\,, \tag{39}$$

Here

$$\varrho_0(\xi) = \frac{G_0}{8J}\sqrt{\frac{G_0}{w}}\,\mathrm{sech}^2\,(\mu_0\xi)\,, \qquad \mu_0 = G_0/4J$$

is the solution for a free soliton at rest. In this case (14) is exactly satisfied by the function

$$a(\xi, t) = \Phi(\xi)\exp\left[-i\vartheta(t)\right], \tag{40}$$

if

$$\Phi(\xi) = \sqrt{\mu_0/2}\,\mathrm{sech}\,\mu_0\xi\,. \tag{40a}$$

At $|\xi| > \Delta\xi$ equation (13) is satisfied approximately, the function (40) and its derivatives tending rapidly to zero. In the region $|\xi| \leqq \Delta\xi$, under the condition (38) the sound wave has the same phase. Equation (13) thus reduces to

$$\frac{\partial\vartheta(t)}{\partial t} + \frac{\beta DA}{\hbar R}\cos\omega t - \Omega_0 = 0\,. \tag{41}$$

The soliton energy is defined by the integral

$$E = i\hbar \int a^*(\xi, t) \frac{\partial a(\xi, t)}{\partial t} \, d\xi \, .$$

Therefore, when the expressions (40) and (41) are taken into account we have

$$E = \hbar \frac{\partial \theta(t)}{\partial t} = \hbar \Omega_0 - \frac{\beta D A}{R} \cos \omega t \, . \tag{42}$$

The average value of soliton energy (when it is averaged over the period of a sound wave) is thus equal to the energy $\hbar \Omega_0$ of a free soliton. According to (40), the sound wave does not change the shape of a soliton, defined by the function $\Phi^2(\xi) = (\mu_0/2) \operatorname{sech}^2 (\mu_0 \xi)$.

Thus the excitations of a molecular chain in the form of solitons have great stability in retaining the shape, magnitude, and the size of the region occupied by the excitation. This fact has been used by one of the authors [2] to account for the great efficiency of the transfer of energy released in the hydrolysis of ATP molecules in living organisms along the α-helical protein molecules and to elucidate the contraction mechanism of transversely striated animal muscles at the molecular level [4].

Abstract

In this Letter, we established a traveling wave solution by using Cosine-function algorithm for nonlinear partial differential equations. The method is used to obtain the exact solutions for five different types of nonlinear partial differential equations such as, general equal width wave equation (GEWE), general regularized long wave equation (GRLW), general Korteweg–de Vries equation (GKdV), general improved Korteweg–de Vries equation (GIKdV), and Coupled equal width wave equations (CEWE), which are the important soliton equations.

Keywords: GEWE; GRLW; GKdV; GIKdV; CEWE; Cosine-function method

1. Introduction

The study of numerical methods for the solution of nonlinear partial differential equations has enjoyed an intense period of activity over the last 40 years from both theoretical and practical points of view. Improvements in numerical techniques, together with the rapid advances in computer technology, have meant that many of the partial differential equations arising from engineering and scientific applications, which were previously intractable, can now, be routinely solved [1]. Finite difference methods approximate the differential operators and hence, solve the difference equations. In finite element method the continuous domain is represented as a collection of a finite number N of subdomains known as elements. The collection of elements is called the finite element mesh. For time dependent problems, the differential equations are approximated by the finite element method to obtain a set of ordinary differential equations in time. These differential equations are solved approximately by finite difference methods or other methods. In all finite difference and finite elements it is necessary to have a boundary and initial conditions. But the Adomian decomposition method, which has been developed by George Adomian (Solving Frontier Problem of Physics: The Decomposition Method, Kluwer Academic Publishers, Boston, MA, 1994) depends only on the initial conditions to obtain solution in series form which almost converges to the exact solutions of the problem. In recently years, some other ansatz methods have been developed, such as, the tanh method [2,3], the extended tanh-function method [4,5], the modified extended tanh-function method [6–11], variational iteration method [12–17], the generalized hyperbolic-function [18,19], the separation of variables method [20,21] and the sine–cosine method [22,23].

The aim of this Letter is extended the cosine function-method to find the exact solutions of some important nonlinear partial differential equations such as the general equal width wave (GEW) equation, the general Regularized long wave (GRLW) equation,

the general Korteweg–de Vries (GKdV) equation, the general improved Korteweg–de Vries (GIKdV) equation and the coupled equal width wave equations, which are the five of important soliton equations.

2. The cosine function method

Consider the nonlinear partial differential equation in the form

$$F(u, u_t, u_x, u_{xx}, u_{xxt}, \ldots) = 0, \tag{1}$$

where $u(x,t)$ is the solution of nonlinear partial differential equation Eq. (1). We use the transformations,

$$u(x,t) = f(\xi), \tag{2}$$

where $\xi = x - ct$. This enables us to use the following changes:

$$\frac{\partial}{\partial t}(\cdot) = -c\frac{d}{d\xi}(\cdot), \qquad \frac{\partial}{\partial x}(\cdot) = \frac{d}{d\xi}(\cdot), \qquad \frac{\partial^2}{\partial x^2}(\cdot) = \frac{d^2}{d\xi^2}(\cdot), \quad \ldots. \tag{3}$$

Using Eq. (3) to transfer the nonlinear partial differential equation Eq. (1) to nonlinear ordinary differential equation

$$G(f, f', f'', f''', \ldots) = 0. \tag{4}$$

The solution of Eq. (4) can be expressed in the form:

$$f(\xi) = \lambda \cos^{\beta}(\mu\xi), \qquad |\xi| \leqslant \frac{\pi}{2\mu}, \tag{5}$$

where λ, β and μ are unknown parameters which will be determined. Then we have:

$$\begin{aligned} f' &= \frac{df(\xi)}{d\xi} = -\lambda\beta\mu\cos^{\beta-1}(\mu\xi)\sin(\mu\xi), \\ f'' &= \frac{d^2 f(\xi)}{d\xi^2} = -\lambda\beta\mu^2\cos^{\beta}(\mu\xi) + \lambda\mu^2\beta(\beta-1)\cos^{\beta-2}(\mu\xi) - \lambda\mu^2\beta(\beta-1)\cos^{\beta}(\mu\xi). \end{aligned} \tag{6}$$

Substituting Eq. (6) into the nonlinear ordinary differential equation Eq. (4) gives a trigonometric equation of $\cos^{\alpha}(\mu\xi)$ terms. To determine the parameters first balancing the exponents of each pair of cosine to determine α. Then we collect all terms with the same power in $\cos^{\beta}(\mu\xi)$ and put to zero their coefficients to get a system of algebraic equations among the unknowns β, λ and μ. Now, the problem is reduced to a system of algebraic equations that can be solved to obtain the unknown parameters β, λ and μ. Hence, the solution considered in Eq. (5) is obtained. The above analysis yields the following theorem:

Theorem. *The exact analytical solution of the nonlinear partial differential equations Eq. (1) can be determined in the form Eq. (5) where all constants found from the algebraic equations after its solutions.*

3. Applications

In order to illustrate the effectiveness of the proposed method five examples in mathematical are chosen as follows

3.1. Test problem

3.1.1. The general equal width wave equation (GEWE)

Consider the following problem: Find functions $u(x,t)$ satisfying the general equal width wave equation (GEWE) [24–27] in the form,

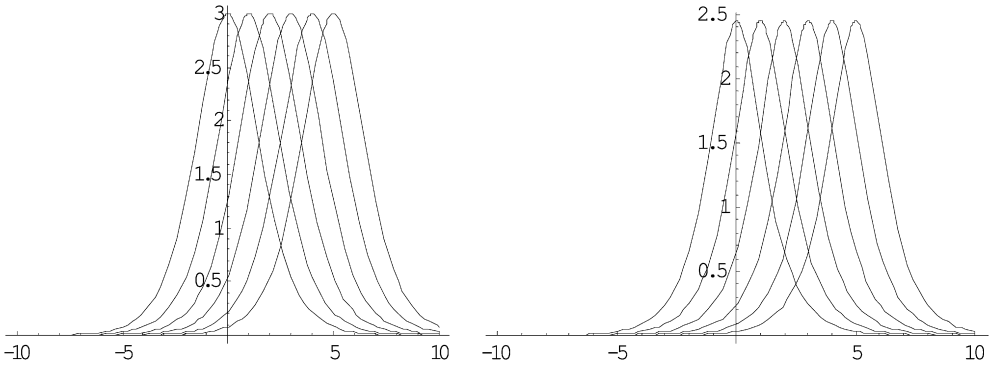
$$u_t + \varepsilon u^p u_x - \nu u_{xxt} = 0. \tag{7}$$

By using the wave variable $\xi = x - ct$ and $u(x,t) = f(\xi)$ then GEWE equation becomes

$$-c\frac{df(\xi)}{d\xi} + \varepsilon f^p(\xi)\frac{df(\xi)}{d\xi} + c\nu\frac{d^3 f(\xi)}{d\xi^3} = 0. \tag{8}$$

Integrating Eq. (8) gives

$$-cf(\xi) + \frac{\varepsilon}{p+1}\big(f(\xi)\big)^{p+1} + c\nu\frac{d^2 f(\xi)}{d\xi^2} = 0. \tag{9}$$



(a) (b)

Fig. 1. (a) Soliton solution for EWE; (b) soliton solution for MEWE.

Table 1
The conservative quantities the EWE, MEWE and GEWE equations with increase time

T / p	I_1			I_2		
	1	2	3	1	2	3
0	12	7.6953	6.04182	28.8	16	11.4365
1	12	7.6953	6.04182	28.8	16	11.4365

Substituting Eq. (6) into (9) gives:

$$-c\lambda\cos^{\beta}(\mu\xi)+\frac{\varepsilon\lambda^{p+1}}{p+1}\cos^{(p+1)\beta}(\mu\xi)-c\nu\lambda\beta\mu^2\cos^{\beta}(\mu\xi)+\nu c\lambda\beta(\beta-1)\mu^2\cos^{\beta-2}(\mu\xi)-c\nu\lambda\beta(\beta-1)\mu^2\cos^{\beta}(\mu\xi)=0. \tag{10}$$

The last equation is satisfied only if the following system of algebraic equations holds:

$$\begin{aligned}&-c\lambda-c\lambda\nu\beta\mu^2-c\lambda\mu^2\nu\beta(\beta-1)=0, \qquad (p+1)\beta=\beta-2,\\ &\frac{\varepsilon\lambda^{p+1}}{p+1}+c\lambda\mu^2\nu\beta(\beta-1)=0,\end{aligned} \tag{11}$$

using MATHEMATICA package software for solving the system Eq. (11) we obtain:

$$\beta=\frac{-2}{p}, \qquad \mu=\pm\frac{ip}{2\sqrt{\nu}} \quad \text{and} \quad \lambda=2^{-1/p}\left(\frac{c(2+3p+p^2)}{\varepsilon}\right)^{1/p}, \tag{12}$$

substituting Eq. (12) into Eq. (5) we obtain the exact soliton solution of the GEWE equation in the form

$$u(x,t)=2^{-1/p}\left(\frac{c(2+3p+p^2)}{\varepsilon}\right)^{1/p}\cos^{-2/p}\left(\frac{\pm ip}{2\sqrt{\nu}}(x-ct)\right). \tag{13}$$

As a special case when $p=1$ gives the soliton solution of the EWE equation as in [24], when $p=2$ gives the soliton solution of the MEWE equation as in [29] and also we can get the soliton solution of the GEWE equation as in [30]. Fig. 1 shows the soliton solution for the EWE, MEWE and GEWE equations with increase time. Also, we can calculate the conservative quantities when $p=1$ and 2 as given in Table 1. It is to be noted that the obtained results are quite good with that obtained [28–30].

3.1.2. The general regularized long wave (GRLW) equation

We consider the general regularized long wave equation for long waves in shallow water written as [31–35]:

$$u_t+u_x+\varepsilon u^p u_x-\nu u_{xxt}=0. \tag{14}$$

Using the transformation $u(x,t)=f(\xi)$ where $\xi=x-ct$, then the GRLW equation becomes

$$-c\frac{df(\xi)}{d\xi}+\frac{df(\xi)}{d\xi}+\varepsilon f^p(\xi)\frac{df(\xi)}{d\xi}+c\nu\frac{d^3f(\xi)}{d\xi^3}=0. \tag{15}$$

Integrating Eq. (15) gives

$$(1-c)f(\xi)+\frac{\varepsilon}{p+1}\big(f(\xi)\big)^{p+1}+c\nu\frac{d^2f(\xi)}{d\xi^2}=0. \tag{16}$$

Substituting Eq. (6) into Eq. (16) becomes

$$(1-c)\lambda\cos^{\beta}(\mu\xi)+\frac{\varepsilon\lambda^{p+1}}{p+1}\cos^{(p+1)\beta}(\mu\xi)-c\nu\lambda\beta\mu^2\cos^{\beta}(\mu\xi)$$
$$+c\nu\lambda\beta(\beta-1)\mu^2\cos^{\beta-2}(\mu\xi)-c\nu\lambda\beta(\beta-1)\mu^2\cos^{\beta}(\mu\xi)=0. \tag{17}$$

By equating the exponents and the coefficients of each pair of the cosine function we obtain the following system of algebraic equations:

$$(1-c)\lambda-c\nu\lambda\beta\mu^2-c\nu\lambda\mu^2\beta(\beta-1)=0,\qquad (p+1)\beta=\beta-2,$$
$$\frac{\varepsilon\lambda^{p+1}}{p+1}+c\nu\lambda\mu^2\beta(\beta-1)=0. \tag{18}$$

By using MATHEMATICA package software for solving the system Eq. (18) we get:

$$\beta=\frac{-2}{p},\qquad \mu=\pm\frac{\sqrt{1-c}\,p}{2\sqrt{\nu c}}\quad\text{and}\quad \lambda=2^{-1/p}\left(\frac{-2+2c-3p+3cp-p^2+cp^2}{\varepsilon}\right)^{1/p}. \tag{19}$$

Then by substituting Eq. (19) into Eq. (5) then, the exact soliton solution of the GRLW equation can be written in the form:

$$u(x,t)=2^{-1/p}\left(\frac{-2+2c-3p+3cp-p^2+cp^2}{\varepsilon}\right)^{1/p}\cos^{-2/p}\left(\pm\frac{\sqrt{1-c}\,p}{2\sqrt{\nu c}}(x-ct)\right). \tag{20}$$

3.1.3. The GKdV and GIKdV equations

The general Korteweg–de Vries (GKdV) equation [36,37], for long waves in shallow water has the form:

$$u_t+\varepsilon u^p u_x+\gamma u_{xxx}=0. \tag{21}$$

In the same manner to solve Eq. (21) by cosine-function method, we obtain the following system of equations as follows:

$$-c\lambda-\gamma\lambda\beta\mu^2-\gamma\lambda\mu^2\beta(\beta-1)=0,\qquad (p+1)\beta=\beta-2,$$
$$\frac{\varepsilon\lambda^{p+1}}{p+1}+\gamma\mu^2\beta(\beta-1)=0. \tag{22}$$

This can be solved using MATHEMATICA package software to get

$$\beta=\frac{-2}{p},\qquad \mu=\pm\frac{i\sqrt{c}\,p}{2\sqrt{\gamma}},\qquad \lambda=2^{-1/p}\left(\frac{c(2+3p+p^2)}{\varepsilon}\right)^{1/p}. \tag{23}$$

So the exact soliton solution of GKdV equation can be written in the form

$$u(x,t)=2^{-1/p}\left(\frac{c(2+3p+p^2)}{\varepsilon}\right)^{1/p}\cos^{-2/p}\left(\pm\frac{i\sqrt{c}\,p}{2\sqrt{\gamma}}(x-ct)\right). \tag{24}$$

In a similar way, when we consider the general improved Korteweg–de Vries (GIKdV) equation in the form [27,37]

$$u_t+\varepsilon u^p u_x+\gamma u_{xxx}-\nu u_{xxt}=0. \tag{25}$$

The exact soliton solution of this soliton equation can be deduced to the form:

$$u(x,t)=2^{-1/p}\left(\frac{c(2+3p+p^2)}{\varepsilon}\right)^{1/p}\cos^{-2/p}\left(\pm\frac{i\sqrt{c}\,p}{2\sqrt{\gamma+c\nu}}(x-ct)\right). \tag{26}$$

3.1.4. Coupled equal width wave equation (CEWE)

In this case we consider the coupled equal width wave equations, in the normalized form

$$u_t+uu_x-u_{xxt}+vv_x=0,\qquad v_t+vv_x-v_{xxt}=0, \tag{27}$$

where the subscripts t and x denoting to the differentiation with respect to time and space respectively, the boundary conditions $u,u',u''\to c_1$ and $v,v',v''\to c_2$ as $x\to\pm\infty$ such that c_1, c_2 are arbitrary constants. Suppose $u(x,t)=f(\xi)$ and $v(x,t)=g(\xi)$ then the coupled EWE becomes

$$-c\frac{df(\xi)}{d\xi}+f(\xi)\frac{df(\xi)}{d\xi}+c\frac{d^3f(\xi)}{d\xi^3}+g(\xi)\frac{dg(\xi)}{d\xi}=0,$$

$$-c\frac{dg(\xi)}{d\xi} + g(\xi)\frac{dg(\xi)}{d\xi} + c\frac{d^3g(\xi)}{d\xi^3} = 0. \tag{28}$$

We define the two functions

$$f(\xi) = \lambda_1 \cos^{\beta_1}(\mu_1\xi), \qquad g(\xi) = \lambda_2 \cos^{\beta_2}(\mu_2\xi). \tag{29}$$

Substituting Eq. (29) into Eq. (28) we obtain a system of algebraic equations

$$\begin{aligned}
&-c\lambda_1 - c\lambda_1\beta_1\mu_1^2 - c\lambda_1\mu_1\beta_1(\beta_1-1) = 0, \qquad \beta_1 + 2\beta_2 + 2 = 0,\\
&\frac{\lambda_1^2}{2} + \frac{\lambda_2^2}{2} + c\lambda_1\mu_1^2\beta_1(\beta_1-1) = 0, \qquad -c\lambda_2 - c\lambda_2\beta_2\mu_2^2 - c\lambda_2\mu_2\beta_2(\beta_2-1) = 0, \qquad \beta_2 + 2 = 0,\\
&\frac{\lambda_2^2}{2} + c\lambda_2\mu_2^2\beta_2(\beta_2-1) = 0.
\end{aligned} \tag{30}$$

Solving the system of Eq. (30), with the aid of MATHEMATICA, we have

$$\begin{aligned}
&\lambda_1 = (0.5 - 2.95804i)c, \qquad \beta_1 = 2, \qquad \mu_1 = \pm 0.5i,\\
&\lambda_2 = 3c, \qquad \beta_2 = -2, \qquad \mu_2 = \pm 0.5i.
\end{aligned} \tag{31}$$

So we obtain the exact soliton solution of the CEWE equation in the form

$$\begin{aligned}
&u(x,t) = (0.5 - 2.95804i)c\cosh^2\big[0.5(x-ct)\big],\\
&v(x,t) = 3c\operatorname{sech}^2\big[0.5(x-ct)\big].
\end{aligned} \tag{32}$$

4. Conclusion

In this Letter, the cosine-function method has been successfully applied to find the solution for five nonlinear partial differential equations such as GEWE, GRLW, GKdV, GIKdV and CEWE equations. The cosine-function method is used to find a new exact solution. Thus, we can say that the proposed method can be extended to solve the problems of nonlinear partial differential equations which arising in the theory of solitons and other areas.

Some Aspects of Charge Transfer in Biological Systems

Felix Gutmann

ABSTRACT: The following modes of biological charge transfer are discussed: via solitons, as electronic conductance as hydrated proteins, via surface charge transfer complexes, and by protonic charge transfer complexes. Electron transfer involving the cytochromes is treated in the light of electrochemical measurements including voltammetry. A hypothesis for the lateral, surface conductance of biological membranes is proposed, based on electron donor–acceptor surface interactions giving rise to polaritons.

1. Introduction

In a way, all biological charge transfer is electrochemical in nature. Thus, this field is so huge that the following discussion will have to be confined to a few selected aspects. Many relevant topics are treated by the other contributors to this volume.

Regular and periodic organization of molecules is essential for the living state, and fundamental to its processes are structured instabilities which are reflected in the solid state by, e.g., charge transfer complexes. Many *in vivo* properties are difficult to explain by classical chemical processes in solution but appear to fit solid state physical processes in cells. Solid state events involving conduction are evident in animate aggregations and may well be an essential characteristic of life, which may be an electromagnetic phenomenon. A growing body of reviews and texts[1] is

Felix Gutmann • School of Chemistry, Macquarie University, North Ryde, N.S.W. 2113, Australia.

F. Gutmann et al. (eds.), *Modern Bioelectrochemistry*
© Plenum Press, New York 1986

available to support these views. Chelate metal complexes of purines, pyrimidines, and their nucleosides have been reviewed in detail.[2]

For charge transfer to occur, free charges must either be initially, inherently present, or injected from outside, or else be generated within the system by means of an injection of energy.

When a molecule is excited by a sufficiently energetic event, an electron can be ejected. The resulting molecular cation polarizes electrons from its immediate environment in a time of about 10^{-16} s, and this polarization energy stabilizes the final state of the system. Frohlich's excitation may play here

When two opposite charges in a medium of relative permittivity ε_r approach one another, the Coulombic energy of attraction between them equals kT at a critical distance R_c so that[3]

$$R_c = e^2/4\varepsilon_r\varepsilon_0 kT$$

or (1)

$$R_c = 55.9/e_r \text{ nm}$$

A limit therefore exists for the quantity of charge of one kind which can be imposed without resulting in recombination.[3] This limits the amounts to about 10^{17} electronic charges/cm^3, while there are about 10^{21} molecules/cm^3. Electric neutrality need not be preserved in organic media. In an organic layer of about 5 nm the total of such uncompensated space charge is approximately 10^{-10} C/cm^2, which, if it were uniformly distributed, would yield a rather small electric field of about 10^3 V cm^{-1}. Potential differences of about 5 mV across 5 nm, i.e., 10^4 V cm^{-1}, do not represent a serious problem for space charge limitation of current flow through biological systems typically several nanometers thick. It also follows that only one molecule in several thousand can be charged if compensating charges are absent. Thus, modeling a biological system, a localized representation based on individual charged species is preferable to a representation of a charge density distributed over all the molecules.[3]

If the distance between M^+ and M^- is less than R_c, they exist as an ion pair, i.e., in a charge transfer state. If M^+ and M^- are locked into original lattice states then the distance can have only certain values. From the energies for linear polyacenes, determined accurately by Silinsh,[4] it appears that, as the number of rings increased,* charge separation in the

* Silinsh estimated[4] the energy (E_{CT}) of the charge transfer state of pentacene to be about one order of magnitude smaller than that of naphthalene. As the number of conjugated rings increases it becomes easier to separate the charges in a CT state; the photoinduced M^+M^- thermalized CT state of pentacene has, under some conditions, charge separation distances as large as 12.5 nm.[5]

charge transfer state is facilitated. This could be significant for biological systems containing highly conjugated molecules such as chlorophyll.[3]

Electrochemical methods have been applied to the study of a variety of biological charge transfer problems. Thus, to give just a few examples, voltammetry has been used to study tissue,[6] zeta potentials have been related to cystic fibrosis,[7] an electrophoretic mobility test of macrophage for malignancy has been suggested[8] and polarography has been applied, *inter alia*, to the study of carcinogenicity of several chemical compounds by the Czech school.[9]

2. *Solitons*[73]

The important role played by solitons* in biological transfer remains to be clarified: solitons are said[11] to arise from localized disordered regions on, say, a membrane surface in the presence of the transmembrane electric field; the local perturbation then tends to spread and to move leading to changes in the orientation of the lipid membrane molecules. The soliton energy is considerably below the "energy band gap" of a polypeptide chain but may initiate proton transfer[12] in a hydrogen bonded chain in the presence of an electrostatic field.

Solitons may result in energy transporting along biological macromolecules. Their genesis and propagation as phonons in macromolecules establish important system properties in these molecules. Electromagnetic energy may be converted to soliton conducted energy as a transductive step. These solitons propagate quite slowly along the molecule, exhibiting threshold and possibly "windowed" characteristics in relation to the exciting energy. In transductive coupling of exciting events on cell membranes, they thus offer a vehicle for highly selective relationships in the electrochemical environment. In the transmembrane coupling of cell surface events to specific intracellular enzyme systems or organelles, either at internal membrane sites or via the cytoskeletal system to submembrane regions, solitons may also play a major role.

Binding of drug molecules to helical protein molecules[67] may inhibit soliton propagation. Further studies along these lines may allow "tailoring" of new drugs with optimal therapeutic capabilities. Their actions may be modulated by concurrent exposure to selected electromagnetic fields. Similar selective modulations of tissue functions by modification of the

* A soliton[10] is a localized collective excited state likely to arise in nonlinear dispersive media. The soliton is capable of migrating over relatively long distances with very little energy dissipation. It may be electrically charged or may be neutral such as a kink in a polymeric chain, or a domain wall.

electromagnetic environment may be seen in wound healing, tissue regeneration, and cancer therapy. These studies in biological interactions with the electromagnetic environment may yield important new knowledge about biophysical bases of circadian and other biological rhythms, with important therapeutic implications in endrocrine and immune disorders.

The solitons are thought[68] to induce simultaneously a displacement of the vibrational energy levels of the macromolecular chain and a rearrangement of the aqueous environment, until some sort of resonance is attained between these two processes, and a transition between charge and discharge regimes occurs. The result is a region of highly structured water and what often is called a Fröhlich regime, characterized by the existence of coherent electrical oscillations having frequencies of the order of 10–100 gHz, and discussed by Fröhlich himself in Chapter 8 of this volume. In other words, the metabolic energy reaches definite, localized sites within the macromolecular chain, e.g., DNA or protein. The energy causes a local deformation which travels along the chain as a soliton, causing the two effects mentioned above. Eventually, the soliton energy is transferred into the aqueous phase as a Fröhlich polarization wave. Maintained by the continuing supply of metabolic energy, this wave then plays a major part in affecting the cell organization.

One main problem still remains, viz., the isolation and characterization of the solitons as appearing in biological systems.

3. *Conduction and Biological Structure*

Much of what follows is based on discussions by Pethig and coworkers.[13] (See his contribution to this volume, Chapter 7.)

Proteins have the general structure of polypeptide chains with –C–C–N– as a repeat unit; see Figure 1.

Each peptide unit lies in a plane because it consists of a delocalized system of π electrons associated with π orbitals of the C and O atoms together with the lone electron-pair orbital of the N atom. Such an electron resonance structure is sufficient to produce significant diamagnetic anisotropy in the protein.[14] Some two dozen amino-acid residues make up polypeptides, but only glycine and proline have a first atom in the side chain R which is not a carbon atom. Thus, many features of regularity are present which may cooperate in forming energy bands, particularly in the extended arrays of α helices and β-pleated sheets. In fact, spectra of DNA

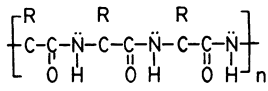

FIGURE 1. General structure of proteins.

and RNA are not basically different from those of their constituent groups because randomization of the constituents washes out all features of the electronic spectrum. Tong[15] suggests that this is due to the presence of geometry-independent lines and allowed energy bands. Altieri and Krizan,[16] using a self-consistent method, show term energies of reasonable magnitude to exist if DNA and related models are characterized as intrinsic semiconductors with a band energy gap of approximately 2 eV. Many proteins have a semiconduction activation energy of about this value.[17]

Whether charge carriers can migrate freely through proteins depends greatly on these energy bands. Coherent electronic motion can occur if broad bands of electronic states are available for the ground states (valency bands) and the excited states (conduction bands). If the bands of the extended states are less than about 2 kT, or if the energy states are localized, charge transport takes place by activated hopping or by tunneling processes.[13]

It appears that all proteins in the natural "pure" state are insulators. The valence band of the extended states is completely occupied by electrons, and the band gap is so large that at physiological temperatures the possibility of promoting electrons across the gap is negligible. Then, calculations[13] indicate that the energy band widths are greater for atomic interactions along the polypeptide backbone chains (–C–C–N–C–C–N–) than those arising from the hydrogen-bonded network interactions which stabilize the protein's tertiary structure. Thus, water molecules in a gramicidine A channel form a linear structure along the channel axis and containing about seven molecules.[96] The majority of semiconduction experiments have involved soluble proteins, probably because these are easily purified and crystallized. However, the structural proteins, those which support the main functional elements, are usually discarded in purification processes, as residues. Experimental evidence has existed for some time for electronic conduction in sea-animal integuments, e.g., crab shells.[12] In order to function, such structural proteins will generally be complexed with other molecules in a manner analogous to dopants and thereby facilitate charge transport.

4. Hydration and Charge Transfer

4.1. Proteins

In their natural state many proteins are bound into hydrophobic lipid matrices. The energetics of charge separation and mobility are governed largely by the dielectric constant of the surrounding medium. Calculations[13] have shown that the internal structures have an effective

high-frequency relative permittivity of about 2.6, which value does not increase much upon hydration. Even in the presence of a fully extended hydrogen-bonded network, conduction along the backbone is more likely, but the particular properties of a protein will depend on its precise conformation, environment, and interactions with other molecules. Thus, it has been shown[19] that the measured conductances and permittivities of bovine serum albumin and lysozyme are determined by the degree of hydration as well as of the NaCl concentration in the salt solution used as the medium. The electrical behavior is governed by protein–water interactions; the conductance is due to a proton site-to-site hopping process.[19]

Considerable differences in the resistivity between that of ordinary proteins and that of electron transfer proteins have been reported[20,21] and also between ferrocytochrome-*c* and ferricytochrome-*c*. This is attributed to the electronic state of the central metal atom.[20] The anhydrous cytochromes exhibit resistivities many orders of magnitude higher; thus anhydrous ferricytochrome c_3 has a room temperature of $4.1 \times 10^{12}\ \Omega$ cm and the ferrocytochrome c_3 a value of 1.6×10^{10}; these data are even more remarkable because the ferri compound is said[24] not to follow an Arrhenius type relationship in its temperature dependence while the ferro compound is reported to yield a negative value for its thermal activation energy. Cytochromes will be discussed in more detail in the next section.

Another interesting example for severe hydration effects in relation to charge transfer is the purple membrane of *Halobacterium halobium*: it acts as a photoelectret, producing at least semipermanent electric charges upon illumination; this activity has been shown to be greatly affected by hydration.[95]

Water in proteins has been determined from hydration isotherms obtained gravimetrically and the more recent quartz crystal resonator techniques.[39] The steady state conductivity of protein samples increases rapidly with water absorbed. The weight percentage, m, relates to the conductivity according to the Spivey equation,[40]

$$\lambda = \lambda_D \exp(\alpha m) \tag{2}$$

where λ_D is the dry-state conductivity and α a constant. For m of about 5 wt %, a change occurs such that $\alpha = 1.3$ for $m < 5$ wt % and $\alpha = 0.9$ for $m > 5$ wt %. This may be explained by assuming that at 5 wt % nearly all the protein primary sorption sites are occupied by water molecules and the population of secondary hydration sites begins. The frequency f_m of maximum loss of dielectric dispersion is also found[13] to increase with increasing hydration following the relationship

$$\tau = \tau_0 \exp(-\beta m) \tag{3}$$

where τ is the relaxation time and β a constant. Again at 5 wt % the value of the constant changes.[13] Although f_m changes, the area under the dielectric loss factors ε'' vs. $\log(f)$ curve does not change with hydration, suggesting[13] that the observed dielectric dispersions are not directly related to the relaxation of water dipoles.

4.2. Cytochromes

Cytochrome-c_3 is specially interesting because this gobular hemoprotein (molecular weight about 12,500) is a defined chemical entity and known[22] to be the electron carrier in the respiratory chain of, *inter alia*, *Desulfovibrio vulgaris*. The electron transfer rate in its reversible electrochemical electrode[98] redox reaction has the enormous value of 0.1 cm sec^{-1}. Its resistivity in the ferro- as well as the ferri-form is shown in Figure 2. The conductivity was ohmic and appears to be electronic in nature[20]; values are said[20] to be well reproducible. The low-temperature branch of ferrocytochrome-*c* exhibits the usual Arrhenius form, but the high-temperature region shows a most unusual behavior, as seen from Figure 2. The resistivities of these two forms are reported[20] to differ by 11 orders of magnitude, with the reduced form having the extraordinarily low value of 57 Ω cm at the transition temperature T_M, a value comparable to that of germanium. It is remarkable that even anhydrous films of tetrahemoprotein cytochrome C_3 exhibit[23] good conductivity at 292 K.

The polypeptide chain within the cytochrome molecule has virtually no conductivity at all, while the complete hemoprotein exhibits a conductivity of the order of 10^{-9}–$10^{-11}(\Omega\,\text{cm})^{-1}$, suggesting a considerable contribution of the heme units to the overall electron transfer. Since the porphyrin subunit is about 13 Å diameter, sufficient delocalization of π electrons should be expected[20] to impart conductivity. It has been

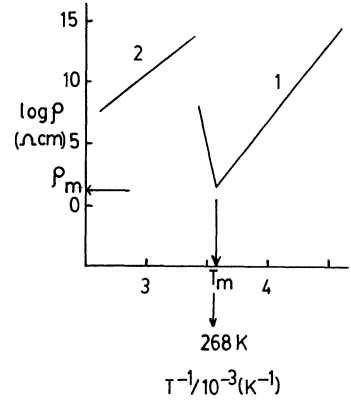

FIGURE 2. Temperature dependence of the resistivity of (1) ferrocytochrome-c_3 and (2) ferricytochrome-c_3.[20]

hypothesized that some part of the hemes in cytochrome-c_3 are exposed to the protein surface so that electrons may tunnel through a peptide residue.[19] The heme–heme interaction in the cytochrome c_3 molecule was inferred from NMR and Mössbauer spectroscopy. Cytochrome c_3 undergoes a reversible oxidoreduction by catalytic action of hydrogenase.[26]

Table 1 collects the electrical conductivity data of several protein solids.[27] The ferri-forms of both cytochromes have a similar resistivity in magnitude at room temperature. On the other hand, very drastic differences appeared in the resistivity of the ferro-form.

The contribution of heme to the electrical conduction of biological materials is clear because the polypeptide chain itself has a resistivity 10^{14} Ω cm. On the other hand, the resistivity of one hemoprotein is about 10^9–10^{11} Ω cm.

Taking into account the size of porphyrin, 1.3 nm in diameter, the distance is small enough to cause the overlapping of π electrons. Electrochemical measurement of the reduction of cytochrome c_3 on a mercury electrode also suggests[31] that some parts of hemes are exposed to the protein surface and/or the electrons tunnel through a peptide residue.

Rapid direct electron transfer between cytochrome c and a gold electrode takes place in the presence of 4,4′-bipyridyl and 1,2-bis(4-pyridyl)ethylene, which form an adsorbed layer on the electrode surface thus facilitating the electron-transfer reaction.[32] There are some strik-

TABLE 1. Electrical Conductivity of Several Protein Solids[a]

Substance	Temperature range (°C)	E in $E/2kT$ (eV)	Resistivity (Ω cm) at temperature indicated (°C)
Cytochrome c oxidized[b]	—	2.7	6.1×10^{16}(30)

ing analogies between the reaction of cytochrome *c* at this electrode and its reaction with cytochrome oxidase with respect to the effect of chemical modification of the cytochrome *c* lysine residues and the effect of poly-L-lysine on the electrode reaction. The results suggest that cytochrome *c* binds to the 4,4′-bipyridyl-modified gold electrode surface prior to electron transfer in a manner similar to its interaction with the oxidase.

The electron transfer reaction between cytochrome *c* and cytochrome oxidase proceeds via a protein complex in which the ε-amino groups of the cytochrome *c* lysine residues are believed[33] to play an imporant role. Chemical modification of these lysines is well known[34] to affect the cytochrome *c*–oxidase electron-transfer reaction. The importance of lysine residues in the protein–protein interaction is further illustrated by the effect[35] of poly-L-lysine, a competitive inhibitor of the cytochrome *c*–oxidase reaction which acts by binding to the oxidase.[36] Both *N*-acetimidyllysyl and *N*-guanidinyllysyl horse heart cytochrome *c* are electroactive at a gold electrode in the presence of 4,4′-bipyridyl or 1,2-bis(4-pyridyl)ethylene, giving rise to quasireversible diffusion-controlled dc and ac voltammograms indistinguishable from those (Figure 3) of the native protein,[37] with a half-wave potential, $E_{1/2}r = 0.25$ V vs. NHE. Similarly[36] both are enzymatically active[37] in the cytochrome–oxidase system. The enzymatically inactive *N*-trifluoroacetyl and *N*-maleyl derivatives are both electroinactive.[32]

Poly-L-lysine inhibits the electrode reaction of native horse heart cytochrome *c*, as shown by dc voltammetry (Figure 3), again analogous to its inhibiting effect on the cytochrome *c*–oxidase reaction. The effect on the ac cyclic voltammetry peak current, i_p(ac), is more marked. The varation with poly-L-lysine concentration is consistent with adsorption of poly-L-lysine onto the electrode surface, decreasing the effective free electrode area.

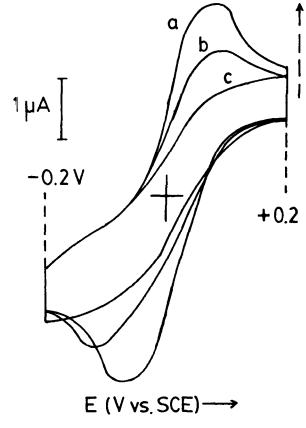

FIGURE 3. dc Voltammogram of horse heart ferricytochrome *c*, 0.4 nM in 0.1 *M* $NaClO_4$, 0.02 *M* phosphate buffer, pH 7, saturated solution of 1,2-bis(4-pyridyl)ethylene in the potential range from +0.2 to −0.2 V vs. SCE with poly-L-lysine: (a) 0 mg ml^{-1}, (b) 1 mg ml^{-1}, (c) 1.5 mg ml^{-1}, dc potential scan rate, 100 mV s^{-1}. After Eddowes *et al.*[32]

The electron-transfer reaction of the native protein has been studied[32] by ac impedance measurements. The heterogeneous electron-transfer rate was found to be as fast as that determined[38] for the ferri/ferrocyanide couple ($0.3–3.0 \times 10^{-4}$ msec^{-1}).

Double-potential-step chronocoulometry, rotating disk, and ac rotating ring disk indicate[32] that the native cytochrome binds to the 4,4′-bipyridyl-modified gold electrode surface prior to electron transfer. Thus it appears that 4,4′-bipyridyl acts by forming a suitable surface at the electrode–solution interface to which the cytochrome can bind. The binding of the protein to the electrode may therefore be similar in kind to that observed in the cytochrome *c*–oxidase reaction, involving the ε-amino groups of lysine residues in the vicinity of the cytochrome *c* heme crevice. The similarities to the cytochrome *c*–oxidase reaction may result from a preferred orientation of the cytochrome when bound at the electrode surface or to cytochrome oxidase such that the exposed heme edge is adjacent to the electrode surface or the cytochrome oxidase, thereby enabling rapid electron transfer to occur.

Hydrated melanin exhibits a reversible switching behavior[41]; upon application of an electric field above a certain threshold value this substance changes reversibly and reproducibly from a state of high resistivity to one of low resistivity. The value of the critical switching field depends on the source, nature, and mode of preparation of the pigment; only hydrated specimens show the effect. Cope proposes[42] that the high-resistivity form may be considered as an emulsion of electrons in an electron-poor matrix; copious electron injection by virtue of the switching field then inverts the emulsion yielding electron-poor islands in an electron-rich matrix. This should affect the redox potential, and this has indeed been observed.[43] The model is further supported by the negative photoconductivity reported[44] for melanin: this effect, viz., a drop in conductivity upon illumination, is rare in organic materials; it was first reported[45] in 1965 for chlorpromazine. It is thought to be associated with the presence of centers capable of existing in two different valency, or electronic, states.

5. *Charge Transfer and Adsorption. Surface Effects*

5.1. *Introduction*

Surface effects in aqueous media always involve electric double layers characterized by more or less—depending on location—immobilized charges and by a firmly held layer of structured water exhibiting a permittivity considerably below that of its bulk value. There is an extensive literature on this subject[46]; see also the discussion in Pethig's article in this volume.

An adsorbate behaves as an electron donor if the energy of its lowest unoccupied level evaluated in its adsorbed state is situated at or above the Fermi level; the adsorbate, conversely, acts as an acceptor if the highest occupied level of the system substrate plus adsorbate is at or below the Fermi level. Surface complexes are often dimerlike with their energy states well localized within the energy gap, and resulting in a depletion of states in the vicinity of the Fermi levels; any excess charge tends to accumulate on the surface complex,[47] raising the carrier hopping probability. Some surface complexes consist of an adatom plus its nearest neighbor on the surface, again a dimerlike structure.[49] The first stage of an adsorption process involves a charge transfer, donor–acceptor, interaction between the adsorbent and the adsorbate,[48] resulting in an increased effective ionization potential, or electron affinity, of the adsorbed donor or acceptor, and a rise in the local energy levels of the substrate. This stage is followed[48] by electron, or hole, transfer into stabilized vacant energy levels of the adsorbate. Surface excitons and polaritons are likely to arise on surfaces,[50] their binding energy is reported to be of the order of 0.1 eV.[51]

The topic of surface CTC is basic to the theories of catalysis and is usually treated in that context.[52]

Surface CTC of chlorpromazine (CPZ) has been shown to be involved[53] in hypothermia and sedation of mice; *in vitro* surface adducts between chlorpromazine and collagen have been demonstrated, as well as with lignocain and with phenytoin.[54] The existence of such CPZ surface adducts has been directly confirmed by electroreflectance measurements.[94]

If an acceptor is incorporated into a cationic micelle, then the rate of reactions involving hydrated electrons is increased by a factor of about 60 times that prevailing at outside negatively charged anionic micelles.[55]

Since counterions interact with, and are attracted by the, say, hydrophillic heads of the colloidal particles, micellar assemblages of such particles should be catalytically active. This, in general, has been found to be the case,[56] and should be a rewarding field for the study of micellar CTC as well as electrocatalysis. Formation of micellar CTC is also reported to result in considerably shifted ion exchange equilibria.[57]

5.2. Membranes

5.2.1. The Transmembrane Conductance

This topic has been extensively studied and many reviews and treatises dealing with it are available.[59] In this volume, it is discussed in contributions by Pethig (Chapter 7) and by Habib and Bockris (Chapter 3).

5.2.2. *Membrane Surfaces*

The surface of a biological membrane exhibits electron donating as well as electron accepting centers, though the surface as a whole is not, in general, electrically neutral, exhibiting the well-known membrane potential. We now wish to suggest that interactions with an external molecular electron acceptor or donor produces a conformational change of the complementary region on the membrane surface, perhaps initiated by Poole–Frenkel, thermally assisted field emission of carriers. The resulting transient voltage pulse may then be reversed by an opposing membrane potential which transfers the carrier back and thus restores the initial steric configuration on the membrane surface.

This hypothesis requires a finite, nonzero, conductance in the surface plane of the membrane because the electron, or hole, initially transferred forms a movable excited surface state, i.e., a polariton.[60] This may well give rise to a soliton, given a supply of energy at the proper locale.

No direct contact between donor and acceptor is envisaged; charge transfer is expected to occur once the donor approaches the acceptor, or vice versa, within tunneling distance, say 20 Å. The donor–acceptor charge transfer thus yields a pattern of surface charges and of sterically oriented proteins. Moreover, the highly nonuniform, inhomogeneous local electrical fields in the vicinity of the charges produce large, local, mechanical forces which are liable to lead to the opening or closing of ionically conducting transmembrane channels. One could then still further hypothesize that it is this surface charge pattern which is involved in the recognition of "self" and the disturbance of which plays a part in uncontrolled growth, viz., carcinogenesis. It may be significant in this context that of 289 carcinogens listed in the latest, Tenth, Collective Index of Chemical Abstracts, all but one—benzene—are electron acceptors or have pronounced electron accepting sites in their molecular structure.

The transmembrane, transcellular transient mentioned has indeed been observed,[61] e.g., in the hyphae of the water mould *Achyla bisexualis* as well as in other fungi.

The electron involved in the donor–acceptor interaction need not originate from the actual surface layer but may well come from the interior of the bilipid membrane, for example, from intramembrane proteins. The electron escape depth in organic materials is comparable to intermolecular distances.[62]

Alternatively, it may arise from an "activating ion" which enters into a surface complex with an adsorbed enzyme; it has been shown[97] that the stability of such complexes is greatly affected by the electric double layer structure of the membrane surface. As the electrostatic screening is

increased, the complex tends to become less stable and the enzyme activity drops.[97]

It is notable that all condensed polycyclic aromatics with a planar molecular structure are carcinogenic—and all have the same and relatively high value of polarization energy, viz., 1.7 eV and thus are capable of acting as efficient electron donors as well as acceptors.[63] Whether a given protein is capable of insertion into the membrane is chiefly determined by hydrophobic forces, but the final orientation of the protein depends on electrostatic interactions such as the forces arising from surface charge asymmetries—which are a feature of the hypothesis proposed above—and from local electrochemical events.[64] Any changes in the electrical surface pattern are likely to propagate to adjacent cell membranes by a process akin to epitaxy, as has been demonstrated for inorganic layers by Distler[65] for distances of up to about 230 Å. A photoelectret process is said[65] to be involved.

6. *Proton Transfer Complexes*

The electron transfer involved in the formation of a charge transfer complex may in suitable systems be coupled to a proton transfer,[69] resulting in proton transfer complexes. This holds, especially for surface reactions, e.g., at electrodes, and a fortiori in nonaqueous media, because the proton affinity of water is so very high, viz., about 8.9 eV.[70]

The proton affinity A_p is defined as the enthalpy of the reaction

$$X + H^+ \rightarrow XH^+ \tag{4}$$

In the gas phase, where there are energy contributions from solvation or polarization, A_p may be measured by means of ion cyclotron spectroscopy.[80] Proton affinities are often given in kJ/mole; 1 kJ/mole equals 0.0104 eV; 1 kcal/mole equals 0.0436 eV. Exchange repulsion energies do not enter into proton affinities.[72] The "relative protonicity" of solvents, akin to the donicity concept for electrons, is discussed by Bayless *et al.*[74]

Hydroxy-dinitro pyridines, e.g., act as electron acceptors and/or as proton donors to, e.g., napthalene derivatives.[71]

The field of protonic CTC has been opened up by Matsunaga and his school,[69] and has been reviewed by Morokuma.[72] This author points to the close linkage existing in such adducts between proton and concurrent electron transfer; one does not occur without the other. The proton complex is said[72] to involve an electron transfer from, e.g., an amine to the

proton. There is evidence that the electron transfer in some cases may be catalyzed by the presence of a proton and thus enhanced above its thermally controlled rate.[75]

Proton transfer may, sometimes, be really nothing more than a case of conventional hydrogen bonding, but in many cases the simultaneous transfer of an electron and a proton produces a new different type of adduct; then the difference between mere hydrogen bonding; and complex formation may indeed be dramatic, as pointed out by Arnett and Mitchell.[76] There is no correlation between the heats of protonation and of hydrogen bonding.[76]

Ion pair and hydrogen bonded complexes[77] are beyond the scope of this paper. Here, only a few representative examples of protonic complexes can be discussed.

The 1:1 and 1:2 complexes between oxalic acid and ε amino acids also involve a proton transfer from the carboxyl group of the oxalix acid to the carboxyl ion of the amino acid; there is a similar interaction in the 1:1 complex between malonic acid and glycine.[78] These adducts may well involve a great deal of proton delocalization resulting in the formation of proton energy bands rather than energy levels. Proton tunneling is a well-established fact,[79] and even halogen ions have been shown to be able to tunnel between two suitable energy levels. Ionic charge transfer complexes between benzyl radicals and halide ions have also been reported.[80]

The average time of residence of the proton at a temporary equilibrium site is of the order of one vibrational period of the OH group and of the average lifetime of H_3O^+, viz., about 2.5×10^{-13} s; since the dielectric relaxation time of water is about 10^{-11} s, it appears that dielectric relaxation and frictional processes are not involved in proton transfer.[81] However, in what appears to be protonic charge transfer complexes between, e.g., aliphatic amines and phenols, a considerable increase in viscosity is reported.[82]

Intramolecular proton transfer in electronically excited molecules has been reviewed[83]; in salicyclic acid esters it is said to lead to deexcitation of the excited electron[89]; the free energy change involved in that proton transfer is reported as about 0.13–0.22 eV.[84]

The effect has been shown to accompany at least some cases of electronic excitation[85] in organic molecules, such as aromatic compounds. These effects have hardly been touched upon as far as they affect biologically important transitions, as they are bound to do. This is an important and rather new field which should be explored.

Electron excitation causes only a very small change in the enthalpy of hydrogen bonding; a value of about 0.0044 eV is reported.[86]

Bacteriorhodopsin is a pigment found as a single protein component of the purple membrane of *Halobacterium halobium* and similar extreme

halophiles.[87] The purple membrane converts light energy by translocating protons across the membrane to generate an electrochemical potential. A review[88] of this subject has been published. The naturally recurring crystalline structure has been determined with electron microscopy at 7 Å resolution. The protein field is folded into seven α-helical chains, all of which span the hydrophobic core of the membrane.[88] The chromophore has been located in a lysine residue in a sequence of the second helical chain from the amino terminal group[89]; cf. discussions of methyl-glyoxal-protein complexes. The chromophere's double bond chain makes an angle of about 20° to the plane of the membrane,[90] with its ionone ring close to the center of the membrane.[91]

The role of bacterio-rhodopsin in the proton pumping activity of halobacteria has been further investigated by Bagyinka *et al.*,[92] while the light transduction via the pigmented bilipid membranes, of the purple membrane of *H. halobium*, has been studied by Ti Tien.[93]

Acknowledgments

The author is indebted to Professor Gerald C. Huth of the School of Medicine, University of Southern California, and to Dr. Bevan Reid, Queen Elizabeth II Institute of Medical Research, University of Sydney, for many stimulating discussions. Thanks are also due to Professor John O'M. Bockris and to the Chemistry Department of Texas A&M University for their hospitality.

SPECIFICITY OF THE FRÖHLICH INTERACTION OF ERYTHROCYTES

L.S. SEWCHAND and S. ROWLANDS
Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received 27 September 1982
Revised manuscript received 17 November 1982

The aggregation of mixtures of red blood cells from different species of mammals provides evidence for the specificity of the Fröhlich quantum mechanical interaction between living cell membranes.

We have shown [1,2] that there is an ultra-long-range ($\sim\mu$m) attraction between human erythrocytes and that this interaction is in accord with Fröhlich's theory [3,4] of quantum-mechanical coherent vibrations in the membranes, organelles and macromolecules of living cells.

A Fröhlich interaction should be specific; that is attractive, repulsive or null, depending on the relative frequencies or phases of the vibrations in the interacting entities and on the dispersion, with frequency, of the dielectric constant of the surroundings [4]. We have adduced [2,5] the experiments of Sewchand and Canham [6] as evidence of specificity in the erythrocyte interaction. Mixtures of erythrocytes from different species will aggregate into rouleaux and Sewchand and Canham [6] showed that the ordering of the cells in the rouleaux is not random. Cells from the same species adhere to each other significantly more frequently than expected from the results of passive aggregation experiments and from theory [7]. Sewchand and Canham studied ten pairs of different species and the only exception was the combination of erythrocytes from rats and mice. Rats and mice are of the same biological family and their exception suggests that we are dealing with a living rather than a physicochemical phenomenon [2].

The flaw in the argument for specificity is that colliding cells may come apart again. When human erythrocytes, executing brownian movement in their own plasma, touch they adhere, and, on the time scale of the slow movement, quickly slide together face to face to form rouleaux [8]. If, in the interspecies experiments [6], this occurred with like cells but, on the contrary, unlike cells had a small probability of coming apart after contact, the results of Sewchand and Canham [6] would have a trivial explanation. Accordingly we have used our aggregation technique [2,5] on mixtures of cells. Plasma cannot be used as the suspending medium because of immunological incompatibility. The cells were suspended in phosphate-buffered-saline [5] to which had been added a rouleau-forming agent, polyvinylpyrrolidone MW 360,000 [9]. The mixture was placed in a sealed haemacytometer chamber and the aggregation process was recorded by time lapse cinémicroscopy [1,2,5,9].

We carried out four experiments with dog–human mixtures and ten experiments with cat–human mixtures, both of which are known [6] to give non-random rouleaux. In each experiment about 200 cells were in view, of which about 40 pairs would collide and 10–15 of these pairs would come from the different species. Careful scrutiny of the fourteen films revealed no case of cells, once in contact, coming apart again. The non-randomness of the arrangement of the cells in the resulting rouleaux was obvious in the cat–human experiments because of the marked difference in the diameter of the cells from these two species [6].

We also analysed the experiments by our previously described method [2,5] which measures deviations from brownian movement. Deviations are expressed as multiples of a rate constant (interaction coefficient, Ξ [2,5]). $\Xi = 1$ if the motion is brownian. $\Xi > 1$ im-

plies an attraction. With a solution of polyvinylpyrrolidone rather than plasma [1,2,5] as the suspending solution, cells tend to interact variably with the surface of the haemacytometer and so can lead to inconsistent values for the drag coefficients [2,5]. This led us to reject all the dog–human experiments and five of the cat–human experiments for quantitative assessment. The interaction coefficients from the remaining five experiments were compared with those from seven experiments, four of which employed cat cells only and three of which employed human cells only (table 1). There is a difference between the two series which is highly significant by the "t" test for the differences between averages [10]. The figures suggest a reduced but positive interaction between the two species, but the variability in the figures is too great to draw firmer conclusions. These experiments will not be repeated by the current method because it has now been superseded by quasi-elastic-light scattering which is much quicker and less prone to artefact. Our published results [2,5] have been confirmed qualitatively and quantitatively by this method (O.G. Fritz Jr., private communication).

Although quantitatively these experiments were a disappointment because of technical difficulties, the observation that cells never come apart after initial contact makes Sewchand and Canham's experiments [6] on the non-randomness of the order in mixed rouleaux into firm evidence for the specificity of the interaction between erythrocytes from different species.

Fröhlich [4] and Webb [11] have reviewed the evidence for the presence of vibrations of the predicted frequency [4] in micro organisms and in cells in tissue culture. Pohl [12,13] has detected an attraction by dividing cells for inorganic particles of high dielectric constant and we have shown that a *specific* interaction exists between erythrocytes which is dependent on a membrane potential and a supply of metabolic energy [1,2,5]. Over a limited range of organisms all the major predictions of Fröhlich's theory of coherent excitations in biological systems are confirmed.

Statistical-Mechanical Theory of Irreversible Processes. I.

General Theory and Simple Applications to Magnetic and Conduction Problems

By Ryogo KUBO

Department of Physics, University of Tokyo

(Received March 2, 1957)

A general type of fluctuation-dissipation theorem is discussed to show that the physical quantities such as complex susceptibility of magnetic or electric polarization and complex conductivity for electric conduction are rigorously expressed in terms of time-fluctuation of dynamical variables associated with such irreversible processes. This is a generalization of statistical mechanics which affords exact formulation as the basis of calculation of such irreversible quantities from atomistic theory. The general formalism of this statistical-mechanical theory is examined in detail. The response, relaxation, and correlation functions are defined in quantummechanical way and their relations are investigated. The formalism is illustrated by simple examples of magnetic and conduction problems. Certain sum rules are discussed for these examples. Finally it is pointed out that this theory may be looked as a generalization of the Einstein relation.

§ 1. Introduction

The principal purpose of the present paper is to develop a general scheme for the calculation of kinetic coefficient, or admittance for external forces such as electric or magnetic susceptibility for alternating field, electric conductivity, heat conductivity and so on. The most common method traditionally employed to calculate such non-equilibrium quantities is to set up the so-called kinetic equation or transport equation for the molecular distribution functions. This will be solved for stationary or periodic conditions. It is however to be remineded that the kinetic equation is itself an approximation and cannot be derived without a certain condition which is rather strict and is not often satisfied.[1] For weakly interacting particles, it may be justified if the nature of interaction is appropriate. But certainly it is not always true, and we may not be able even to write down any equation of that sort.

On the other hand, the recent development of the thermodynamic of irreversible processes[2] indicates the possibility of constructing a general statistical-mechanical theory at least for those irreversible processes which are not far apart from thermal equilibrium. In fact, there have been a number of attempts in this direction[3]. A remarkable progress has been made by Kirkwood[4] who showed that the friction constant, for instance, of a Brownian particle is determined by the correlation of forces acting on the particle. This may be looked as a particular case of the so-called dissipation-fluctuation theorem. As was discussed from a general point of view by Callen, Welton,[5] Takahasi[6] and others, the general admittance for an external disturbance is related to the expectation of the square of Fourier component of certain physical quantity which fluctuates in time in thermal equilibrium. Thus it is shown that, as far as linear responses are concerned, the admittance is reduced to the calculation of time-fluctuations in equilibrium.

This idea was used by the present author as the basis of the theory of magnetic resonance problem. In a previous paper[7] the author developed a quantum-mechanical theory of this and has shown a certain method of practical application. A straightforward application of this theory was made by Nakano[8] for the conduction problem. He showed that the simplest approximation of the fundamental expression of conductivity gives the well-known Grüneisen's formula.

A generalized form of Nyquist's theorem can be easily derived by application of perturbation theory either classical or quantum-

mechanical. The complete conductivity tensor for a given frequency of applied electric field can be rigorously expressed in terms of electric current components fluctuating spontaneously in equilibrium state[9]. We emphasize here that this expression is quite rigorous though admittedly somewhat abstract. It is however of great value, because the traditional theory of conductivity has not been aware of existence of such rigorous expression (although the Heisenberg-Kramers dispersion formula is an equivalent). The abstract nature of the formula may be compared to that of general theory of statistical mechanics. The statistical mechanics can give a rigorous expression for the equation of state in terms of partition function, but its calculation is not necessarily easy.

This theory of electric conduction has been actively discussed in last two years in Japan since the appearance of our paper on magnetic resonance[7] and its application to conduction problem by Nakano. Feynman also discussed this when he visited Japan in the summer of 1955. Also it has been discussed by Lax, Luttinger, Kohn and possibly by some others in the United States. Recently Mori[20] has published a paper on the same problem.

In the present paper, which will be the first part of a series of papers devoted to the development of statistical mechanics of irreversible processes along this line and to its applications, we shall examine in detail the implications of this new method.

In § 2, we shall treat the response of a system to an external force by simple perturbation method. In order to make the idea clearer we first discuss the classical case. Quantum-mechanical formulation is quite in parallel with this classical theory. However, we notice a difficult problem of quantum-mechanical observation which might disturb the natural development of the motion. It will be pointed out that the logical basis of the whole theory is closely related to the ergodic properties of the system and the physical quantities we are concerned with. This is discussed in § 3 in connection with the definition of relaxation functions which describe the relaxation of the system after removal of external disturbance.

In § 4, the correlation functions are introduced which describe the time correlation of two quantities at different time points. The relation between the correlation function and the relaxation function is derived. This is somewhat complicated in quantum-mechanical case.

§ 5 is devoted to the application of general argument to simple examples of magnetic and conduction phenomena. This is mostly to illustrate the general idea. The symmetry of the relaxation and response functions is discussed in § 6. The Onsager's reciprocity is seen most clearly by this formalism. The complete form of fluctuation-dissipation theorem will be given in § 7 taking the example of conductivity tensor.

As an interesting application of the theory, some general rules for the admittance is discussed in § 8. The most general sum rule is mentioned with regard to the symmetric part of conductivity tensor. The integration of this over the whole range of frequency must be constant irrespective of the presence of interactions or magnetic field and at any temperature. Another type of sum rule is derived for the antisymmetric part of conductivity. An interesting sum rule for the magnetic problem is that the integrated absorption intensity of circular wave by magnetic media is directly related to the gyromagnetic ratio of magnetic particles.

In § 9, it will be pointed out that the theory may be looked as a generalization of Einstein relation which relates the mobility and the diffusion constant. The general nature of Einstein relation is thus most clearly revealed.

In the present paper we confined ourselves to such type of external disturbance which can be expressed definitely as an additional term in the Hamiltonian of the system. Thus the heat flow, or mass flow phenomena under the gradient of temperature or chemical potential is logically out of the frame of this treatment. This problem has been treated recently by Mori.[10] We shall, however, discuss this in a forthcoming paper from a somewhat different point of view.

We also have applied the present theory to the galvanomagnetic effect at high magnetic field[11]. This is an example for which the traditional transport equation has to be modified. Our theory will be reported in another paper.

§ 2. Response Function and Admittance of an Isolated System

Let us consider an isolated system, the Hamiltonian of which is denoted by $\mathscr{H}$. The dynamical motion of the system determined by $\mathscr{H}$ is called the "*natural motion*" of the system. We suppose that an external force $F(t)$ is applied to the system, the effect of which is represented by the perturbation energy,

$$\mathscr{H}'(t) = -AF(t) . \tag{2.1}$$

The motion of the system is perturbed by this force, but the perturbation is small if the force is weak. We confine ourselves to weak perturbation and ask for the response of the system in the linear approximation. The response is observed through the change $\Delta B(t)$ of a physical quantity B. The problem is now to express $\Delta B(t)$ in terms of the natural motion of the system.

First, we shall treat this in classical mechanics. We conceive a statistical ensemble which is represented by a distribution function $f(p, q)$ in the phase space. The *natural motion* is described by the equation of motion,

$$\frac{\partial f}{\partial t} = -\sum\left(\frac{\partial f}{\partial q}\frac{\partial \mathscr{H}}{\partial p} - \frac{\partial f}{\partial p}\frac{\partial \mathscr{H}}{\partial q}\right) = (\mathscr{H}, f), \tag{2.2}$$

where p and q mean the set of the canonical moments and coordinates and the bracket means the Poisson bracket,

$$(A, B) = \sum\left(\frac{\partial A}{\partial q}\frac{\partial B}{\partial p} - \frac{\partial A}{\partial p}\frac{\partial B}{\partial q}\right). \tag{2.3}$$

We assume that the distribution function is given by f at $t=-\infty$, that is, at the infinite past. It is assumed to be in equilibrium, that is, $(\mathscr{H} f)=0$. The perturbation (2.1) is inserted adiabatically at $t=-\infty(F(-\infty)=0)$. The distribution function $f'(t)$ obeys the equation

$$\frac{\partial f'(t)}{\partial t} = (\mathscr{H}, f') + (\mathscr{H}'(t), f) . \tag{2.4}$$

Since we take the linear approximation, we put

$$f'(t) = f + \Delta f$$

and replace (2.4) by

$$\frac{\partial \Delta f}{\partial t} = (\mathscr{H}, \Delta f) - F(t)(A, f) . \tag{2.5}$$

The solution is easily found to be

$$\Delta f(t) = -\int_{-\infty}^{t} e^{i(t-t')L}(A, f)\, F(t')\, dt' \tag{2.6}$$

where the operator L is defined by the operation[4]

$$iLg \equiv (\mathscr{H}, g) . \tag{2.7}$$

Therefore, the change $\Delta B(t)$ of a dynamical quantity B is statistically given by

$$\begin{aligned}\Delta B(t) &= \int \Delta f(t) \cdot B(p, q)\, d\Gamma \\ &= -\int d\Gamma \int_{-\infty}^{t} \left\{e^{i(t-t')L}(A, f)\right\} \cdot F(t') B\, dt' \\ &= -\int d\Gamma \int_{-\infty}^{t} (A, f) B(t-t') F(t')\, dt' ,\end{aligned} \tag{2.8}$$

$d\Gamma$ being the volume element of the phase space. The last expression is obtained from the second remembering that the transformation $\exp(iLt)$ is the natural motion which conserves the measure of the phase space and that $B(t)$ means the dynamical motion of the phase function $B(p, q)$ which follows the equation

$$\dot{B}(p, q) = (B, \mathscr{H}) .$$

This corresponds to the Heisenberg equation of motion in quantum-mechanics. Eq. (2.8) means that the response $\Delta B(t)$ is a superposition of the effects of pulses $F(t')\, dt'$, $-\infty < t' < t$. The response for an unit pulse will be called the *response function* or the *after-effect function* $\phi_{AB}(t)$. From Eq. (2.8) we find at once that it is given by

$$\phi_{BA}(t) = -\int d\Gamma (A, f)\, B(t) \tag{2.9}$$

which describes the response ΔB at the time t after the pulse. The response $\Delta B(t)$, (2.8), is written as

$$\Delta B(t) = \int_{-\infty}^{t} \phi_{BA}(t-t')\, F(t')\, dt' . \tag{2.10}$$

The above consideration applies even when the initial distribution is very sharp, as far the perturbation is weak enough. But our aim is rather to apply this for a macroscopic system, in which case the statistical average itself acquires a realistic meaning. If A and B are both macroscopic quantities, we may think the ensemble average $\Delta B(t)$ is what we actually observe, because a macroscopic system can be conceived to consist of smaller systems so that observed value of ΔB is a sum of a number of components and has only

a very small relative fluctuation.

Let us now turn to quantum mechanics. The distribution function in phase space is now replaced by the density matrix ρ. The initial ensemble which represents statistically the initial state of the system is specified by the density matrix ρ satisfying $[\mathscr{H}, \rho]=0$, whereas the motion of the ensemble under the perturbation (2.1) is represented by $\rho'(t)$, which obeys the equation,

$$\frac{d}{dt}\rho'(t)=\frac{1}{i\hbar}[\mathscr{H}+\mathscr{H}'(t), \rho'(t)] . \quad (2.11)$$

With the initial condition

$$\rho'(-\infty)=\rho ,$$

we expand $\rho'(t)$ as

$$\rho'(t)=\rho+\Delta\rho(t) .$$

The same procedure as we used for (2.5) leads us at once to

$$\Delta\rho(t)=-\frac{1}{i\hbar}\int_{-\infty}^{t} \exp(-i(t-t')\mathscr{H}/\hbar)[A, \rho] \times\exp(i(t-t')\mathscr{H}/\hbar) F(t')\,dt' . \quad (2.12)$$

Incidentally, we note that it is sometimes very convenient to introduce the operator $a^{\times}$ operating on another operator b by following definition, i.e.,

$$a^{\times}b=[a, b] , \quad (2.13)$$

for which one find the rule,

$$e^{a^{\times}}b=e^{a}be^{-a} . \quad (2.14)$$

With this notation, Eq. (2.11) and (2.12) can be written as

$$\dot{\rho}'(t)=\frac{1}{i\hbar}(\mathscr{H}^{\times}+\mathscr{H}'(t)^{\times})\rho'(t) \quad (2.15)$$

$$\Delta\rho(t)=-\frac{1}{i\hbar}\int_{-\infty}^{t} \exp(-i(t-t')\mathscr{H}^{\times}/\hbar)\times \times[A, \rho]F(t')dt' \quad (2.16)$$

This will make clear the similarity of Eqs. (2.6) and (2.12).

The response $\Delta B(t)$ of the quantity B is statistically

$$\begin{aligned}\Delta B(t)&=\mathrm{Tr}\,\Delta\rho(t)B\\ &=-\frac{1}{i\hbar}\mathrm{Tr}\int_{-\infty}^{t}\exp(-i(t-t')\mathscr{H}/\hbar)\\ &\quad\times[A, \rho]\exp(i(t-t')\mathscr{H}/\hbar)BF(t')\,dt'\\ &=-\frac{1}{i\hbar}\mathrm{Tr}\int_{-\infty}^{t}[A, \rho]B(t-t')F(t')\,dt'\end{aligned} \quad (2.17)$$

where $B(t)$ is the Heisenberg representation of B following the equation

$$\dot{B}(t)=\frac{1}{i\hbar}[B(t), \mathscr{H}], \quad B(0)=B . \quad (2.18)$$

Eq. (2.17) corresponds to Eq. (2.8)

The response function or the after-effect function is now

$$\phi_{BA}(t)=-\frac{1}{i\hbar}\mathrm{Tr}\,[A, \rho]\,B(t) \quad (2.19)$$

corresponding to Eq. (2.9). We naturally have Eq. (2.10) for (2.17) with the use of response function (2.19). If the force is periodic, i.e.,

$$F(t)=F_0\cos\omega t ,$$

the response $\Delta B(t)$ will be conveniently written as

$$\Delta B(t)=\mathrm{Re}\,\chi_{BA}(\omega)\,F_0\,e^{i\omega t} \quad (2.20)$$

with the complex admittance $\chi_{BA}(\omega)$, for which we have from Eq. (2.10)

$$\chi_{BA}(\omega)=\int_0^{\infty}\phi_{BA}(t)\,e^{-i\omega t}\,dt , \quad (2.21)$$

or more exactly

$$\chi_{BA}(\omega)=\lim_{\varepsilon\to 0+}\int_0^{\infty}\phi_{BA}(t)\,e^{-i\omega t-\varepsilon t}\,dt .$$

We summarize the above by the theorem:

Theorem 1. *The linear response of a physical quantity B to an external force $F(t)$ is represented by Eq. (2.10) as the superposition of after-effects. The after-effect function or the response function is given by*

$$\phi_{BA}(t)=\int d\Gamma(f, A)\,B(t) \quad \text{(classical)} \quad (2.22a)$$

$$=\frac{1}{i\hbar}\mathrm{Tr}\,[\rho, A]\,B(t) \quad \text{(quantal)} . \quad (2.22b)$$

The admittance $\chi_{BA}(\omega)$ is given by

$$\chi_{BA}(\omega)=\lim_{\varepsilon\to 0+}\int_0^{\infty}e^{-i\omega t-\varepsilon t}\,dt\int d\Gamma(f, A)\,B(t)$$

(classical) (2.23a)

$$=\lim_{\varepsilon\to 0+}\int_0^{\infty}e^{-i\omega t-\varepsilon t}\,dt\,\frac{1}{i\hbar}\mathrm{Tr}\,[\rho, A]\,B(t) .$$

(quantal) (2.23b)

Eqs. (2.22) may be written as

$$\phi_{BA}(t)=\int d\Gamma f(A, B(t)) \quad \text{(classical)} \quad (2.24a)$$

$$=\frac{1}{i\hbar}\mathrm{Tr}\,\rho[A, B(t)] \quad \text{(quantal)} \quad (2.24b)$$

which are sometimes more convenient. One must however be careful about the boundary conditions of f or ρ, which may, however,

be replaced by a suitable potential under certain circumstances.

As we mentioned before, there is no difficulty in classical cases to interprete the response thus obtained as the average which approximates closely the actual observation for large systems. In quantum-mechanical cases, however, we must note that there exists a certain difficulty. ΔB as given by Eq. (2.17) is the quantum-mechanical expectation of the first order change of B at the time t. This means that we prepare at $t=-\infty$ an ensemble of systems which corresponds to the statistical operator ρ. At a certain time t, we pick up a number of systems and observe B. The average of the observed values will be $\Delta B(t)$. We shall not follow these systems after this observation. At a later time point t', we choose different systems which have not been observed before. This is the way to follow the time change $\Delta B(t)$ to avoid the quantum-mechanical disturbance of observation process.

For the most of practical applications, we are rather interested in a continuous observation of a particular system, which is however macroscopic. The use of ensemble average for the actual observation will be justified by the same argument we made for the classical case. But the quantum-mechanical disturbance of observation is another thing. We may, however, expect for most of macroscopic quantities which we observe this disturbance can be neglected. This is a condition for macroscopic observations. Unfortunately, exact conditions for the existence of such quantities are not known.

Thus we shall rather introduce without proof the assumption that the identification of the statistically calculated $\Delta B(t)$ with the actully observed time variation is legitimate at least for those macroscopic quantities we shall be concerned with. We should however make reservation that this assumption may not be necessary for the identification of the admittance calculated by Eq. (2.23b) with what will be actually observed, because the observation of admittance, for example, the refractivity and absorption in optical problems, is not the observation of the response function itself. As a matter of fact, Eq. (2.23b) is equivalent to the well known dispersion formula of Heisenberg and Kramers[12] plus the absorption calculated by time-dependent perturbation method.[7] The dispersion formula represents the oscillation of expectation value of dipole moments if the formula is applied to optical problems. This is not directly observed. We observe the refraction by measuring the number of photons passed through the material. The logical relation between this and that is not clear enough, but the most common apologize is the use of correspondence principle. Any further analysis of this delicate problem is not our main purpose in this paper so we shall leave it for a future occasion.

Before concluding this section, we remark that the method employed here is also applicable to higher approximations than the linear. For this purpose we note Eq. (2.5) can be used for successive approximation, namely

$$\frac{\partial \Delta_k f}{\partial t}=(\mathscr{H}, \Delta_k f)-F(t')(A, \Delta_{k-1} f)\,, \tag{2.25}$$

where $\Delta_k f$ means the k-th term of the expansion

$$f'(t)=f+\Delta_1 f+\Delta_2 f+\cdots\cdots\,. \tag{2.26}$$

The solution of Eq. (2.25) has the same from as Eq. (2.6), f being replaced by $\Delta_{k-1} f(t')$. Therefore we obtain the complete solution of Eq. (2.4) as

$$\begin{aligned} f'(t)&=f+\sum_{k=1}^{\infty}(-)^k\int_{-\infty}^{t}\int_{-\infty}^{t_1}\cdots\int_{-\infty}^{t_{k-1}} e^{iL(t-t_1)}\Big(A, e^{iL(t_1-t_2)}(A, \cdots e^{iL(t_{k-1}-t_k)}(A, f))\cdots\Big) \\ &\qquad\times F(t_1)\,F(t_2)\cdots F(t_k)\,dt_1\cdots dt_k \\ &=f+\sum_{k=1}^{\infty}(-)^k\int_{-\infty}^{t}\int_{-\infty}^{t_1}\cdots\int_{-\infty}^{t_{k-1}} e^{iLt}\Big(A(t_1), (A(t_2), \cdots (A(t_k), f)\cdots\Big)F(t_1)\cdots F(t_k)dt_1\cdots dt_k\,. \end{aligned} \tag{2.27}$$

where $A(t)$ is defined by

$$A(t)=A(p_t, q_t)\,, \quad p_{t=0}=p\,, \quad q_{t=0}=q\,.$$

The same expression is obtained for quantum-mechanical case, namely

$$\rho'(t)=\rho+\sum_{k=1}^{\infty}\left(-\frac{1}{i\hbar}\right)^k\int_{-\infty}^{t}\int_{-\infty}^{t_1}\cdots\int_{-\infty}^{t_{k-1}}\exp\left(-it\mathscr{H}^{\times}/\hbar\right)A(t_1)^{\times}A(t_2)^{\times}\cdots A(t_k)^{\times}\rho F(t_1)\cdots F(t_k)\,dt_1\cdots dt_k \tag{2.28}$$

where the cross means the commutator operation with the operation on its right hand side (see Eqs. (2.13) and (2.14)). These solutions allow us to write down the expression of responses in higher approximation. For instance, the second order change of B at the time t can be written as

$$\Delta_2 B(t)=\left(\frac{1}{i\hbar}\right)^2\mathrm{Tr}\int_{-\infty}^{t}\int_{-\infty}^{t_1}[A(t_1-t_2)[A,\,\rho]]\,B(t_1-t_2)F(t_1)F(t_2)dt_1dt_2 \tag{2.29}$$

The corresponding classical formula is similar so that it is omitted here.

§ 3. Relaxation Function and Other Useful Formulae for Canonical Ensemble

In the following we consider quantum-mechanical problems, because the classical limit is easily obtained from quantum-mechanical formulae by replacing $[\ ,\ ]/i\hbar$ by Poission bracket or by making $\hbar\to 0$.

First let us observe the behavior of the response function $\phi_{BA}(t)$ in the limit $t\to\infty$. It may approach to a limiting value or may not approach to any definite value. If it does, we must have

$$\lim_{t\to\infty}\phi_{BA}(t)=0 \text{ (if the limit exists).} \tag{3.1}$$

This is evident from Abel's theorem

$$\lim_{t\to\infty}\phi_{BA}(t)=\lim_{\varepsilon\to 0+}\varepsilon\int_0^{\infty}\phi_{BA}(t)\,e^{-\varepsilon t}\,dt \tag{3.2}$$

which holds if the left hand side exists. The right hand side is zero unless $\phi_{BA}(t)$ has a finite Fourier-amplitude at zero frequency. If $\phi_{BA}(t)$ has finite Fourier components for a set of discrete frequencies, $\phi_{BA}(t)$ will oscillate indefinitely and does not have any limit. But, for calculation of admittance we have the convergence factor $e^{-\varepsilon t}$ so that we may even in this case regard the relation (3.1) to hold. If $\phi_{BA}(t)$ is expressed by a Fourier integral with continuous Fourier spectrum, Eq. (3.1) is generally true. This corresponds to actual cases of large systems, because the complicated interaction within the system is always enough to split the energy levels into a structure so fine that the observation can not discriminate. The error in the observation of frequency certainly introduces an average which allows us to replace the originally discrete Fourier spectrum by continuous spectrum. Classically this corresponds to ellimination of long Poincaré cycles.

If the perturbation is applied continuously from $t=-\infty$ up to $t=0$ and is cut off at $t=0$, then the response ΔB will relax following the formula

$$\Delta B(t)=\int_{-\infty}^{0}\phi_{BA}(t-t')dt'F=F\int_t^{\infty}\phi_{BA}(t')dt',\qquad t>0\,. \tag{3.3}$$

Therefore, the function

$$\Phi_{BA}(t)=\lim_{\varepsilon\to 0+}\int_t^{\infty}\phi_{BA}(t')\,e^{-\varepsilon t'}\,dt' \tag{3.4}$$

describes the relaxation of ΔB after removal of the outer disturbance. This will be called the relaxation function.

Here, for later reference we note the theorem:

Theorem 2. *The admittance $\chi_{BA}(\omega)$ can be calculated by the following formulae*;

$$\begin{aligned}\chi_{BA}(\omega)&=\lim_{\varepsilon\to 0+}\int_0^{\infty}\phi_{BA}(t)\,e^{-i\omega t-\varepsilon t}\,dt\\&=\lim_{\varepsilon\to 0+}\frac{1}{i\omega+\varepsilon}\left\{\dot{\phi}_{BA}(0)+\int_0^{\infty}\phi_{BA}(t)\,e^{-i\omega t-\varepsilon t}dt\right\}\\&=\Phi_{BA}(0)-i\omega\int_0^{\infty}\Phi_{BA}(t)\,e^{-i\omega t}\,dt\,.\end{aligned} \tag{3.5}$$

These transformations are rather evident.

The expression of $\phi_{BA}(t)$ has already been given by Eq. (2.22). We note here that other functions $\dot{\phi}_{BA}(t)$ and $\Phi_{BA}(t)$ have convenient transform if the statistical ensemble is assumed to be *canonical*. For this purpose, we observe the identity

$$\begin{aligned}&[A,\exp(-\beta\mathscr{H})]\\&=\exp(-\beta\mathscr{H})\int_0^{\beta}\exp(\lambda\mathscr{H})[\mathscr{H},A]\\&\qquad\times\exp(-\lambda\mathscr{H})\,d\lambda\end{aligned}$$

$$=\frac{\hbar}{i}\exp(-\beta\mathscr{H})\int_0^S \exp(\lambda\mathscr{H})\dot{A} \times\exp(-\lambda\mathscr{H})\,d\lambda$$

$$=\frac{\hbar}{i}\exp(-\beta\mathscr{H})\int_0^\beta \dot{A}(-i\hbar\lambda)\,d\lambda \tag{3.6}$$

or

$$[\rho_\beta, A]=i\hbar\int_0^\beta \rho_\beta\dot{A}(-i\hbar\lambda)\,d\lambda \tag{3.7}$$

which is easily seen by writing the expression in matrix form in the representation diagonalizing $\mathscr{H}$.

Let us now assume that the system we observe is statistically represented by the canonical density matrix,

$$\rho=\exp(-\beta(\mathscr{H}-\Psi)),\quad \beta=1/kT,$$
$$\exp(-\beta\Psi)=\mathrm{Tr}\exp(-\beta\mathscr{H})\,. \tag{3.8}$$

By Eq. (2.22b) we have

$$\phi_{BA}(t)=\frac{1}{i\hbar}\mathrm{Tr}[\rho, A]B(t)$$
$$=\int_0^\beta \mathrm{Tr}\,\rho\dot{A}(-i\hbar\lambda)B(t)\,d\lambda$$
$$=-\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)\dot{B}(t)\,d\lambda \tag{3.9}$$

and also

$$\dot{\phi}_{BA}(t)=\frac{1}{i\hbar}\mathrm{Tr}[\rho, A]\dot{B}(t)$$
$$=\frac{1}{i\hbar}\mathrm{Tr}\,\rho[A, \dot{B}(t)]=\frac{-1}{i\hbar}\mathrm{Tr}\,\rho[\dot{A}, B(t)]$$
$$=\int_0^\beta \mathrm{Tr}\,\rho\dot{A}(-i\hbar\lambda)\dot{B}(t)\,d\lambda \tag{3.10}$$

One may use any of these expressions depending on the nature of the quantities A and B. This will be illustrated later by examples.

With the aid of Eq. (3.9), the relaxation is transformed into

$$\Phi_{BA}(t)=\frac{i}{\hbar}\int_t^\infty \mathrm{Tr}\,\rho[B(t'), A]\,dt' \tag{3.11a}$$
$$=\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)B(t)d\lambda-\beta\mathrm{Tr}\rho A^0B^0 \tag{3.11b}$$

where A^0 and B^0 are the diagonal parts of A B with respect to $\mathscr{H}$. The second term on the right hand side of Eq. (3.11) is the limit

$$\lim_{t\to\infty}\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)B(t)\,d\lambda$$
$$=\lim_{t\to\infty}\frac{1}{t}\int_0^t dt\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)B(t)\,d\lambda$$
$$=\beta\,\mathrm{Tr}\,\rho A^0B^0 \tag{3.12}$$

because this limit process selects the zero-frequency component of $B(t)$. The limit of the first expression, if it exists, must be equal to the last.

We may also define the function

$$\Phi^e{}_{BA}(t)=\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)(B-B(t)) \tag{3.13}$$

which we shall call the *excitation* function for convenience, because this describes the increase of $\Delta B(t)$ when a constant force is applied from $t=0$. Thus

$$\lim_{t\to\infty}\Phi^e{}_{BA}(t)=\Phi_{BA}(0)\,. \tag{3.14}$$

In particular, for $t=0$, we have from Eq. (3.11) and Eq. (3.5)

$$\chi_{BA}(0)=\Phi_{BA}(0)=\Phi^e{}_{BA}(\infty)$$
$$=\int_0^\beta \mathrm{Tr}\,\rho A(-i\hbar\lambda)Bd\lambda-\beta\,\mathrm{Tr}\,\rho A^0B^0$$
$$=\int_0^\beta \mathrm{Tr}\,\rho(A(-i\hbar\lambda)-A^0)(B-B^0)d\lambda \tag{3.15}$$

where $\chi_{BA}(0)$ is the static admittance.

Eq. (3.15) is a little embarrassing, since the isothermal admittance, $\chi_{BA}{}^T$, is

$$\chi_{BA}{}^T=\int_0^\beta \mathrm{Tr}\,\rho(A(-i\hbar\lambda)-\overline{A})(B-\overline{B})\,d\lambda \tag{3.16}$$

where $\overline{A}$ and $\overline{B}$ and the equilibrium expectations of A and B in thermal equilibrium with $F=0$.

Eq. (3.16) is obtained by using the expansion

$$\exp\{-\beta(\mathscr{H}-FA\}$$
$$=\exp(-\beta\mathscr{H})\{1+\int_0^\beta A(-i\hbar\lambda)d\lambda F+0(F^2)\}$$

for the expression

$$\Delta B=\frac{\mathrm{Tr}\exp\{-\beta(\mathscr{H}-FA)\}B}{\mathrm{Tr}\exp\{-\beta(\mathscr{H}-FA)\}}-\frac{\mathrm{Tr}\exp(-\beta\mathscr{H})B}{\mathrm{Tr}\exp(-\beta\mathscr{H})}.$$

$\chi_{BA}{}^T$ is defined by

$$\chi_{BA}{}^T=\Delta B/F\,.$$

Expressions (3.15) and (3.16) are different unless

$$\mathrm{Tr}\,\rho A^0B^0=\overline{A}\,\overline{B}=\mathrm{Tr}\,\rho A\cdot\mathrm{Tr}\,\rho B\,. \tag{3.17}$$

This will not however hold without certain restrictions imposed on A and B. In fact, $\chi_{BA}(0)$ as given by Eq. (3.15) is the static admittance of an isolated system on which the force F is inserted adiabatically. On the other hand $\chi_{BA}{}^T$, Eq. (3.16), is isothermal,

that gives the response when the system is in thermal contact with the heat reservoir. Thus they need not be equal.

But, there are situations in which the difference is quite negligible. For instance, suppose a magnetic system is magnetized by external field. If the magnetic energy is only a very small fraction of the total energy, the magnetization process treated by Eq. (3.15) is practically isothermal. This means that, if the heat capacities associated with A and B are only a small fraction of total heat capacity, the equality (3.17) must be practically satisfied.

It is noted here that this is concerned with the ergodic property of the system. Khinchin[13] has shown that the ergodicity for a quantity A, namely

$$\langle A\rangle=\lim_{t\to\infty}\frac{1}{t}\int_0^t A(t)\,dt \tag{3.18}$$

must hold if the autocorrelation of A satisfies the relation

$$\lim_{t\to\infty}\langle A(0)A(t)\rangle=\langle A\rangle^2\,. \tag{3.19}$$

Here $\langle A\rangle$ means the phase average of a phase function $A(p, q)$ over a microcanonical ensemble. The ergodicity of A, (3.18), means that the time average of A starting from any point P on the ergodic surface approaches to $\langle A\rangle$ independent of the initial point P. This will hold on the assumption of (3.19) for almost all of P except a set of measure zero. This Khintchin's theorem can be reversed. It can be proved that the correlation function $\langle A(0)A(t)\rangle$ satisfies Eq. (3.19) if (3.18) holds uniformly.

In classical limit, (3.11b) in replaced by

$$\Phi_{BA}(t)=\beta\{\langle A(0)B(t)\rangle-\langle A^0B^0\rangle\}\,, \tag{3.20}$$

where $\langle\ \rangle$ means the phase average, and A^0 means the invariant part of $A(p_t, q_t)$ with respect to the natural motion. Eq. (3.16) becomes classically

$$\chi_{BA}{}^T=\beta\langle(A-\langle A\rangle)(B-\langle B\rangle)\rangle\,. \tag{3.21}$$

In general we must expect

$$\begin{aligned}\Phi_{BA}(0)&=\Phi_{BA}{}^e(\infty)=\chi_{BA}(0)\\&=\beta\langle(A-\mathrm{A}^0)(B-B^0)\rangle\fallingdotseq\chi_{BA}{}^T\,.\end{aligned} \tag{3.22}$$

The left hand side is the static admittance for an isolated system. This means that

$$\lim_{t\to\infty}\langle A(0)(B(t)\rangle\fallingdotseq\langle A\rangle\langle B\rangle \tag{3.23}$$

and hence that the ergodicity (3.18) does not hold. This is quite true as one would easily understand by the example of magnetization process of an ideal magnetic system. The isothermal and adiabatic susceptibilities are different, the later being zero.

However, our aim is to apply the whole theory to realistic systems which contain various interactions. As we have mentioned before, we should expect that

$$\chi_{BA}(0)=\chi_{BA}{}^T \tag{3.24}$$

will hold if the total system is large enough compared to the degrees of freedom associated with the observed quantities A and B.

For a very large system, the canonical distribution is almost equivalent to a microcanonical distribution, the relative fluctuation being very small. The ensemble average in Eqs. (3.20), etc., can be regarded as that over an ergodic surface. Therefore, Eq. (3.24) must hold if the quantities A, B, and $A(0)B(t)$ are ergodic, namely

$$\begin{aligned}\langle A\rangle&=\lim_{t\to\infty}\frac{1}{t}\int_0^t A(t)\,dt\,,\\\langle B\rangle&=\lim_{t\to\infty}\frac{1}{t}\int_0^t B(t)\,dt\,,\\\langle A(0)\,B(t)\rangle&=\lim_{t'\to\infty}\frac{1}{t'}\int_0^{t'}\langle A(t')B(t'+t)\rangle\,dt'\end{aligned} \tag{3.25}$$

Here the right hand sides of the equations are primarily determined by the location of the initial point of time average, but they do not depend on that. That is the assertion of ergodicity.

If the requirement of ergodicity, (3.25), is fulfilled, we shall have

$$\begin{aligned}&\lim_{t\to\infty}\langle A(0)\,B(t)\rangle\\&\quad=\lim_{t\to\infty}\lim_{t'\to\infty}\frac{1}{t'}\int_0^{t'}\langle A(t')B(t'+t)\rangle\,dt'\\&\quad=\lim_{t\to\infty}\frac{1}{tt'}\int_0^t\int_0^{t'}\langle A(t')\,B(t'+t)\rangle\,dt'dt\\&\quad=\langle\langle A\rangle\langle B\rangle\rangle=\langle A\rangle\langle B\rangle\,.\end{aligned} \tag{3.26}$$

Thus Eq. (3.22) holds.

The above arguments apply to quantum-mechanical cases with small modifications that the function $\int_0^\beta\langle A(-i\hbar\lambda)\,B(t)\rangle\,d\lambda$ enters in place of the correlation function.

Let us consider a magnetic system for illustration. The system, M, of the magnetic units are embedded in another large system,

R, with a certain interaction between M and R. The total system S we consider is $M+R$. If the heat capacity of R is large compared with M, R is a sort of heat bath for M. If we treat only M, assuming a canonical distribution and ignore the interaction between M and R, the relaxation function calculated by (3.11) describes only the internal process inside the subsystem M. The magnetic susceptibility, for instance, obtained from this, is adiabatic. For this canonical distribution, the ergodicity such as (3.25) will not hold.

If we consider the interaction and suppose, for instance, that it induces a Markoffian process for the transition of M among its various states, the ergodicity (3.25) will become true; the Markoffian assumption makes it easy to treat the relaxation process. The Markoffian assumption may be adequate if the interaction is weak and satisfies certain conditions which may be required. If such conditions are not satisfied, we are forced to deal directly with the combined system $M+R$. The relaxation function or the response function has to be treated with the complete Hamiltonian for $M+R$. In this case, the ergodicity (3.25) may be approximately true if the subsystem M is small compared to R. A rigorous formulation of mathematical proof of this is not easy, so that we merely anticipate this.

§ 4. Correlation Functions

We have seen in the previous section that the relations function $\Phi_{BA}(t)$ in classical case for canonical ensemble is essentially the correlation function of A and B; namely

$$\Phi_{BA}(t)=\beta\langle A(0)B(t)\rangle-\beta\langle A^0B^0\rangle \quad \text{(classical)} \tag{4.1}$$

where the bracket means the phase average over the canonical distribution. Or, the excitation function is

$$\Phi_{BA^e}(t)=\beta\langle A(0)(B-B(t))\rangle\,. \tag{4.2}$$

Other functions, for example, the response functions, are also proportional to certain correlation functions; e.g.

$$\phi_{BA}(t)=-\beta\langle A(0)\dot{B}(t)\rangle\,. \tag{4.3}$$

These are also valid for the microcanonical ensemble provided that the system in question is large.

Now the question arises how the correlation functions are defined in quantum-mechanics. We may define this by

$$\Psi_{BA}(t)=\mathrm{Tr}\,\rho\{A(0)B(t)\}=\mathrm{Tr}\,\rho\{A(t_1)B(t_1+t)\} \tag{4.4}$$

where ρ is the equilibrium density matrix, either canonical or microcanonical. The bracket means the symmetrized product,

$$\{AB\}=\frac{1}{2}(AB+BA)\,.$$

We may call this the time correlation of B and A at the time interval t, although it is not the correlation of two sets of actually observed values of B and A at different time points. The disturbance due to the observation is not taken into account. If the nature of the system and of A and B is such that this disturbance is not serious, which will be true for macrosopic systems and macroscopic observations, the function (4.4) describes the actual correlation. Since ρ is equilibrium density matrix, the time variation of A and B makes a stochastic time series which is stationary in time. For the sake of brevity, we rewrite the relaxation function as

$$\Phi_{BA}(t)=\int_0^\beta \mathrm{Tr}\,\rho(A(-i\hbar\lambda)-A^0)(B-B^0)\,d\lambda \tag{4.5}$$

and in the following we shall deal with quantities A and B which satisfy the condition

$$\mathrm{Tr}\,\rho A=\mathrm{Tr}\,\rho B=0\,, \tag{4.6}$$

which is achieved merely by substracting the invariant part from each of the quantities.

We can show easily that the relaxation function and the correlation function are mutually connected by the following theorem:

Theorem 3. *Let the Fourier transforms of* $\Phi_{BA}(t)$ *and* $\Psi_{BA}(t)$ *be*

$$f_{BA}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi_{BA}(t)\,e^{-i\omega t}\,dt\,,$$

$$g_{BA}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Psi_{BA}(t)\,e^{-i\omega t}\,dt\,, \tag{4.7}$$

then we have

$$g_{BA}(\omega)=E_\beta(\omega)f_{BA}(\omega) \tag{4.8}$$

where $E_\beta(\omega)$ *is the average energy of the oscillator with the frequency* ω *at temperature* $T=1/k\beta$,

$$E_\beta(\omega)=\frac{\hbar\omega}{2}\coth\frac{\beta\hbar\omega}{2}\,. \tag{4.9}$$

Eq. (4.8) *is equivalent to*

$$\Phi_{BA}(t)=\int_{-\infty}^{\infty}\Gamma(t-t')\Psi_{BA}(t')\,dt' \tag{4.10}$$

where $\Gamma(t)$ *is defined*

$$\Gamma(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{e^{i\omega t}}{E_\beta(\omega)}\,d\omega=\frac{2}{\hbar\pi}\log\coth\frac{\pi}{2\beta\hbar}|t|\,, \tag{4.11}$$

or to

$$\Psi_{BA}(t)=E_\beta\left(\frac{d}{idt}\right)\Phi_{BA}(t)\,. \tag{4.12}$$

The easiest way of the proof is to write first the functions $\Phi_{BA}(t)$ and $\Psi_{BA}(t)$ as double series over the quantum states of $\mathscr{H}$ and rearrange the double sum. An alternative method is to assume a function-theoretical conditions, i.e.,

$$\lim_{Ret\to\pm\infty}\mathrm{Tr}\,\rho AB(t)=0\,, \tag{4.13}$$

and that $\mathrm{Tr}\,\rho AB(t)$ is analytic in the domain

$$0\leqq\mathrm{Im}\,t\leqq\beta\hbar\,.$$

The condition (4.13) is fulfilled if one extends the meaning of the limit process as was discussed in § 2 and § 3. The second condition is equivalent to the existence $\mathrm{Tr}\,\rho AB$ and $\mathrm{Tr}\,\rho BA$.

Now Eq. (4.8) is derived as follows. By definition we can write

$$\begin{aligned}f_{BA}(\omega)&=\frac{1}{2\pi}\int_{-\infty}^{\infty}\int_0^\beta\mathrm{Tr}\,\rho AB(t+i\hbar\lambda)\exp(-i\omega t)d\lambda dt\\&=\frac{1}{2\pi}\int_{-\infty}^{\infty}\int_0^\beta\mathrm{Tr}\,\rho AB(t+i\hbar\lambda)\\&\qquad\times\exp\{-i\omega(t+i\hbar\lambda)-\lambda\hbar\omega\}\,d\lambda dt\\&=\frac{1}{2\pi}\int_0^\beta d\lambda\exp(-\lambda\hbar\omega)\\&\qquad\times\int_{-\infty+i\hbar\lambda}^{\infty+i\hbar\lambda}\mathrm{Tr}\,\rho AB(t)\exp(-i\omega t)\,dt\,.\end{aligned}$$

Thus interchanging the order of integration and shifting the path of integration, we obtain by the above-mentioned assumptions

$$f_{BA}(\omega)=\frac{1-\exp(-\beta\hbar\omega)}{\hbar\omega}\times\frac{1}{2\pi}\int_{-\infty}^{\infty}\mathrm{Tr}\,\rho AB(t)\exp(i\omega t)\,dt\,. \tag{4.14}$$

Similarly we can show that

$$\int_{-\infty}^{\infty}\mathrm{Tr}\,\rho AB(t)e^{-i\omega t}\,dt=\exp(\beta\hbar\omega)\int_{-\infty}^{\infty}\mathrm{Tr}\,\rho B(t)\,A\exp(-i\omega t)\,dt \tag{4.15}$$

by shifting the integration path to $-i\hbar\beta-\infty$ to $-i\hbar\beta+\infty$. In the above transformations, we took ρ as canonical given by Eq. (3.8).

Eqs. (4.15) gives

$$\int_{-\infty}^{\infty}\mathrm{Tr}\,\rho AB(t)e^{-i\omega t}\,dt=\frac{2}{1+\exp(-\beta\hbar\omega)}g_{BA}(\omega)\,,$$

so that Eq. (4.14) leads Eq. (4.8).

Eq. (4.10) is easily obtained from (4.8). The kernel $\Gamma(t)$, (4.11) is calculated using the partial fraction expansion of $\tanh z/z$. We note further that it has the property

$$\lim_{\hbar\to0}\Gamma(t)=\beta\delta(t)\,, \tag{4.16}$$

which in naturally to be expected.

§ 5. Simple Examples

It will be adequate to insert here simple examples to illustrate the general idea developed in the previous sections. The author has applied this in a previous paper[7] to the problem of magnetic resonance absorption. An uniform magnetic field $\boldsymbol{H}(t)$ is applied to a magnetic system, the total magnetic moment of which is denoted by $\boldsymbol{M}$. The perturbation energy due to $\boldsymbol{H}(t)$ is now

$$\mathscr{H}'(t)=-\boldsymbol{M}\boldsymbol{H}(t)\,. \tag{5.1}$$

The natural motion of the magnetic moment in the absence of the external field is represented by $\boldsymbol{M}(t)$. Then, the response function $\phi_{\mu\nu}(t)$ for the magnetization in μ-direction when the external field $\boldsymbol{H}(t)$ lies in ν-direction, is by Eq. (2.22).

$$\begin{aligned}\phi_{\mu\nu}(t)&=\frac{i}{\hbar}\langle[M_\mu(t),\,M_\nu]\rangle\\&=\int_0^\beta\langle\dot{M}_\nu(-i\hbar\lambda)M_\mu(t)\rangle\,d\lambda\,,\end{aligned} \tag{5.2}$$

and the relaxation function is, by Eq. (3.11),

$$\Phi_{\mu\nu}(t)=\int_0^\beta\langle(M_\nu(-i\hbar\lambda)-M_\nu{}^0)(M_\mu(t)-M_\mu{}^0)\rangle\,d\lambda \tag{5.3}$$

where $M_\nu{}^0$ and $M_\mu{}^0$ mean the diagonal parts of M_ν and M_μ with respect to the unperturbed Hamiltonian $\mathscr{H}$.

If we consider a system with unit volume, the admittance becomes the magnetic susceptibility. Thus the complex magnetic susceptibility tensor can be expressed either by $\phi_{\mu\nu}(t)$ or $\Phi_{\mu\nu}(t)$. The convenient expression is, by Eq. (3.5)

$$\chi_{\mu\nu}(\omega)=\Phi_{\mu\nu}(0)-i\omega\int_0^\infty\Phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\,. \tag{5.4}$$

The static susceptibility is, in particular,

$$\chi_{\mu\nu}(0)=\int_0^\beta \langle (M_\nu(-i\hbar\lambda)-M_\nu^0)(M_\mu-M_\mu^0)\rangle\, d\lambda \tag{5.5}$$

which is the susceptibility for the isolated system and is not necessarily equal to the isothermal susceptibility,

$$\chi_{\mu\nu}{}^T=\int_0^\beta \langle M_\nu(-i\hbar\lambda)M_\mu\rangle d\lambda-\beta\langle M_\nu\rangle\langle M_\mu\rangle. \tag{5.6}$$

In the expression for $\chi_{\mu\nu}(0)$, the diagonal parts of M_ν and M_μ are substracted. This corresponds to the fact the magnetization in an isolated system proceeds adiabatically, the occupation probabilities of the levels remaining unchanged. On the other hand they are changed in isothermal process for $\chi_{\mu\nu}{}^T$. The difference becomes smaller if the environment is taken into account in greater extent.

In the classical limit, Eq. (5.5) becomes

$$\chi_{\mu\nu}(0)=\frac{1}{kT}\langle (M_\nu-M_\nu^0)(M_\mu-M_\mu^0)\rangle\,. \tag{5.7}$$

while Eq. (5.6) becomes

$$\chi_{\mu\nu}{}^T=\frac{1}{kT}\langle\, (M_\nu-\langle M_\nu\rangle)(M_\mu-\langle M_\mu\rangle)\,\rangle\,. \tag{5.8}$$

The last expression is first noticed by Kirkwood[14] for the classical theory of dielectric polarization. Eq. (5.7) is its extension to adiabatic susceptibility, and Eq. (5.4) to general complex susceptibility for non-equilibrium states. It is evident that the similar formulae are obtained for dielectric polarizations.

As a second example we shall consider the electric conductivity. For an electric $\boldsymbol{E}(t)$, the perturbation energy is

$$\mathscr{H}'(t)=-\sum_i e_i \boldsymbol{r}_i \boldsymbol{E}(t) \tag{5.7}$$

where e_i is the charge of the i-th particle in the system and $\boldsymbol{r}_i$ its position vector. The response of current in μ-direction when a pulse of electric field is applied in ν-direction at $t=0$ is, by Eq. (2.22) or Eq. (3.9)

$$\begin{aligned}\phi_{\mu\nu}(t)&=\frac{1}{i\hbar}\mathrm{Tr}\,[\rho,\ \sum_i e_i x_{i\nu}]\sum e_i\,\dot{x}_{i\mu}(t)\\ &=\int_0^\beta \langle\, J_\nu(-i\hbar\lambda)\, J_\mu(t)\,\rangle\, d\lambda\end{aligned} \tag{5.10}$$

where

$$J_\mu=\sum e_i\,\dot{x}_{i\mu}$$

is the total current in the system.

If we take the volume of the system as unity, the conductivity tensor $\sigma_{\mu\nu}(\omega)$ for periodic field is given by

$$\sigma_{\mu\nu}(\omega)=\int_0^\infty e^{-i\omega t}\,dt\int_0^\beta d\lambda\,\langle\, J_\nu(-i\hbar\lambda)\, J_\mu(t)\,\rangle\,. \tag{5.11}$$

This is an exact expression for the conductivity. In particular, for the static conductivity we have

$$\sigma_{\mu\nu}=\int_0^\infty\int_0^\beta d\lambda\,\langle\, J_\nu(-i\hbar\lambda)\, J_\mu(t)\,\rangle\,. \tag{5.12}$$

This may be expressed in another form,

$$\sigma_{\mu\nu}=\lim_{s\to 0+}\frac{1}{s}\left\{\phi_{\mu\nu}(0)+\int_0^\infty \dot{\phi}_{\mu\nu}(t)\,e^{-st}\,dt\right\} \tag{5.13}$$

where

$$\dot{\phi}_{\mu\nu}(t)=-\frac{1}{i\hbar}\,\mathrm{Tr}\,\rho[J_\nu,\, J_\mu(t)]\,. \tag{5.14}$$

The above expressions of conductivity tensor are, as a matter of fact, what one would obtain by simple application of dispersion formula of Heisenberg and Kramers. But they are more convenient and much clearer for physical interpretation. Nakano[8] has shown that the Grüneisen formula is obtained from (5.11) as the first approximation. We emphasize again that the formulae given in the above are exact although they are admittedly rather abstract and have to be approximated in some way to deduce useful answers for assumed physical models. We can show that the usual method of employing Boltzmann-Bloch type transport equations makes a certain approximation to calculate these exact expressions. But the transport equation can not always be justified since the Markoffian assumption involved is only valid under rather strict conditions for the scattering processes.[1] The exact theory will certainly give a starting point of actual calculations when the traditional methods are not justified. A good example of this is provided by the problem of electronic conduction in strong magnetic field.[11] This will be treated in a forthcoming paper.

§ 6. Symmetry Relations

We note here some symmetry properties of the response and relaxation functions and those of the admittance. Let us consider for convenience the relaxtion function defined by Eq. (3.11), for which we have the theorem:

Theorem 4. *The relaxation function $\Phi_{BA}(t)$ has the following properties;*

1) *$\Phi_{BA}(t)$ is real* (6.1)

2) $\Phi_{BA}(-t)=\Phi_{AB}(t)$ (6.2)

3) *reciprocity law: if a static magnetic field* $\boldsymbol{H}$ *is present, the reversal of the direction of* $\boldsymbol{H}$ *results in*

$$\Phi_{BA}(t, \boldsymbol{H})=\varepsilon_A\varepsilon_B\Phi_{BA}(-t, -\boldsymbol{H}) =\varepsilon_A\varepsilon_B\Phi_{AB}(t, -\boldsymbol{H}) \quad (6.3)$$

where ε_A *or* ε_B *is* $+1$ *or* -1 *according to the quantity* A *or* B *is even or odd with respect to the reversal of time.*

The proof is simple. The complex conjugate of $\Phi_{BA}(t)$ is calculated as follows.

$$\begin{aligned}\overline{\Phi}_{BA}(t)&=\int_0^\beta \mathrm{Tr}\,\rho B(t)\,A(i\hbar\lambda)\,d\lambda\\ &=\int_0^\beta \mathrm{Tr}\,\rho B(t-i\hbar\lambda)\,A\,d\lambda\\ &=\int_0^\beta \mathrm{Tr}\,\rho B(t-i\hbar(\beta-\lambda))\,A\,d\lambda\\ &=\int_0^\beta \mathrm{Tr}\,\rho AB(t+i\hbar\lambda)d\lambda=\Phi_{BA}(t)\,.\end{aligned}$$

The transformation from the second to the third line is simply the change of integration variable from λ to $\beta-\lambda$.

Similarly, we may proceed as

$$\begin{aligned}\Phi_{BA}(-t)&=\int_0^\beta \mathrm{Tr}\,\rho AB(-t+i\hbar\lambda)\,d\lambda\\ &=\int_0^\beta \mathrm{Tr}\,\rho A(t-i\hbar\lambda)B\,d\lambda\\ &=\int_0^\beta \mathrm{Tr}\,\rho BA(t+i\hbar\lambda)\,d\lambda=\Phi_{BA}(t)\,.\end{aligned}$$

Eq. (6.3) follows from the fact that the simultaneous reversal of t and $\boldsymbol{H}$ changes the q-representation of the Hamiltonian and the wave function to their complex conjugates. A corollary of the theorem is the symmetry of other functions such as $\phi_{BA}(t)=-\dot{\Phi}_{BA}(t)$. This is clear and so is omitted here.

The second corollary is the symmetry of admittance. We write down here the symmetry of the quantity defined by

$$\sigma_{BA}(\omega)=\int_0^\infty \Phi_{BA}(t)\,e^{-i\omega t}\,dt \quad (6.4)$$

for which we have

$$\mathrm{Re}\,\sigma_{BA}(\omega)=\mathrm{Re}\,\sigma_{BA}(-\omega)\,, \quad (6.5)$$

$$\mathrm{Im}\,\sigma_{BA}(\omega)=-\mathrm{Im}\,\sigma_{BA}(-\omega)\,, \quad (6.6)$$

$$\sigma_{BA}(\omega, -\boldsymbol{H})=\varepsilon_A\varepsilon_B\sigma_{AB}(\omega, \boldsymbol{H})\,. \quad (6.7)$$

Eq. (6.7) is the well-known Onsager's relation.[15] The derivation here made is very simple.

As examples, we note the symmetry of magnetic susceptibility tensor and that of the conductivity tensor. The susceptibility tensor has the symmetry

$$\begin{aligned}\mathrm{Re}\,\chi_{\mu\nu}(\omega, \boldsymbol{H})&=\mathrm{Re}\,\chi_{\mu\nu}(-\omega, \boldsymbol{H})\\ &=\mathrm{Re}\,\chi_{\nu\mu}(\omega, -\boldsymbol{H})\,,\\ \mathrm{Im}\,\chi_{\mu\nu}(\omega, \boldsymbol{H})&=-\mathrm{Im}\,\chi_{\mu\nu}(-\omega, \boldsymbol{H})\\ &=\mathrm{Im}\chi_{\nu\mu}(\omega, -\boldsymbol{H})\,.\end{aligned} \quad (6.8)$$

For the conductivity tensor we have the same relations

$$\begin{aligned}\mathrm{Re}\,\sigma_{\mu\nu}(\omega, \boldsymbol{H})&=\mathrm{Re}\,\sigma_{\mu\nu}(-\omega, \boldsymbol{H})\\ &=\mathrm{Re}\,\sigma_{\nu\mu}(\omega, -\boldsymbol{H})\,,\\ \mathrm{Im}\,\sigma_{\mu\nu}(\omega, \boldsymbol{H})&=-\mathrm{Im}\,\sigma_{\mu\nu}(-\omega, \boldsymbol{H})\\ &=\mathrm{Im}\,\sigma_{\nu\mu}(\omega, -\boldsymbol{H})\,.\end{aligned} \quad (6.9)$$

Thus, for the change ω to $-\omega$, the real part is even while the imaginary part is odd. For the reversal of $\boldsymbol{H}$, the symmetric part is even and the antisymmetric part is odd.

§ 7. Fluctuation-Dissipation Theorems

We have shown in § 4 that the response and relaxation functions can be expressed by correlation functions. Thus the admittance can also be expressed in terms of correlation functions. This is rather trivial for classical cases, but in quantum mechanics it becomes rather complicated. The relation between the admittance and the Fourier components correlation functions is usually called the fluctuation-dissipation theorem. Thus our aim here is to give this theorem in its complete form.

We treat as a typical example the case of electric conduction. Let us rewrite Eq. (5.11) in terms of the Fourier component of response function $\phi_{\mu\nu}(t)$, i.e.,

$$f_{\mu\nu}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\,. \quad (7.1)$$

Eq. (5.11) is transformed as

$$\begin{aligned}\sigma_{\mu\nu}(\omega)&=\int_0^\infty \phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\\ &=\int_0^\infty dt\int_{-\infty}^{\infty}d\omega'\,f_{\mu\nu}(\omega')\,e^{i\omega' t-i\omega t}\\ &=\pi f_{\mu\nu}(\omega)+i\int_{-\infty}^{\infty}\frac{f_{\mu\nu}(\omega')}{\omega'-\omega}\,d\omega'\,.\end{aligned} \quad (7.2)$$

Thus we obtain at once

$$\mathrm{Re}\,\sigma^s{}_{\mu\nu}(\omega)=\pi f^s{}_{\mu\nu}(\omega)\equiv\frac{\pi}{2}\left\{f_{\mu\nu}(\omega)+f_{\nu\mu}(\omega)\right\}$$

$$\mathrm{Im}\,\sigma^{a}_{\mu\nu}(\omega)=\frac{\pi}{2}f^{a}_{\mu\nu}(\omega)\equiv\frac{\pi}{2i}\left\{f_{\mu\nu}(\omega)-f_{\nu\mu}(\omega)\right\} \tag{7.3}$$

$$\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)=\int_{-\infty}^{\infty}\frac{f^{s}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$

$$\mathrm{Re}\,\sigma^{a}_{\mu\nu}(\omega)=i\int_{-\infty}^{\infty}\frac{f^{a}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega' , \tag{7.4}$$

where the superscript s or a means the symmetric or the anti-symmetric part of the tensor. By the theorem 4 one has the symmetry

$$\overline{f_{\mu\nu}}(\omega)=f_{\nu\mu}(\omega) , \tag{7.5}$$

which shows $f^{s}_{\mu\nu}(\omega)$ is real while $f^{a}_{\mu\nu}(\omega)$ is purely imaginary. Eqs. (7.3) and (7.4) give the well-known Kramers-Kronig relation. Note that it holds for each of the symmetric and antisymmetric parts separately.

Now let us introduce the correlation function of current components,

$$\Psi_{\mu\nu}(t)=\mathrm{Tr}\,\rho\{j_{\nu}(0)\,j_{\mu}(t)\} , \tag{7.6}$$

which describes the correlation of spontaneous current fluctuating in equilibrium. We can show the following theorem:

Theorem 5. *The conductivity tensor $\sigma_{\mu\nu}(\omega)$ is connected with correlation function of current components, (7.6), by the following relations:*

$$E_{\beta}(\omega)\,\mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)=\pi g^{s}_{\mu\nu}(\omega)=\int_{0}^{\infty}\Psi^{s}_{\mu\nu}(t)\cos\omega t\,dt \tag{7.7a}$$

$$E_{\beta}(\omega)\,\mathrm{Im}\,\sigma^{a}_{\mu\nu}(\omega)=\frac{\pi}{i}g^{a}_{\mu\nu}(\omega)=-\int_{0}^{\infty}\Psi^{a}_{\mu\nu}(t)\sin\omega t\,dt \tag{7.7b}$$

$$\Psi^{s}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}E_{\beta}(\omega)\,\mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)\cos\omega t\,d\omega \tag{7.8a}$$

$$\Psi^{a}_{\mu\nu}(t)=-\frac{2}{\pi}\int_{0}^{\infty}E_{\beta}(\omega)\,\mathrm{Im}\,\sigma^{a}_{\mu\nu}(\omega)\sin\omega t\,d\omega , \tag{7.8b}$$

and

$$\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)=\int_{-\infty}^{\infty}\frac{1}{E_{\beta}(\omega')}\cdot\frac{g^{s}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$
$$=-2\int_{0}^{\infty}\Gamma(\tau)\cos\omega\tau d\tau\int_{\tau}^{\infty}\Psi^{s}_{\mu\nu}(t)\sin\omega t\,dt$$
$$-2\int_{0}^{\infty}\Gamma(\tau)\sin\omega\tau d\tau\int_{0}^{\tau}\Psi^{s}_{\mu\nu}(t)\cos\omega t\,dt \tag{7.9a}$$

$$\mathrm{Re}\,\sigma^{a}_{\mu\nu}(\omega)=-\frac{1}{i}\int_{-\infty}^{\infty}\frac{1}{E_{\beta}(\omega')}\frac{g^{a}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$
$$=2\int_{0}^{\infty}\Gamma(\tau)\cos\omega\tau d\tau\int_{\tau}^{\infty}\Psi^{a}_{\mu\nu}(t)\cos\omega t\,dt$$
$$-2\int_{0}^{\infty}\Gamma(\tau)\sin\omega\tau d\tau\int_{0}^{\tau}\Psi^{a}_{\mu\nu}(t)\sin\omega t\,dt \tag{7.9b}$$

$$\Psi^{s}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)\,\mathrm{Re}\,\Delta(\omega,t)\,d\omega \tag{7.10a}$$

$$\Psi^{a}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}\mathrm{Re}\,\sigma^{a}_{\mu\nu}(\omega)\,\mathrm{Im}\,\Delta(\omega,t)\,d\omega , \tag{7.10b}$$

where the kernel $\Delta(\omega, t)$ is defined by

$$\Delta(\omega,t)=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{du}{u-\omega}E_{\beta}(u)e^{iut} . \tag{7.11}$$

These expressions reduce, in classical limit, to

$$\mathrm{Re}\,\sigma_{\mu\nu}(\omega)=\int_{0}^{\infty}\Psi_{\mu\nu}(t)\cos\omega t\,dt$$
$$\mathrm{Im}\,\sigma_{\mu\nu}(\omega)=-\int_{0}^{\infty}\Psi_{\mu\nu}(t)\sin\omega t\,dt \tag{7.12}$$

First we note that the symmetry of $\Psi_{\mu\nu}(t)$ is the same as that we have for $\phi_{\mu\nu}(t)$ (Theorem 4). Eqs. (7.7) and the first parts of (7.9a) and (7.9b) are obvious from Eq. (4.8). Eq. (7.8a, b) is simply the inverse of Eq. (7.7a, b). We need some calculation to derive (7.9) and (7.10) but the details are omitted here. Only we note for the convenience of reference that the function (7.11) can be transformed to

$$\mathrm{Re}\,\Delta(\omega,t)=-E_{\beta}(\omega)\sin\omega t\cdot\mathrm{sign}\,t+\frac{1}{\pi\beta}\sum_{n=1}^{\infty}\frac{(n\pi)^{2}\exp(-2n\pi|t|/\beta\hbar)}{(n\pi)^{2}+(\beta\hbar\omega)^{2}/4} \tag{7.13a}$$

$$\mathrm{Im}\,\Delta(\omega,t)=E_{\beta}(\omega)\cos\omega t\cdot\mathrm{sign}\,t-\frac{1}{\pi\beta}\sum_{n=1}^{\infty}\frac{(n\pi/2)\beta\hbar\omega\exp(-2n\pi|t|/\beta\hbar)}{(n\pi)^{2}+(\beta\hbar\omega)^{2}/4}\mathrm{sign}\,t . \tag{7.13b}$$

An useful corollary of the theorem is the expression of static conductivity $\sigma_{\mu\nu}(0)$. We have the formulae;

$$\sigma^{s}_{\mu\nu}(0)=\beta\int_{0}^{\infty}\Psi^{s}_{\mu\nu}(t)\,dt\equiv\frac{\beta}{2}\int_{-\infty}^{\infty}\Psi^{s}_{\mu\nu}(t)\,dt \tag{7.14}$$

$$\sigma^{a}_{\mu\nu}(0)=2\int\Gamma(\tau)\,d\tau\int_{\tau}^{\infty}\Psi^{a}_{\mu\nu}(t)\,dt$$
$$=2\int_{0}^{\infty}\Psi^{a}_{\mu\nu}(t)\int_{0}^{t}\Gamma(\tau)\,d\tau . \tag{7.15}$$

Thus the symmetric part of the static conductivity is calculated either as the integration of the response function or as that of the correlation function. The situation is more complicated for the antisymmetric part. If one wishes to use the correlation function instead of the response function, one has to be careful about a quantum effect which appears as $\Gamma(\tau)$ in Eq. (7.15).

Another remark is that, even at finite frequencies, the symmetric part is easily obtained if the correlation function is known. This is, of particular interest, for instance, in the case of magnetic problem[7]. For a linearly polarized radiation, the absorption is determined by the imaginary part of susceptibility tensor, for which we have from Eq. (5.4)

$$\chi''_{xx}(\omega)=-\mathrm{Im}\,\chi_{xx}=\frac{\omega}{2E_\beta(\omega)}\int_{-\infty}^{\infty}\langle\{M_x(0)M_x(t)\}\rangle\cos\omega t\,dt\ . \tag{7.16}$$

The corresponding expression for conduction is (7.7a) itself, i.e.,

$$\sigma_{xx}(\omega)=\frac{1}{2E_\beta(\omega)}\int_{-\infty}^{\infty}\langle\{J_x(0)J_x(t)\}\rangle\cos\omega t\,dt \tag{7.17}$$

The last equation is the well-known Niquist's theorem[16]. If the fluctuating current is expanded into the Fourier components, Eq. (7.17) reduces to

$$\sigma_{xx}(\omega)=\frac{\pi}{E_\beta(\omega)}\langle|J_x(\omega)|^2\rangle\ . \tag{7.18}$$

§ 8. Sum Rules

It is interesting that the exact expressions of admittance derived in the above give proof of certain general laws. The simplest example of this is the well-known sum-rule of oscillator strength. This is generalized in the following way.

We consider the expression (6.4), from which we obtain

$$\frac{1}{\pi}\int_{-\infty}^{\infty}\sigma_{BA}(\omega)d\omega=2\int_0^{\infty}\Phi_{BA}(t)\delta(t)dt=\Phi_{BA}(0). \tag{8.1}$$

and

$$\lim_{\omega\to\infty}i\omega\,\sigma_{BA}(\omega)=\Phi_{BA}(0) \tag{8.2}$$

by Abel's theorem if the left hand side does exist.

Let us now apply this for electric conduction. By Eq. (5.10) one can write

$$\phi_{\mu\nu}(t)=\frac{1}{i\hbar}\mathrm{Tr}\,\rho\left[\sum e_i x_{i\nu},\ \sum e_j\dot{x}_{j\mu}(t)\right] \tag{8.3}$$

If the Hamiltonian $\mathscr{H}$ has the general form

$$\mathscr{H}=\sum_i\left[p_{i\nu}-\frac{e_i}{c}A_\nu(\boldsymbol{r}_i)\right]^2\Big/2m_i+V(\boldsymbol{r}_1,\cdots\boldsymbol{r}_N),$$

$\boldsymbol{A}$ being the vector potential we have the commutation rule

$$[x_{i\nu},\ \dot{x}_{j\mu}]=\frac{i\hbar}{m_i}\delta_{ij}\,\delta_{\mu\nu} \tag{8.4}$$

which gives

$$\phi_{\mu\nu}(0)=\sum_{i=1}^{N}\frac{e_i^2}{m_i}\delta_{\mu\nu}=\sum_r\frac{n_r e_r^2}{m_r} \tag{8.5}$$

where r means the species of charge carriers, n_r being the number of carriers of r-th kind.

Eq. (8.3) is derived from Eq. (5.10) by changing the order in the trace operation. One might doubt whether this is justfied or not, pointing out that the operators $x_{i\nu}$ may be singular if one uses the Born-Karman boundary conditions. As a matter of fact this will not affect the validity of the proof, because the commutators are actually regular operators. It might be worth while to see what one has in classical case. Classically we may proceed as (see Eq. (2.22a))

$$\begin{aligned}\phi_{\mu\nu}(t)&=\int d\Gamma(f,\ \sum e_i x_{i\nu})\sum e_j\dot{x}_{j\mu}(t)\\&=-\int d\Gamma\sum_i e_i\frac{\partial f}{\partial p_{i\nu}}\cdot\sum e_j\dot{x}_{j\mu}(t)\\&=\int d\Gamma\, f\sum_i\sum_j e_i e_j\frac{\partial}{\partial p_{i\nu}}\dot{x}_{j\mu}(t)\ .\end{aligned} \tag{8.6}$$

Thus we have

$$\begin{aligned}\phi_{\mu\nu}(0)&=\int d\Gamma f\sum_i\sum_j e_i e_j\frac{\partial}{\partial p_{i\nu}}\cdot\frac{1}{m_j}\left\{p_{j\mu}-\frac{e_j}{c}A_\mu(\boldsymbol{r}_j)\right\}\\&=\int d\Gamma f\sum_i e^2{}_i/m_i\,\delta_{\mu\nu}\end{aligned} \tag{8.7}$$

This is exactly the same as Eq. (8.5). This does not prove directly the validity of (8.3), but will be enough to make it convincing. As as proof one may introduce a suitable potential to avoid the difficulty of singular operators $x_{i\nu}$, and make it vanish if one wants.

Thus we have proved the sum rule

$$\frac{2}{\pi}\int_0^{\infty}\mathrm{Re}\,\sigma^s{}_{\mu\nu}(\omega)d\omega=\sum_r\frac{e^2{}_r n_r}{m_r}\delta_{\mu\nu} \tag{8.8}$$

and

$$\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\sigma^{s}_{\mu\nu}=-\sum_{r}\frac{e^2_r n_r}{m_r}\delta_{\mu\nu} \tag{8.9}$$

which hold for any system irrespective of the interaction of particles, the temperature, the statistics and even in the presence of magnetic field. This is the most general form of the sum rule.

For a system of electrons, Eqs. (8.8) and (8.9) are written as

$$\frac{2}{\pi}\int_0^\infty \mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)\,d\omega=\frac{ne^2}{m}\delta_{\mu\nu} \tag{8.10}$$

$$\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)\to-\frac{e^2n}{m\omega}\delta_{\mu\nu}\quad(\omega\to\infty)\,. \tag{8.11}$$

Here we should remember that m is the true mass of electrons. The integration of $\sigma(\omega)$ has to be carried over all range of frequencies.

If one considers electrons in a crystal and confines himself to the electrons in a particular band neglecting interband transitions, the sum rule has to be modified to

$$\begin{aligned}\frac{2}{\pi}\int_0^\infty &\mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)\,d\omega\\ &=-\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)\\ &=e^2\,\mathrm{Tr}\,\{\rho\cdot\partial^2E(p)/\partial p_\nu\partial p_\mu\}\,.\end{aligned} \tag{8.12}$$

This holds if the electron system is described by the Hamiltonian

$$\mathscr{H}=\sum_i E(p_i)+V(r_1,\cdots r_N) \tag{8.13}$$

where $E(p)$ is the energy of an electron with the crystal moments p. Also one has to omit the interband elements of the potential V. The theorem (8.12) is wider than that usually given in text books only for the oscillator strength connecting one-electron states.

Another interesting result is obtained from the second expression of (3.5) when applied to conduction problem. This give

$$\begin{aligned}&\frac{1}{\pi}\int_{-\infty}^{\infty}\{i\sigma_{\mu\nu}(\omega)\,\omega-\phi_{\mu\nu}(0)\}d\omega\\ &=-\lim_{\omega\to\infty}\omega^2\left\{\sigma_{\mu\nu}(\omega)-\frac{\phi_{\mu\nu}(0)}{i\omega}\right\}=\dot{\phi}_{\mu\nu}(0)\end{aligned} \tag{8.14}$$

The tensor

$$\dot{\phi}_{\mu\nu}(0)=-\frac{i}{\hbar}\,\mathrm{Tr}\,\rho\,[J_\mu,J_\nu] \tag{8.15}$$

is antisymmetric. Therefore Eq. (8.14) is rewritten as

$$\begin{aligned}&-\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Im}\,\sigma^{a}_{xy}(\omega)\,\omega d\omega\\ &=\lim_{\omega\to\infty}\omega^2\sigma^{a}_{xy}(\omega)=-\sum_r\frac{n_re_r^3H_z}{m_r^2c}\,.\end{aligned} \tag{8.16}$$

Both sides of this equation are identically zero unless the system is in a magnetic field (or rotating, in which case e_rH_z/m_rc must be replaced by the angular frequency of the rotation). This is seen from the fact that the velocity of charged particles in magnetic field is

$$\boldsymbol{v}=\frac{1}{m}\left(\boldsymbol{p}-\frac{e}{c}\boldsymbol{A}\right)$$

and the commutation rule is now

$$[v_x,v_y]=-\frac{eH_z}{m^2c}\frac{\hbar}{i}\,. \tag{8.17}$$

This gives

$$\frac{i}{\hbar}\,\mathrm{Tr}\,\rho\,[J_x,J_y]=\sum n_re_r^3\,H_z/m_r^2c\,, \tag{8.18}$$

which is the last expression in Eq. (8.16).

In particular, for electrons we have

$$\begin{aligned}\frac{2}{\pi}\int_0^\infty\mathrm{Im}\,\sigma^{a}_{\mu\nu}(\omega)\omega d\omega&=-\lim_{\omega\to\infty}\omega^2\sigma^{a}_{\mu\nu}(\omega)\\ &=\frac{ne^3}{m^2c}H_z\,.\end{aligned} \tag{8.19}$$

This is another type of sum-rule which holds quite generally, but is not usually remarked. Eq. (8.19) may also be written as

$$\sum_l\mathrm{Im}\langle k|J_x|l\rangle\langle l|J_y|k\rangle=-\frac{ne^3}{2m^2c}H_z \tag{8.20}$$

for a system of n electrons.

Similar arguments can also be made for tensors of other kinds. For instance, the magnetic susceptibility tensor satisfies the rules,

$$-\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Im}\,\chi^{s}_{\mu\nu}(\omega)\,\frac{d\omega}{\omega}=\chi^{s}_{\mu\nu}(0)\,, \tag{8.21}$$

$$\lim_{\omega\to\infty}\mathrm{Re}\,\chi^{s}_{\mu\nu}(\omega)=0\,, \tag{8.22}$$

$$\begin{aligned}&\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Re}\,\chi^{a}_{\mu\nu}(\omega)\,d\omega\\ &=-\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\chi^{a}_{\mu\nu}(\omega)=\frac{i}{\hbar}\,\mathrm{Tr}\,\rho[M_\mu,M_\nu]\,.\end{aligned} \tag{8.23}$$

The relation (8.21) is well-known. This states that the properly weighted integration of absorption intensity for linearly polarized radiation is equal to the static susceptibility. The third relation, (8.23), requires more at-

tention.

If M_μ is written as

$$M_\mu=\sum_i \gamma_i I_{i\mu} ,$$

where I_i is the angular momentum associated with the magnetic moment, we have

$$\frac{i}{\hbar}[M_x, M_y]=-\sum \gamma_i^2 I_{iz} .$$

Therefore Eq. (8.23) can be written as

$$\frac{1}{2}\int_0^\infty \mathrm{Re}\,\chi^a{}_{xy}(\omega)\,d\omega = -\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\chi^a{}_{xy}(\omega)=-\sum\gamma_i^2\overline{I}_{iz}=-\sum\gamma_r\overline{M}_{rz} \tag{8.24}$$

where $\overline{M}_{rz}$ means the magnetization due to r-th component in the system.

For circularly polarized radiation, the rate of energy absorption per unit volume is

$$Q=\frac{\omega}{2}H_1^2\{\chi'_{xy}-\chi'_{yx}+\chi''_{xx}+\chi''_{yy}\}$$

H_1 being the amplitude of the magnetic field of radiation. Thus, $\mathrm{Re}\,\chi^a{}_{xy}(\omega)$ is related to the absorption intensity of circular waves. The total integration of the absorption intensity is directly connected with the gyromagnetic ratio γ. This may not be of much value if γ can be measured accurately by sharp resonance. But one has to remember that (8.24) is generally valid even in the presence of strong interaction between magnetic moments. Thus the effects related to the absorption of circular wave may be used for the determination of γ, for instance, for electronic magnetic moments in ferromagnets or paramagnets. This sort of experiments may be considered to corresponds in a sense to those of gyromagnetic effects.

§ 9. Einstein Relations

We note here that the expression of conductivity given by Eq. (5.12) or (7.14) is the most general form of Einstein relation, which connects the conductivity or the mobility with the diffusion constant.

To see this, let us take the simplest example of charged particles which are moving independently. By Eq. (7.14), the conductivity is

$$\sigma^s{}_{\mu\nu}=\frac{ne^2}{kT}\int_0^\infty \langle v_\nu(0)\,v_\mu(t)\rangle\,dt , \tag{9.1}$$

if we regard the system to be classical. If we admit

$$\lim_{t\to\infty}\langle v_\nu(0)v_\mu(t)\rangle=\langle v_\nu\rangle\langle v_\mu\rangle=0$$

we can transform the right hand side of Eq. (9.1) as

$$\begin{aligned}&\int_0^\infty\langle v_\nu(0)v_\mu(t)\rangle\,dt\\ &=\lim_{T\to\infty}\frac{1}{2T}\int_0^T\int_0^T\langle v_\nu(t')v_\mu(t)\rangle\,dt\,dt'\\ &=\lim_{T\to\infty}\frac{1}{2T}\langle(x_\nu(T)-x_\nu(0))(x_\mu(T)-x_\mu(0))\rangle\\ &=D_{\mu\nu} .\end{aligned} \tag{9.2}$$

where $D_{\mu\nu}$ is the diffusion constant defined by the third expression of Eq. (9.2). Eqs. (9.2) and (9.1) give at once

$$\sigma^s{}_{\mu\nu}=e^2nD_{\mu\nu}/kT \tag{9.3}$$

which is the well known Einstein relation.

For a system of interacting particles, the exact form of Einstein relation is

$$\sigma^s{}_{\mu\nu}=e^2\overline{\Delta n^2}D_{\mu\nu}/kT \tag{9.4a}$$

$$=e^2D_{\mu\nu}\Big/\left(\frac{\partial\mu}{\partial n}\right)_T \tag{9.4b}$$

where $D_{\mu\nu}$ is the diffusion constant in isothermal conditions, $\overline{\Delta n^2}$ the average fluctuation of particle density, and μ the chemical potential of the particle. This relation gives, for the diffusion constant,

$$\begin{aligned}D^s{}_{\mu\nu}&=\left(\frac{\partial\mu}{\partial n}\right)_T\int_0^\infty dt\int_0^\beta \mathrm{Tr}\,\rho I_\nu(-i\hbar)I_\mu(t)d\lambda\\ &=\left(\frac{\partial\mu}{\partial n}\right)_T\frac{1}{2}\int_{-\infty}^\infty dt\,\mathrm{Tr}\,\rho\{I_\nu I_\mu(t)\}\end{aligned} \tag{9.5}$$

where

$$I_\nu=\sum_i v_{i\nu}$$

is the total particle flow per unit volume. Eq. (9.5) can be used for the calculation of diffusion constant in gases and also condensed phases. This will be discussed further in a forthcoming paper.

It might be worth while to note that Eq. (9.4) indicates at once how the factor $1/kT$ appearing in the expression of electric conductivity, Eq. (7.14) cancels out for degenerate Fermi particles. In this case, $\overline{\Delta n^2}$ is proportional to T, or in other words $(\partial\mu/\partial n)_T$ is a constant of the order of μ_0/n, μ_0 being the Fermi-level at the absolute zero.

ABSTRACT This paper discusses the results of homology modeling and resulting calculation of key structural and physical properties for close to 300 tubulin sequences, including α, β, γ, δ and ε -tubulins. The basis for our calculations was the structure of the tubulin dimer published several years ago by Nogales *et al.* (1998), later refined to 3.5 Å resolution by Löwe *et al.* (2001). While, it appears that the α, β and γ-tubulins segregate into distinct structural families, we have found several differences in the physical properties within each group. Each of the α, β and γ- tubulin groups exhibit major differences in their net electric charge, dipole moments and dipole vector orientations. These properties could influence functional characteristics such as microtubule stability and assembly kinetics, due to their effects on the strength of protein-protein interactions. In addition to the general structural trends between tubulin isoforms, we have observed that the carboxy-termini of α and β-tubulin exists in at least two stable configurations, either projecting away from the tubulin (or microtubule) surface, or collapsed onto the surface. In the latter case, the carboxy-termini form a lattice distinctly different from that of the well-known A and B lattices formed by the tubulin subunits. However, this C-terminal lattice is indistinguishable from the lattice formed when the microtubule-associated protein tau binds to the microtubule surface. Finally, we have discussed how tubulin sequence diversity arose in evolution giving rise to its particular phylogeny and how it may be used in cell- and tissue-specific expression including embryonal development.

KEY WORDS: *tubulin, microtubule, isoform, homology model, dipole*

Introduction

Microtubules (MTs) are cylindrical protein filaments found in all eukaryotes and are critically involved in a variety of cellular processes including cellular motility, cytoplasmic transport and mitosis (Hyams, 1994). Their component protein, tubulin forms a heterodimer that is composed of two homologous polypeptides, designated α and β tubulin (Postingl, 1981; Krauhs, 1981). Each individual tubulin heterodimer is 8 nm in length and interacts laterally and longitudinally to form protofilaments and then MTs (Downing and Nogales, 1998). In addition to microtubules, whose protofilament numbers vary betweens 8 and 17, under special experimental conditions tubulin can also give rise to polymorphic assemblies that include sheets, macrotubes, ribbons and several additional, exotic structures (Unger, 1990).

Microtubules undergo cycles of rapid growth and disassembly in a process known as dynamic instability which has been extensively studied both *in vivo* and *in vitro* (Mitchison and Kirschner, 1984). This instability appears to be critical for proper MT function, especially during mitosis (Kirschner and Schulze, 1986). The assembled tubulin dimer hydrolyzes a bound guanosine triphosphate (GTP) at its exchangeable nucleotide binding site to GDP; the kinetics of this process in β tubulin is critical in regulating dynamic instability by affecting the loss of the "lateral cap" (the top tubulin layer in the growing MT that stabilizes the entire structure).

In addition to forming MTs, tubulin interacts with a large number of ancillary proteins. Some of these, such as tektin, may play structural roles, while others like *tau* or MAP2 are known as microtubule-associated proteins (MAPs) are involved in MT assembly, stability and may also mediate interactions with other

proteins. Yet another subset of proteins, such as kinesin and dynein, are motor proteins that move cargoes, such as cellular vesicles, along MTs as part of active intracellular transport (Kikkawa, 2001; Wang and Sheetz, 2000).

An interesting feature of tubulin is its presence as multiple isoforms in eukaryotic organisms and its numerous post-translational modifications, such as phosphorylation, acetylation, detyrosination and polyglutamylation (Banerjee, 2002; Luduena, 1998). In addition to the ubiquitous α and β-tubulin, MTs often require the presence of an additional tubulin protein,'γ-tubulin, for correct assembly as a templating protein (Erickson, 2000; Luduena, 1998). Two additional tubulins, designated δ and ε, have also been characterized and although their role in MT assembly remains uncertain (Vaughan, 2000), models of their function in MT assembly have been proposed (Inclan and Nogales, 2001).

At the molecular level, the role of tubulin is extremely complex and seems to be related to the structural variations observed between α and β isoforms (Richards, 2000). The existence and distribution of numerous homologous forms of α and β-tubulin provides a link to the structure of tubulin and the polymerization and stability properties of MTs. It has been demonstrated that

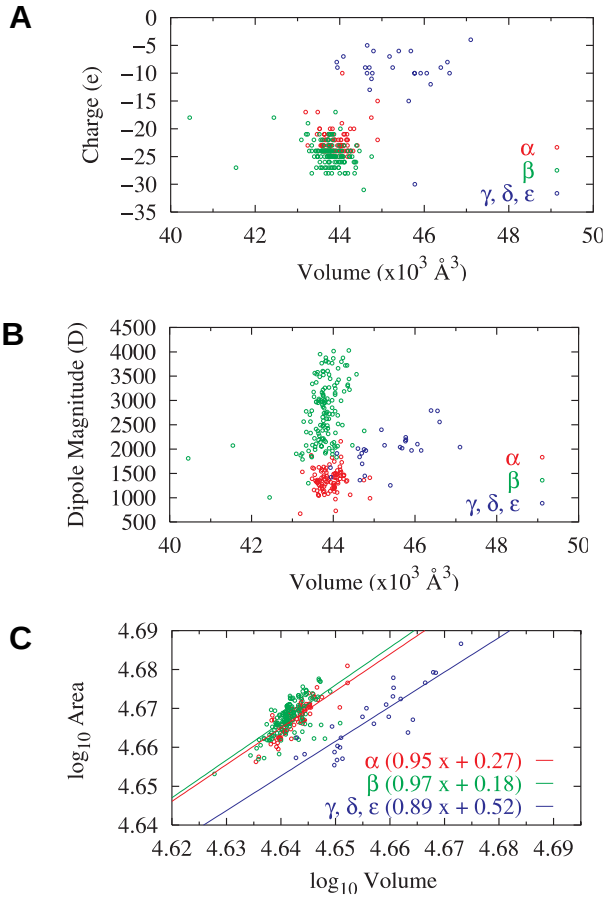

Fig. 1. Illustration of the distribution of physical properties of the monomer models. *Each ring corresponds to one model and is color-coded to show three groups within the library. apparently small overall differences in the structures and therefore binding energies and chemical affinities between different tubulins may translate into significant deviations in the growth and catastrophe rates for MTs. The three-dimensional structure of bovine brain tubulin has been determined crystallographically, resulting in several atomic structures that are available in the Protein Data Bank, entries 1TUB (Nogales, 1998) and 1JFF (Lowe, 2001) being typical examples. Using these structures, it is possible to computationally predict the structures of related tubulin sequences with some degree of accuracy. We have created homology models of nearly 300 different tubulins, representing α and β-tubulins, as well as γ, δ and ε-tubulins from animals, plants, fungi and protists. For most of the resulting tubulin structures, we have been able to estimate the magnitudes and orientations of their dipole moments, charge distributions, surface areas and volumes. The magnitudes and orientations of the dipople moment of the tubulin dimer may play a role in MT assembly and stability due to their contribution to the total energy via dipole-dipole interactions. In addition, we have been able to generate plausible conformations for the carboxy-terminal region of each tubulin monomer. The C-termini of α- and β-tubulin were not resolved in the original crystallographic structures of tubulin due to their flexibility and possibly sample inhomogeneity (Nogales, 1998). The importance of the carboxy-termini is highlighted by the fact that they are the site of most of tubulin's post-translational modifications, that they bind to MAPs and that most of the differences among tubulin isoforms cluster here. We have observed that the carboxy-termini can either project out to a considerable distance from the MT or collapse onto the surface. Our results raise the possibility that the conformational transitions in the C-termini of tubulin may play a significant role in kinesin and dynein movement and that they may have a novel role in ion transport along MTs, especially in the axoplasm of neurons.

Tubulin's diversity

Gene orthologs are homologous proteins with amino acid sequences that have diverged due to mutations accumulated since their separation by speciation events (Fitch, 2000). The variations that occur can be neutral: implying that they are irrelevant to the process of natural selection, crucial: meaning that they adapt the function of a protein to a given selective pressure, or can be somewhere in between. In general, a weak but statistically significant correlation is found between this sequence variability and a protein's solvent accessible surface area (Rodionov and Blundell, 1998). Interestingly, an apparent conservation of the three-dimensional pattern of conserved amino acids has been observed in several families of structurally homologous proteins that points to the existence of a folding nucleus (Mirny and Shakhnovich, 1999). Previous reports agree that buried residues within a protein tend to evolve more slowly, but most of these analyses have been restricted to globular enzymes. Interestingly, the mapping of evolutionary rates onto the sequence of the α/β tubulin dimer demonstrate the opposite pattern (Roger, 1996). The relative rates of evolution at sites within the core of the tubulin proteins are faster than the rates of sites at the surface. The large number of intermolecular interactions between tubulins and other proteins apparently restrains the sites at the protein surface, relative to the constraints imposed by side-chain packing

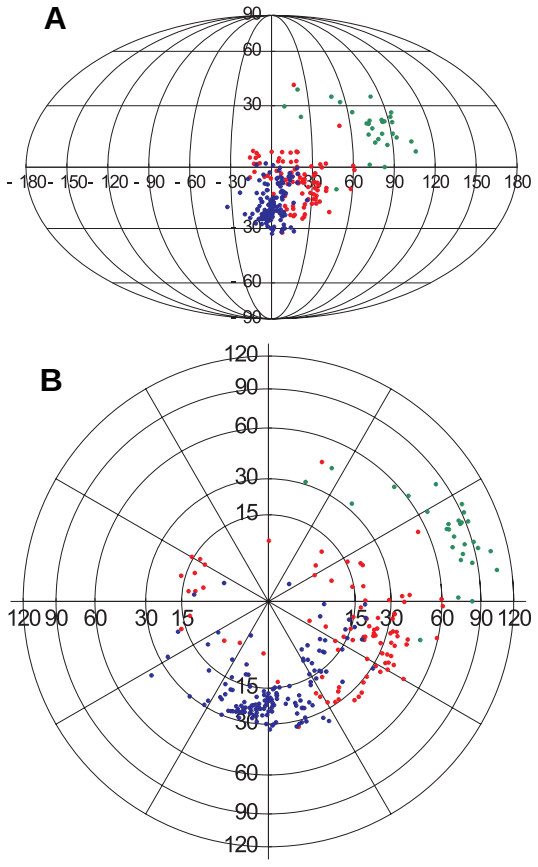

Fig. 2. Distribution of center-of-mass dipole moment orientations within the monomer library. Color-coding is as in Fig. 1. *The center of each plot corresponds to a dipole moment normal to a cylindrical microtubule.* **(A)** *An equal area (Mollweide) projection with the vertical axis representing angle with the protofilament axis and the horizontal axis angle with the protofilament-radial plane.* **(B)** *A polar projection plot, using a nonlinear radial scale for the angle for the normal position; the vertical axis corresponding to the microtubule axis.*

within the core of the proteins. This is consistent with the common assumption that co-evolution of many interacting proteins leads to a high degree of sequence constraint within the proteins where these interactions occur.

Raff *et al.* (1997) emphasized overwhelming evidence in favor of the idea that FtsZ is a homolog of tubulin, the ubiquitous eukaryotic cytoskeletal protein involved in many essential cellular processes including mitosis. Despite only limited primary sequence homology centered on a GTP-binding motif termed the 'tubulin signature sequence', the recently solved crystal structures of FtsZ and tubulin show extensive structural similarity throughout the proteins. In addition, FtsZ, like tubulin, binds and hydrolyzes GTP and assembles into protofilaments that have structures similar to those within MT's. This assembly is GTP-dependent and disassembly occurs when the GTP supply is exhausted, suggesting that FtsZ polymers, like MTs, are dynamically unstable. Tubulin and FtsZ share a common fold of two domains connected by a central helix (Nogales, 1998). Structure-based sequence alignment shows that common residues localize in the nucleotide-binding site and regions that interact with the nucleotide of the next subunit in the protofilament, suggesting that tubulin and FtsZ use similar contacts to form filaments. Surfaces that would make lateral interactions between protofilaments or interact with motor proteins are, however, different.

Most eukaryotic organisms express multiple tubulin genes, with each distinct tubulin isoform having an essential function. It has been shown, that in the testis of *Drosophila* and the touch neurons of *Caenorhabditis elegans*, not every tubulin molecule is interchangeable. For example, the *mec7* and *mec12* tubulins are required for assembly of specialized MTs that contain 15 protofilament. It has been demonstrated that γ tubulin is required for the initiation of MT assembly. Additionally, four new members of the tubulin family have recently been identified (Dutcher, 2001). The first, δ-tubulin was identified as a flagellar assembly mutant in the green algae *Chlamydomonas reinhardti* and has also been found in *Chlamydomonas Euplotes*, human, rat, *Xenopus*, mouse, dog and Trypanosomids. Second, η-tubulin was discovered due to a mutation in *Paramecium* that results in a basal body duplication defect. The ε and ζ-tubulins, were discovered using bioinformatics techniques, however their cellular functions have yet to be determined. ε-tubulin is present in *Chlamydomonas*, human, mouse, rat, *Xenopus* and Trypanosomids. ζ-tubulin has been found in *Trypanosoma* and *Leishmania* and as an expressed sequence tag in *Xenopus laevis*. Interesingly, the δ, ε, ζ and η-tubulins do not appear to have a ubiquitous distribution throughout all eukaryotic organisms, as is the case for the α and β tubulins. The genomes of *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Aradbidopsis thaliana* and *C. elegans* do not have clear homologs to the δ, ε, ζ and η-tubulins. The absence of these tubulins from fungi and plants can be correlated with the lack of centrioles and basal bodies. The high degree of divergence among the new tubulins in both the same and different families suggests that their functions are not as constrained by their primary sequences as those of the α, β and γ-tubulins. The elucidation of the biological function of these new members of the tubulin superfamily will hopefully resolve their roles within the cell.

Early sequence comparisons for tubulin gave valuable insights into the function of α and β-tubulin (Little, 1981; Little and Seehaus, 1988; Burns, 1991; Burns and Surridge, 1994). Alignments between the orthologs and paralogs of α and β-tubulin are unambiguous due to the highly conserved amino acid sequences between these two proteins. Recently, Kuchnir-Fygenson *et al.* (2004) analyzed the homology within the tubulin family using multiple sequence alignment techniques. They compared members of the tubulin super-family from human, *Drosophila*, *Chlamydomonas*, *Trypanosoma* and *Paramecium*. Within this subset, it was shown that all the α-tubulins are 89–95% similar to one another while the β-tubulins were only 88–94% similar. It was also demonstrated that the γ-tubulins have similarities ranging from 72% to 94%, while the three δ-tubulins were only 47–57% similar. The two complete sequences for the ε-tubulin are only 58% similar. A portion of the ε-tubulin gene from *Chlamydomonas* is 79% similar to the human gene over the 87 amino acids within the region that is most conserved between humans and *Trypanosoma*. The predicted *Xenopus* sequences for ζ and η-tubulin, 89 and 97 amino acids long, are 60% and 61% similar to the *Trypanosoma* and *Paramecium* sequences, respectively. Among the 21 full-length tubulin sequences, only 7 amino acids are

conserved and include the the GDP/GTP-binding site, an aspartate within helix 7 and a proline near the M-loop that interacts with the H3 helix within a tubulin from the adjacent protofilament within the MT.

By examining sequence alignments between α- and β-tubulin, Kuchnir-Fygenson *et al.* (2004) identified residues that differ significantly in variability. Most of these residues were shown to be clustered around the nucleotide-binding pocket, where the greatest functional differences between the two types of tubulin exist. The remaining residues associated with large differences in variability are found in the N-terminal loop between helix (H) 1 and beta sheet (S) 2. The statistical distribution of residue variability in both α and β-tubulins is strongly peaked at low values, with >50% of residues scoring in the bottom 10% of the variability range. In the structure-based alignment, the correlation coefficient for variability between the tubulins is R(α/β)= 0.42. This alignment involves two gaps in β-tubulin: a small one in the disordered N-terminal loop (β, 39–40) and a larger one in the loop between S9 and S10 (β, 362–365). Three distinct regions are misaligned to accommodate multiple residues with large differences in variability between the paralogs. These misaligned regions include a total of approximately 100 residues located in helices H1 and H4, sheets S4, S5 and S9, two turns (T4 and T5) and the disordered N-terminal loop (L1). Among these, there are 40 positions that appear to be of particular functional importance where homologous residues differ in variability by more than a standard deviation from the mean. Half of these are clustered around the nucleotide-binding pocket, four are clustered around the taxol binding site on β-tubulin and one participates in lateral binding between MT protofilaments. Of the 20 residues near the nucleotide-binding pocket, 16 are more variable in the «N-site», which binds GTP without catalyzing its hydrolysis and less variable in the «E-site», which hydrolyzes GTP as dimers assemble into protofilaments. Of the four residues that are less variable in the N-site, the tyrosine residue at position 172 in α-tubulin is particularly interesting as a target for directed mutagenesis because it interacts directly with the nucleotide. Because analogous differences in variability were so plausibly connected with functional differences in the other misaligned regions, Kuchnir-Fygenson (2004) predicted that these residues in the N-terminal loop have a role in making the biochemical functions of α and β-tubulin distinct. It is suspected that the functional distinction is related to GTP hydrolysis and that the tenuously structured glycines within β-tubulin are involved in a hydrolysis-driven conformational change that eventually results in a catastrophe event.

We conclude this introductory survey on tubulin diversity stating that while it is tantalizing to speculate about a direct relationship between tubulin structure and function, the precise molecular basis of the properties of tubulin is still not well understood. This is in part because tubulin's highly flexible C-terminal conformation (Keskin, 2002) makes it difficult to crystallize this region.

Tubulin phylogeny

Phylogenetics is the science of estimating and analyzing evolutionary relationships. Phylogenetic relationships among micro-organisms are especially difficult to discern. DNA, RNA and proteins can be considered to be 'information molecules' since they retain a record of an organism's evolutionary history. A logical approach then is to compare nucleic acid or protein sequences from different organisms and estimate the evolutionary relationships based on the degree of homology between the sequences. The nucleotide or amino acid differences within a gene can therefore reflect the evolutionary distance between two organisms. Closely related organisms will exhibit fewer sequence differences than distantly related organisms. Through the molecular approach in determining phylogenetic relationships, the differences are readily quantifiable as sequences from different organisms can be compared and the number of differences computed. These data are often expressed in the form of phylogenetic trees, where the positions and lengths of the "branches" depict the relatedness of sequences between organisms. Interestingly, phylogenetic trees that are produced from different gene sequences may produce different topologies. Possible reasons for these inconsistencies are: (a) disparities in evolutionary rates among lineages, (b) uneven taxonomic sampling, (c) single explosive radiation of major eukaryotic taxa, (d) horizontal DNA transfer between species and (e) gene paralogies (i.e., duplications) and gene conversion. The first two phenomena result in a long-branch attraction artifact in which many slowly evolving sequences cluster to the exclusion of a few rapidly evolving sequences. The long branches that are far apart in the lower portion of the eukaryotic branch may be a result of the experimental procedure. In addition, events like horizontal DNA transfer and gene duplications complicate the analysis of molecular phylogenetic data. Some of these problems are resolved by combining data into consensus trees, for example, by combining protein data from actin, α-tubulin and β-tubulin (Roger, 1996).

Wilson and Borisy (1997) stated that although highly conserved, the variable regions within α and β-tubulins show divergence from other α and β-tubulins within the same species, but can show conservation between different species. Such conservation raises the question of whether the diversity in tubulin sequence can mediate the diversity in MT organization. Recent studies probing the function of β-tubulin isoforms in axonemes of insects suggest that tubulin structure, through interactions with extrinsic proteins, can direct the architecture and supra-molecular organization of MTs. The tubulin gene family includes, at least, three highly conserved subfamilies, α and β and γ-tubulin, that

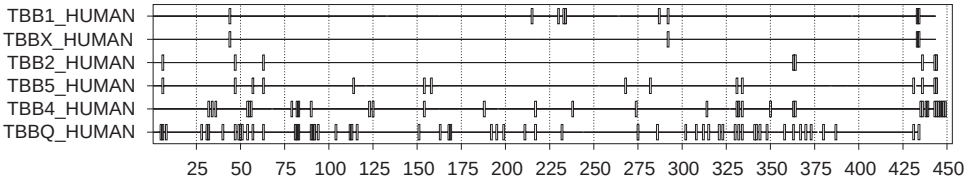

Fig. 3. Comparison amongst human -tubulin sequences. *Each of the horizontal lines represents one sequence and has boxes at horizontal locations corresponding to residues at which the sequence differs from a consensus sequence. Note the presence of a hypervariable region, beginning after residue 425.*

arose from a series of gene duplications early in eukaryotic evolution (Edlind *et al.*, 1996; Keeling and Doolittle, 1996). Currently, α and β-tubulin genes have the widest taxonomic representation and have been identified in early diverging eukaryotic lineages (Burns, 1996; Edlind, 1996; Keeling and Doolittle, 1996). Cleveland *et al.* (1980) concluded that the human genome contains approximately 14 copies of the α and β-tubulin genes.

Adoutte *et al.* (1984) produced a survey of the electrophoretic behavior of the tubulins of 23 species (mostly protists) as well as their reactivity towards 4 anti-tubulin antibodies. This allowed a rough evaluation of evolutionary relatedness between the various groups of protists analyzed. The results indicated a striking agreement between a number of published phylogenies. Gaertig *et al.* (1993) cloned and sequenced the two β-tubulin genes of the ciliated protozoan *Tetrahymena thermophila*. These two genes encode identical 443 amino acid peptides which are 99.7% identical to the β-tubulin proteins of *T. pyriformis* and 95% identical to the human β1-tubulin. *T. thermophila* contains only one α-tubulin gene, implying that all of the diverse MT structures in this unicellular organism must be formed from a single α and a single β-tubulin heterodimer. Additionally, Gaertig *et al.* (1993) also carried out a phylogenetic analysis of 84 complete β-tubulin peptide sequences. This analysis supports the following two hypotheses regarding β-tubulin evolution and function: (a) that multifunctional β-tubulins are under greater evolutionary constraint than β-tubulins present in specialized cells or in cells with very few MT-related functions, which can evolve rapidly; and (b) that cells which form axonemes maintain a homogeneous population of tubulins. Luduena (1998) reviewed the distribution and possible functional significance of the various forms of tubulin. In analyzing the differences among the tubulin isoforms that are encoded by different genes, it was shown that some appear to have no functional significance, while some increase the overall adaptability of the organism to environmental challenges and yet others appear to perform specific functions including formation of particular organelles and interactions with specific proteins (Keeling, 1998).

Dipole orientation of dimers in a microtubule. *The arrows indicate the orientation of the permanent dipole moment with respect to the centers-of-mass of individual tubulin-tubulin dimers with respect to the surface of a microtubule. Note that dipole moments point into the dimers. Figure prepared using MolMol (Koradi, 1996).*

Keeling and Doolittle (1996) sequenced genes from a number of protozoa and constructed phylogenetic trees of α and β-tubulins. These trees were consistent with each other, but inconsistent with other molecular phylogenies. The agreement between α and β-tubulin trees could arise only by the co-adaptation of one molecule to variants of the other as a result of their intimate steric association in MTs. Therefore, these trees may not provide independent support for the phylogenetic results. Relationships between the protist tubulins were also examined by constructing trees of all three types. These trees were found to be of limited value for determining the position of the root within each subfamily because of the great interfamily distances, but they confirmed the classification of all known genes into three monophyletic subfamilies. Divergent genes from *C. elegans* and *S. cerevisiae* representing the novel classes of δ and ε-tubulin were found to be specifically related to γ-tubulins from animals and fungi respectively and therefore are seen as rapidly evolving orthologs of γ-tubulin.

Edgcomb *et al.* (2001) elucidated the relationships among jakobid flagellates and other early-diverging eukaryotic lineages by characterizing α and β-tubulin genes from four jakobids. Tubulin gene phylogenies were in general agreement with mitochondrial gene phylogenies and ultrastructural data. The final representation of major eukaryotic groups was pared down to the alignments of 42 α and 39 β-tubulin sequences that were amenable to more rigorous phylogenetic analyses. A variety of traditional eukaryotic groups that are well established on the basis of morphology or molecular phylogeny were also recovered in either α or β-tubulin trees. In addition, several «higher- order» eukaryotic groupings were observed, such as fungi plus microsporidia, animals plus fungi and ciliates plus apicomplexa (alveolates). Unlike rRNA trees, tubulin phylogenies do not show many inde-

pendent deep-branching lineages leading to a «crown» radiation of eukaryotes but, instead, a deep split occurs within eukaryotes separating two robust groupings, a plant-protist «superclade» and an animals-plus-fungi group, with several protist lineages intervening. It is likely that the extreme conservation of both tubulin genes leaves few phylogenetically informative sites, especially for groups in the plant-protist superclade (Keeling, 1999; 2000).

Homology modeling

The presence of multiple forms of tubulin provides us with the opportunity to create a model library from which we can estimate physical characteristics for a large number of tubulin sequences. Once three-dimensional protein structures are determined, it becomes possible to use techniques, such as homology modeling to predict structures of proteins with similar sequences (Chothia and Lesk, 1986). Homology modeling utilizes several structural motifs from template proteins and pieces them together to form the final model. A scoring function then assesses both the sequence identity between the target sequence and template and the overall quality of the template that is being considered. The scores are ranked and the fold with the best score is assumed to be the one adopted by the target sequence. A computer program uses alignment of the sequences with known related structures to obtain spatial restraints that the output structure must satisfy. Additional restraints derived from statistical studies of representative protein and chemical structures are also used to ensure a physically plausible result. Missing regions are predicted by simulated annealing of a molecular mechanics model. Since the 3D structures of tubulin obtained from crystallography lack the extreme carboxy-termini, we used this capability to create structure within this region of the protein. Our experience with molecular mechanics models of these regions suggests that the residues are too mobile for such structures to be anything more than one of many possible conformations. It is our approxiation that any models with gross errors will be insignificant when comparisons are made amongst several models.

We have performed homology modeling on a set tubulin sequences, containing α and β-tubulins from animals, plants, fungi and protists in the Uniprot Knowledgebase. As an initial step, the Swiss-Prot database Release 40.3 of 08-Nov-2002 (Boeckmann, 2003) (available at http://www.expasy.org/sprot/) was searched for tubulin amino acid sequences. A search using the keyword «tubulin» was manually filtered to separate actual tubulin sequences from those of other tubulin-related proteins. This provided some 290 sequences, representing a wide range of species. Of these, 27 sequences are annotated as being fragmentary leaving 263 complete tubulin monomer sequences. Of particular interest were the 15 human sequences obtained in this process. We believe that this core library is large enough to adequately sample the diversity of tubulin variation, therefore no attempt to systematically add to this set from other data sources has been made, although select sequences of interest from other sources have also been studied.

Appendix A summarizes all the tubulin sequences used in this study. The table names the source organism and for each α, β, γ, δ and ε, gives the name used in the database. It is important to relate the biochemical data encapsulated by the amino acid sequence to the biologically relevant information presented in this table. Fragmentary sequences were processed like all the others, however the results from such sequences must be reviewed before accepting data from them and were filtered out when appropriate in the data sets presented here. In some circumstances it may be appropriate to replace missing regions with a standard sequence to estimate results for these fragments.

Currently, a total of three structures, providing a total of four templates are available in the Brookhaven Protein Databank upon which we can construct homology models of tubulin. The first and most obvious choice, was the initial Nogales structure of the α/β tubulin heterodimer (PDB identifier 1TUB) (Nogales, 1998). However, this structure was solved at a relatively low resolution and contains numerous omissions and misalignments due to difficulties in density fitting. A refinement of the 1TUB structure, PDB identifier 1JFF, was subsequently deposited with a slightly better resolution at 3.5 Å (Lowe, 2001). Along with increased resolution, the 1JFF structure also addressed a number of misalignment errors within the 1TUB structure and therefore makes a better choice for a homology modeling template. However, the 1JFF structure contains a large, nine-residue gap within the α tubulin M loop (serine 277 to leucine 286). Fortunately, this gap was not present in the 1TUB structure, providing us with a template structure for this region. Shortly after we began modeling the tubulin isoforms, a new structure of tubulin complexed with stathmin was released (PDB identifier 1SA0) (Ravelli, 2004). This structure was solved at 3.58 Å and contained most of the a

loop that was not present in the 1JFF structure. The presence of the complete missing a loop in 1TUB and partial loop in 1SAO provided us with adequate templates for modeling this section of the α-tubulins. A fourth template structure from which to build the tubulin homology models was available to us. This structure was that of the *E. coli* cell division protein 1FSZ (Lowe and Amos, 1998). Unfortunately, these five template structures are not entirely unique, the 1TUB and 1JFF being largely the same models.

When generating models of the α tubulin monomers, only the FtsZ and the two α-structures were input to Modeller as templates (Sanchez and Sali, 2000). Similarly, when modeling β-monomers only the FtsZ and the two β structures were used. In other cases all five structures were input. Models were also constructed without including the FtsZ structure, a putative prokaryotic homologue of tubulin (Erickson, 1997; 1998). These were judged to be insignificantly different. After constructing several test models we determined that the presence of extended loops within 1FSZ, that were absent from all of the tubulin sequences tended to alter the alignment scores and produce alignment anomalies between the tubulin alignments. It was therefore decided to eliminate the FtSZ structure from our templates and because of the high sequence homology between the β and α-tubulins we chose to use only 1JFF as our template.

Results

With the resulting library of structural tubulin models, various computational estimates of physical properties of the different tubulins may be made. These include the volume, surface area, net charge and dipole moments. All volumes and surface areas reported herein are calculated using a Connolly solvent accessible surface. Similarly, all dipole moments reported are with respect to the protein center-of-mass or alternatively a geometric mean of the model co-ordinates which is expected to be a good approximation of the former. We performed these calculations on the model structures, typically using analysis tools within the Gromacs (Lindahl, 2001) molecular dynamics package (version 3.1.4). Because only a single δ and a single ε sequence are present and these somewhat resemble γ, it is convenient to consider three groups: α, β and γ\δ\ε. We show some scatter plots of these three groups below in Figs. 1 and 2.

We also analyzed the properties of the C-terminal projection. We first needed to define this region. We used Clustal W (version 1.82) (Thompson, 1994) in order to obtain a multiple sequence alignment amongst the peptides. Such an alignment is illustrated in Fig. 3 which highlights variations in amino acid sequences. The multiple alignment then allows rapid identification of corresponding residues in all of sequences. Because this alignment is done amongst different sequences and with different parameters than the alignments performed with Modeller it may be that slight differences in the alignments have occurred. Studying these may be instructive in understanding some of the uncertainties associated with the Modeller outputs. However, we have ignored this possibility and defined residue 436 to be the first in the tail. This corresponds well to the beginning of the hypervariable region and the last contact of the backbone with the globular structure in 1TUB and 1JFF. From this definition, we can then readily read and analyze the C-terminal projection sequences for each tubulin species.

The library of tubulin structures including α, β and γ from animals, plants, fungi and protists, as well as δ and ε from humans, were analyzed by molecular mechanics to determine their net charges, dipole moment components, dipole orientations, volumes, surface areas and the lengths and charges of their C-termini. The results of our computations in this regard are shown in Appendix B.

Fig. 1A shows a scatter diagram of the net charge/volume ratios of the different tubulins. This plot is striking in that the net charge on the β-tubulins is by far the greatest ranging between 17 and 32 elementary charges (e) depending on the particular β tubulin with an average value in this case at approximately 25 e. Next come the α tubulins with net charges varying between 10 and 25 elementary charges. Finally, the γ, δ and ε tubulins have a much lower value of the net charge; in some cases being very close to zero. There appears to be little if any correlation between the size of a protein and its charge, although the γ-tubulins are noticeably larger in volume. Further, it should be kept in mind, that the charge on a tubulin dimer will be neutralized in solution due to the presence of counter-ions which almost completely screen the net charge. This was experimentally determined for tubulin by the application of an external electric field; the resulting value of an unscreened charge of approximately 0.2 e per monomer was found (Stracke, 2002). What is, however, of great interest in connection with polymerization of tubulin into MT's and with protein-protein and drug-protein binding is the actual distribution of charges on the surface of tubulin. Fig. 4 illustrates this for the Downing-Nogales structure with plus signs indicating the regions of positive charge and minus signs negatively charged locations. This figure shows C-termini in two very upright positions. Each of the different tubulins will show differences in this regard but lack of space prevents us from showing in detail where the differences occur for specific monomers.

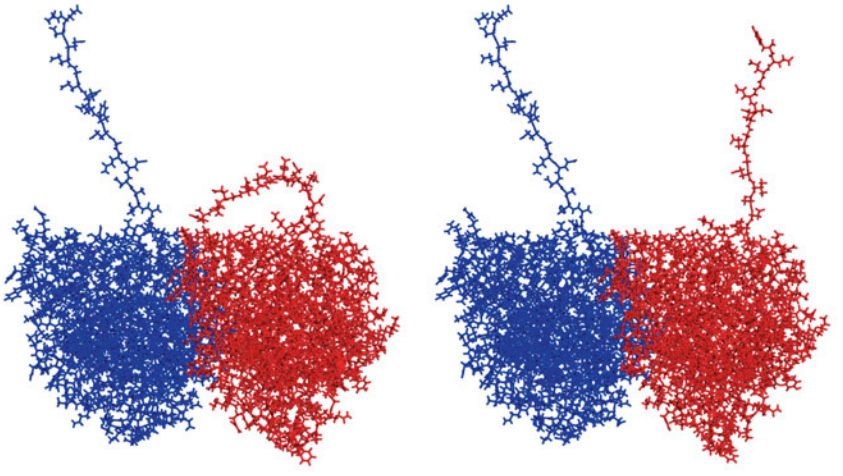

Fig. 7. Examples of C-termini in up and down positions. *Although only the C-terminus on an α - monomer is shown in a lowered state, both C-termini can be in either state.*

Fig. 1C shows the logarithm of surface area against the logarithm of volume for the different tubulins. Note the high level of correlation between the tubulin family and the surface-volume functional dependence. It is worth noting that the γ, δ and ε-tubulins are significantly more compact than the α tubulins, which are slightly more compact than the β-tubulins. We also show a best-fit line to these scatter plots for each of the three families. Note that the α and β families have a very similar slope with a value close to the unity that is indicative of cylindrical symmetry in the overall geometry. The γ, δ and ε-tubulins are characterized by a lower value of the slope indicating a greater amount of spherical symmetry for which surface-to-volume dependence scales with a power of 2/3.

As seen in Fig. 1B, α-tubulins have relatively low dipole moments about their centers-of-mass ranging between 1,000 and

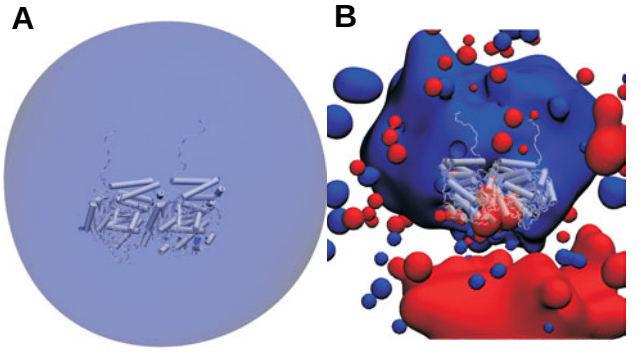

Fig. 8. A tubulin dimer in vacuum (A) *is seen principally as a monomer from the point of view of electrostatic interactions;* **(B)** *it is mainly dipolar when surrounded by counter ions and water. Figure prepared with VMD (Humphrey, 1996).*

2,000 debye, while the β-tubulins are very high in this regard with the corresponding values ranging between 1,000 and 4,000 debye and with the average value close to 3,000 debye. The γ-, δ- and ε-tubulins have dipole moments whose values are in between those two ranges. There is clearly some correlation between the magnitude of the dipole moment and volume for β- and γ-tubulins while the α tubulins are so compact that no correlation is readily apparent. In Fig. 2 we have illustrated the important aspect of dipole organization for tubulin, namely its orientation. Fig. 2A shows a Mollweide projection of dipole orientation in tubulin. The center of the diagram corresponds to the orientation perpendicular to the cylinder surface in a MT. The northerly direction represents the direction along the protofilament towards the plus-end while the southerly direction points towards the minus-end. Points along the horizontal axis are oriented tangentially to the MT surface. We conclude from this diagram and its magnification around the center region in Fig. 2 that both α- and β-tubulins orient their dipole moments in a direction that is close to being perpendicular to the MT surface. Notably, the same cannot be said about the dipole orientation for γ- tubulin, whose dipole orientation is largely tangential to the cylindrical surface of the MT formed out of its subunits.

The C-terminal tails (residues beyond the H-12 helix) display a largely random configuration, in stark contrast to the rest of the monomer. This is due to the inherent flexibility of this region of the sequence and the *in vacuo* simulation techniques employed by Modeler. While the variety of configurations was not unexpected they were included for completeness and do not detract from the rest of the model. Furthermore, they reflect the conformational flexibility of these regions. When tubulin is modeled as a dimer or monomer in solution, implicit or explicit, that simulates physiological conditions we see a variety of conformations for the C-terminal tails. While conformations that point away from the MT dominate (as would be entropically expected) the tails will also occasionally make contact with what would be the surface of the MT. Generally speaking, the C-terminal tails sweep out a large volume of space over several nanoseconds. Our models show that only α- and β-tubulins have C-terminal tails that project outwards from the tubulin, due to their high negative charges. Fig. 6 shows the energy levels of different orientations of the C-termini in a toy model with rigid tails and simplified electrostatics and suggests that there is relatively little energetic difference between the tails projecting straight outward from the rest of the tubulin and lying on the surface of tubulin in certain energy minima. While other surface states are quite strongly disfavored, the surface minima occur in positions where their negative charges form electrostatic bonds with certain positively charged residues on the tubulin surface. This variation is illustrated by Fig. 7. In a more realistic model this would need to be extended to consider different C-terminal structures and surface charges. This aspect is still underway and it will be extended to investigate the effects of post-translational modifications such as phosphorylation and polyglutamation on the equilibrium C-terminal states.

Discussion

The structures of α and β-tubulins are known to be quite similar, being nearly indistinguishable at approximately 6 Å (Li, 2002) despite only a 40% amino acid homology. Since the sequences within the α or β-tubulin family are more similar to each other than to those sequences belonging to the other families of tubulins, it is reasonable to believe that any given sequence should produce a structure very similar to another member of a given family. Further support for this comes from the published structures of Nogales (1998) and Lowe (2001) which are of a porcine sequence, but which were fit to structural data from an inhomogeneous bovine sample. Accordingly, by substituting appropriate amino acid side chains and properly adjusting other residues to accommodate insertions and deletions in the sequence, crystallographic structures can be used as a framework to produce model structures with different sequences with a high degree of confidence. Indeed, we have demonstrated that homology modeling produced a set of models that are essentially indistinguishable from one another. Therefore, homology modeling may not be an appropriate test, as it attempts to move the resulting models towards the templates. The universal convergence that we see here only proves that the structure can accommodate all of the tubulin sequences that we have investigated. While homology modeling or threading may be the best way to generate a large number of models, additional methods are required to test the stability of the resulting conformations obtained from the homology modeling. Having said that, it is still of interest to compare the results of our calculations and find possible consequences of the differences in the physical characteristics between various tubulin isoforms.

The dipole moment of tubulin could play a role in MT assembly and in other processes such as interactions with neighboring proteins and ions, espcially when the dipole moments can be ordered leading to collective effects (Brown and Tuszynski, 1999) or even dynamical propagating states (Trpisova and Tuszynski, 1997). This could be instrumental in the docking process of molecules to tubulin and in the proper steric configuration of a tubulin dimer as it approaches a MT for binding. An isolated (in vacuum) tubulin dimer has an electric field dominated by its net charge as seen in the nearly spherical isopotential surface in Fig. 8A. In contrast, a dimer, shown in Fig.8B, surrounded by water molecules and counter-ions, as is physiologically relevant, has an isopotential surface with two lobes much like the dumbbell shape of a mathematical dipole. In a MT, the individual dimers have near parallel dipole moments relative to their nearest neighbors; this is illustrated in Fig. 5. The greater the individual dipole of each of its units, the less stable the MT will generally be since these near parallel dipole-dipole interactions are repulsive, tending to push apart the MT. Note that the strength of the interaction potential is proportional to the square of the dipole moment; hence MT structures formed from tubulin units with larger dipole moments should be more prone to undergo disassembly catastrophes (Trpisova and Tuszynski, 1997) compared to those MTs that contain low dipole moment tubulins. For organisms that express more than one type of tubulin isoform in the same cell, one can conceive that MT dynamic behavior could be regulated by altering the relative amounts of the different isoforms according to their dipole moments. However, these effects are moderated by local interactions between two dimers, which produces a more complicated electrostatic field than the assembly of dipoles described here would suggest; for details see (Baker, 2001).

In terms of surface/volume ratios, α and β-tubulins are the least compact, while γ, δ and ε are the most compact. There is abundant evidence that both α and β have variable conformations. This is attested to by their interaction with drugs and is consistent with the dynamic instability of MTs. In contrast, there is no evidence of γ, δ and ε participating in dynamic instability nor is there any theoretical reason to imagine such flexibility. It is reasonable to postulate that a less compact structure may have a more flexible conformation.

Isoform composition has a demonstrable effect on MT assembly kinetics (Panda, 1994; Banerjee and Kasmala, 1998). This could be due to changes in the electrostatics of tubulin, in particular, its net charge. This property although significantly screened by counter-ions does affect MT assembly by influencing dimer-dimer interactions over relatively short distances (approximately 5 nm) as well as the kinetics of assembly. These short-range interactions have been recently studied by (Sept, 2003) by calculating the energy of protofilament-protofilament interactions. These authors concluded from their work that the two types of MT lattices (A and B lattices differ in the relative positions of the protofilaments relative to each other) correspond to the local energy minima. However, the matters can be significantly more complicated since not only does tubulin exist as multiple isoforms, but the protein can also undergo various post-translational modifications, such as phosphorylation, acetylation, detyrosination and polyglutamylation (Banerjee, 2002; Luduena, 1998).

Our models predict that the C-terminal tails of α and β can readily adopt the two extreme conformations: either projecting outwards from the tubulin (and the MT surface) or lying on the surface, albeit such that their charged residues can form electrostatic bonds with complimentary charges on the surface. The state of the C-terminus (upright, down, or in intermediate states; see Fig. 7) is easily influenced by local ion concentrations including pH. This conformational complexity has many implications. First, a projecting C-terminus could play a major role in signaling. The fact that tubulin isoforms differ markedly in their C-termini (Sackett, 1995) suggests that specific sequences may mediate the functional roles of the isoforms. These sequences would be readily available for interactions with other proteins in a projecting C-terminus (Sarkar, 2001). Second, the C-termini are the sites of many of the post-translational modifications of tubulin, i.e. polyglutamylation, polyglycylation, detyrosination/tyrosination, removal of the penultimate glutamatic acid and phosphorylation of serine and tyrosine (Redeker, 1998). It is known that the C-termini are essential to normal MT function (Duan, 2002); a projecting C-terminus would be easily accessible to enzymes that effect these modifications and the modification could influence the likelihood of the C-terminus changing conformation. In addition, if the modification plays a role in signaling, then the signal would be readily available in a projecting C-terminus, as mentioned above. Third, projecting C-termini would automatically create spacing between MT's. It is known that MT's are never closely packed and are surrounded by what is sometimes referred to as an «exclusion zone» (Dustin, 1984). This is a region of space around them that is strongly unfavorable to the presence of other MT's in the vicinity. Although MAP's likely play a role in establishing such spacing, electrostatic repulsion among C-terminal ends might also influence this as well. The C-termini are the major sites of binding of the MAP's to tubulin. A projecting C-terminus may

Fig. 10. facilitate MAP binding and, conversely, MAP binding could influence the conformation of the C-terminus. Evidence for this is provided by the work of Makrides *et al*. (2003) who showed that when the MAP tau binds to MT's, it triggers a structural change on the MT surface whereby a structural element, presumably tau, lies on the surface of the MT forming a lattice whose alignment angle is much more acute than that of the lattice of tubulin subunits. This lattice is apparently superimposed on top of the normal MT (A or B) lattice. The orientations of the C-termini when they are lying on the surface of the MT form nearly the same kind of pattern that Makrides *et al*. (2003) observed, a striking confirmation of the potential accuracy of our modeling. The observed angles are listed in the caption of Fig. 9. These results raise the possibility that the orientation of the C-termini of the α and β-subunits determines the arrangement of tau molecules on the MT.

In addition, the state of the C-termini could mediate how motor proteins such as kinesin or dynein bind to and move on MT's. Our models show that kinesin binds preferentially to upright C-termini and not to C-termini lying on the surface of the MT (see Fig. 10). Very minor changes in the local ionic environment or the pH could halt the processive motion of a two-headed kinesin (Wriggers and Schulten, 1998) by collapsing the C-termini. One can postulate that the proportion of C-termini that are in the upright conformation in a given portion of the MT could determine the actual rate of kinesin movement. It is likely that such arguments could apply to other motor proteins as well. One might imagine that the very fine coordination of movements that occurs in processes such as mitosis could be influenced or even caused by the conformational state of the C-termini in particular areas of the MT. Finally, one can speculate that the C-termini could collapse in waves that could simultaneously couple to a wave of ions that could polarize or depolarize a membrane. This could be a form of MT signaling that has not yet been considered in the literature. A quantitative model of ionic wave transmission coupled to coordinated motion of the C-termini of dendritic MT's has been recently developed by Priel *et al*. (2005).

The role and function of MTs in embryos has been discussed in depth by Gordon (1999). Based on important studies of the multi-gene families of tubulin (Lewis and Cowan, 1990), it can be concluded that all tubulins in the same organism appear able to participate in all major functions. Nonetheless, some tubulins are produced primarily in certain tissues at specific stages of development. Interestingly, tissue-specific tubulins are often expressed at lower evolutionary levels in some other tissues. To complicate matters more, nearly identical tubulins may have entirely different patterns of expression. However, some tubulins differ in their ability to participate in dynamic equilibrium phenomena, their role in MT nucleation as well as sperm formation. Particularly intriguing is the fact that tubulins can even differ from one part of the cell in an embryo to another and during mitosis. This is suggestive of a specialized role of tubulin isoform in cell splitter effects. In particular, the role of tubulin isoforms was outlined by Gordon (1999) concluding with the following observations:

1. Different tubulin isoforms are involved in cortical rotation.
2. Tubulins in nematodes may vary between cell types.
3. The origin of tubulin isoforms coincides with the origin of new cell types and specifically with their cell state splitters (Kube-Granderath and Schliwa, 1998).
4. Some tubulin isoforms nevertheless occur in multiple tissues (Lu, 1998).
5. There is a highly probable and very intriguing role of tubulin isoforms in brain complexity and its origin.
6. Tubulin isoforms could be used to distinguish otherwise histologically equivalent cell types.

Two hypotheses regarding multiple tubulin gene sequences have been advanced, both of which may have some factual basis. First, individual tubulin genes may encode functionally divergent polypeptides conferring unique properties to the final MT that is polymerized by the cell. Alternatively, multiple polypeptides may themselves be functionally equivalent but represent the products of duplicated genes that have evolved to possess different regulatory sequences for activation of transcription during alternative

programs of differentiation.

While this paper attempted to shed light on the gross biophysical features distinguishing between different tubulins, we have been able to relate such differences only to the presence of the major sub-families. Very subtle differences in the amino-acid composition within each sub-family while still elude our ability to relate structure and function precisely, may contain significant changes in tubulin's functional domains. Our quest to uncover these relationships is still ongoing.

Appendix A

Tubulin sequences

Achlya klebsiana	β TBB_ACHKL
Acremonium coenophialum	β TBB_ACRCO
Ajellomyces capsulata (Histoplasma capsulatum)	α TBA_AJECA; β TBB_AJECA
Anemia phyllitidis (Fern)	α TBA1_ANEPH, TBA2_ANEPH; β TBB1_ANEPH, TBB2_ANEPH, TBB3_ANEPH; γ TBG_ANEPH
Arabidopsis thaliana (Mouse-ear cress)	α TBA1_ARATH, TBA2_ARATH, TBA3_ARATH, TBA6_ARATH; β TBB1_ARATH, TBB2_ARATH, TBB4_ARATH, TBB5_ARATH, TBB6_ARATH, TBB7_ARATH, TBB8_ARATH, TBB9_ARATH; γ TBG2_ARATH
Aspergillus flavus	β TBB_ASPFL
Aspergillus parasiticus	β TBB_ASPPA
Avena sativa (Oat)	α TBA_AVESA; β TBB1_AVESA
Babesia bovis	β TBB_BABBO
Blepharisma japonicum	α TBA_BLEJA
Bombyx mori (Silk moth)	α TBA_BOMMO; β TBB_BOMMO
Botrytis cinerea (Botryotinia fuckeliana)	β TBB_BOTCI
Brugia pahangi	β TBB1_BRUPA
Caenorhabditis briggsae	β TBB7_CAEBR
Caenorhabditis elegans	α TBA2_CAEEL, TBA8_CAEEL; β TBB2_CAEEL, TBB4_CAEEL, TBB7_CAEEL; γ TBG_CAEEL
Candida albicans (Yeast)	α TBA_CANAL; β TBB_CANAL; γ TBG_CANAL
Cephalosporium acremonium (Acremonium chrysogenum)	β TBB_CEPAC
Chlamydomonas incerta	β TBB_CHLIN
Chlamydomonas reinhardtii	α TBA1_CHLRE, TBA2_CHLRE; β TBB_CHLRE; γ TBG_CHLRE
Chlorella vulgaris	α TBA_CHLVU
Chondrus crispus (Carragheen)	β TBB1_CHOCR
Cicer arietinum (Chickpea) (Garbanzo)	β TBB_CICAR
Cochliobolus heterostrophus (Drechslera maydis)	γ TBG_COCHE
Colletotrichum gloeosporioides (Anthracnose fungus) (Glomerella cingulata)	β TBB1_COLGL, TBB2_COLGL
Colletotrichum graminicola (Anthracnose fungus) (Glomerella graminicola)	β TBB1_COLGR, TBB2_COLGR
Cyanophora paradoxa	β TBB1_CYAPA
Daucus carota (Carrot)	β TBB1_DAUCA, TBB2_DAUCA
Dictyostelium discoideum (Slime mold)	α TBA_DICDI; β TBB_DICDI
Drosophila erecta (Fruit fly)	β TBB2_DROER
Drosophila melanogaster (Fruit fly)	α TBA1_DROME, TBA2_DROME, TBA3_DROME, TBA4_DROME; β TBB2_DROME, TBB3_DROME; γ TBG2_DROME
Ectocarpus variabilis	β TBB5_ECTVR, TBB6_ECTVR
Eimeria tenella	β TBB_EIMTE
Eleusine indica (Goosegrass)	α TBA1_ELEIN, TBA2_ELEIN, TBA3_ELEIN; β TBB1_ELEIN, TBB2_ELEIN, TBB3_ELEIN, TBB4_ELEIN
Emericella nidulans (Aspergillus nidulans)	α TBA1_EMENI, TBA2_EMENI; β TBB1_EMENI, TBB2_EMENI; γ TBG_EMENI
Entamoeba histolytica	α TBA1_ENTHI; γ TBG_ENTHI
Epichloe typhina	β TBB_EPITY
Erysiphe graminis (subsp. hordei) (Grass mildew)	β TBB_ERYGR
Erysiphe pisi (Pea powdery mildew)	β TBB2_ERYPI
Euglena gracilis	α TBA_EUGGR; β TBB_EUGGR
Euplotes aediculatus	γ TBG_EUPAE
Euplotes crassus	β TBB_EUPCR; γ TBG2_EUPCR
Euplotes focardii	β TBB_EUPFO
Euplotes octocarinatus	α TBA_EUPOC; β TBB_EUPOC; γ TBG2_EUPOC
Euplotes vannus	α TBA_EUPVA
Gadus morhua (Atlantic cod)	β TBB1_GADMO
Gallus gallus (Chicken)	α TBA1_CHICK, TBA2_CHICK, TBA3_CHICK, TBA4_CHICK, TBA5_CHICK, TBA8_CHICK; β TBB1_CHICK, TBB2_CHICK, TBB3_CHICK, TBB4_CHICK, TBB5_CHICK, TBB6_CHICK, TBB7_CHICK
Geotrichum candidum (Oospora lactis)	β TBB1_GEOCN, TBB2_GEOCN
Giardia lamblia (Giardia intestinalis)	β TBB_GIALA
Gibberella fujikuroi (Bakanae and foot rot disease fungus) (Fusarium moniliforme)	β TBB_GIBFU
Glycine max (Soybean)	β TBB1_SOYBN, TBB2_SOYBN, TBB3_SOYBN
Haemonchus contortus (Barber pole worm)	α TBA_HAECO
Haliotis discus (Abalone)	β TBB_HALDI
Homarus americanus (American lobster)	α TBA1_HOMAM, TBA2_HOMAM, TBA3_HOMAM; β TBB1_HOMAM, TBB2_HOMAM
Homo sapiens (Human)	α TBA1_HUMAN, TBA2_HUMAN, TBA4_HUMAN, TBA6_HUMAN, TBA8_HUMAN; β TBB1_HUMAN, TBB2_HUMAN, TBB4_HUMAN, TBB5_HUMAN, TBBQ_HUMAN, TBBX_HUMAN; γ TBG1_HUMAN, TBG2_HUMAN; δ TBD_HUMAN; ε TBE_HUMAN
Hordeum vulgare (Barley)	α TBA1_HORVU, TBA2_HORVU, TBA3_HORVU; β TBB_HORVU
Leishmania mexicana	β TBB_LEIME
Leptomonas seymouri	α TBA_LEPSE
Lupinus albus (White lupine)	β TBB1_LUPAL, TBB2_LUPAL
Lymnaea stagnalis (Great pond snail)	β TBB_LYMST
Lytechinus pictus (Painted sea urchin)	α TBA_LYTPI; β TBB_LYTPI
Manduca sexta (Tobacco hawkmoth) (Tobacco hornworm)	β TBB1_MANSE
Mus musculus (Mouse)	α TBA1_MOUSE, TBA2_MOUSE, TBA3_MOUSE, TBA6_MOUSE, TBA8_MOUSE; γ TBG1_MOUSE, TBG2_MOUSE
Mycosphaerella graminicola (Septoria tritici)	α TBA_MYCGR
Mycosphaerella pini (Dothistroma pini)	β TBB_MYCPJ
Naegleria gruberi	α TBA_NAEGR; β TBB_NAEGR
Neurospora crassa	α TBA1_NEUCR, TBA2_NEUCR; β TBB_NEUCR; γ TBG_NEUCR
Notophthalmus viridescens (Eastern newt) (Triturus viridescens)	α TBA_NOTVI
Notothenia coriiceps neglecta (Black rockcod) (Yellowbelly rockcod)	β TBB1_NOTCO
Octopus dofleini (Giant octopus)	α TBA_OCTDO; β TBB_OCTDO
Octopus vulgaris (Octopus)	α TBA_OCTVU

Onchocerca gibsoni	β TBB_ONCGI
Oncorhynchus keta (Chum salmon)	α TBA_ONCKE
Oncorhynchus mykiss (Rainbow trout) (Salmo gairdneri)	α TBAT_ONCMY
Oryza sativa (Rice)	α TBA1_ORYSA; β TBB1_ORYSA, TBB2_ORYSA, TBB3_ORYSA; γ TBG2_ORYSA
Oxytricha granulifera	α TBA_OXYGR
Paracentrotus lividus (Common sea urchin)	α TBA1_PARLI; β TBB_PARLI
Paramecium tetraurelia	β TBB1_PARTE
Patella vulgata (Common limpet)	α TBA2_PATVU
Pelvetia fastigiata	α TBA1_PELFA, TBA2_PELFA
Penicillium digitatum	β TBB_PENDI
Pestalotiopsis microspora	β TBB_PESMI
Phaeosphaeria nodorum (Septoria nodorum)	β TBB_PHANO
Physarum polycephalum (Slime mold)	α TBAD_PHYPO, TBAE_PHYPO, TBAN_PHYPO; β TBB1_PHYPO, TBB2_PHYPO
Physcomitrella patens (Moss)	γ TBG_PHYPA
Phytophthora cinnamomi	β TBB_PHYCI
Picea abies (Norway spruce) (Picea excelsa)	α TBA_PICAB
Pisum sativum (Garden pea)	α TBA1_PEA; β TBB1_PEA, TBB2_PEA, TBB3_PEA
Plasmodium berghei yoelii	α TBA_PLAYO
Plasmodium falciparum	α TBA_PLAFK; β TBB_PLAFA, TBB_PLAFK; γ TBG_PLAFO
Plasmodium falciparum (isolate K1 / Thailand)	α TBA_PLAFK; β TBB_PLAFK
Plasmodium falciparum (isolate NF54)	γ TBG_PLAFO
Pleurotus sajor-caju (Oyster mushroom)	β TBB_PLESA
Pneumocystis carinii	α TBA1_PNECA, TBAA_PNECA; β TBB_PNECA
Polytomella agilis	β TBB_POLAG
Porphyra purpurea	β TBB1_PORPU, TBB2_PORPU, TBB3_PORPU, TBB4_PORPU
Prunus dulcis (Almond) (Prunus amygdalus)	α TBA_PRUDU
Pseudopleuronectes americanus (Winter flounder) (Pleuronectes americanus)	β TBB_PSEAM
Rattus norvegicus (Rat)	β TBB1_RAT
Reticulomyxa filosa	γ TBG_RETFI
Rhynchosporium secalis	β TBB_RHYSE
Saccharomyces cerevisiae (Baker's yeast)	α TBA1_YEAST, TBA3_YEAST; β TBB_YEAST; γ TBG_YEAST
Schizophyllum commune (Bracket fungus)	α TBAA_SCHCO, TBAB_SCHCO; β TBB_SCHCO
Schizosaccharomyces japonicus	γ TBG_SCHJP
Schizosaccharomyces pombe (Fission yeast)	α TBA1_SCHPO, TBA2_SCHPO; β TBB_SCHPO; γ TBG_SCHPO
Solanum tuberosum (Potato)	β TBB1_SOLTU, TBB2_SOLTU
Sordaria macrospora	α TBA_SORMA
Strongylocentrotus purpuratus (Purple sea urchin)	β TBB_STRPU
Stylonychia lemnae α TBA1_STYLE, TBA2_STYLE;	β TBB_STYLE
Sus scrofa (Pig) α TBA_PIG;	β TBB_PIG
Tetrahymena pyriformis	α TBA_TETPY; β TBB_TETPY
Tetrahymena thermophila	α TBA_TETTH; β TBB_TETTH
Thalassiosira weissflogii (Marine diatom)	β TBB_THAWE
Torpedo marmorata (Marbled electric ray)	α TBA_TORMA
Toxoplasma gondii α TBA_TOXGO;	β TBB_TOXGO
Trichoderma viride	β TBB1_TRIVI,'TBB2_TRIVI
Triticum aestivum (Wheat)	α TBA_WHEAT; β TBB1_WHEAT, TBB2_WHEAT,—TBB3_WHEAT, TBB4_WHEAT, TBB5_WHEAT
Trypanosoma brucei rhodesiense	α TBA_TRYBR; β'TBB_TRYBR
Trypanosoma cruzi	α TBA_TRYCR; β TBB_TRYCR
Ustilago violacea (Smut fungus) (Microbotryum violaceum)	γ TBG_USTVI
Venturia inaequalis	β TBB_VENIN
Volvox carteri	α TBA1_VOLCA; β TBB1_VOLCA
Xenopus laevis (African clawed frog)	α TBA_XENLA; β'TBB2_XENLA, TBB4_XENLA; γ TBG_XENLA
Zea mays (Maize)	α TBA1_MAIZE,'TBA2_MAIZE, TBA3_MAIZE, TBA4_MAIZE, TBA5_MAIZE, TBA6_MAIZE; β TBB1_MAIZE, TBB2_MAIZE, TBB3_MAIZE, TBB4_MAIZE, TBB5_MAIZE, TBB6_MAIZE, TBB7_MAIZE,'TBB8_MAIZE; γ TBG1_MAIZE, TBG2_MAIZE, TBG3_MAIZE

Appendix B

Summary of computation results

Each of the 290 Swiss-Prot Sequences is listed below with some results. Fragmentary sequences are marked with an initial “F”. Charges are reported in fundamental charge (electronic) units.

	Name	Net		Volume	Area	C-Terminal Tail		
		|M|	Charge	(Å³)	(Å²)	Charge	Size	Sequence
	TBA1_ANEPH	1.344	-22	43.723	46.120	-8	16	GAESGEGEEGDEGEEY
	TBA1_ARATH	1.574	-24	43.726	46.097	-9	15	GGEGAEDDDEEGDEY
F	TBA1_CHICK	1.904	-21	40.490	43.082	-8	16	GVDSVEGEGEEEGEEY
	TBA1_CHLRE	1.042	-21	43.643	45.934	-6	16	GAESAEGAGEGEGEEY
	TBA1_DROME	1.225	-22	44.031	46.824	-6	15	GMDSGDGEGEGAEEY
	TBA1_ELEIN	1.407	-24	43.861	46.749	-9	16	GAEFDEGEEGDEGDEY
	TBA1_EMENI	1.467	-24	44.070	46.434	-7	14	ASDSLEEEGEEVEY
	TBA1_ENTHI	730	-10	44.061	46.461	-3	14	ALDNTIEGESMTAQ

The Free Energy for Hydrolysis of a Microtubule-Bound Nucleotide Triphosphate Is Near Zero: All of the Free Energy for Hydrolysis Is Stored in the Microtubule Lattice

M. Caplow, R. L. Ruhlen, and J. Shanks

Abstract. The standard free energy for hydrolysis of the GTP analogue guanylyl-(a,b)-methylene-diphosphonate (GMPCPP), which is −5.18 kcal in solution, was found to be −3.79 kcal in tubulin dimers, and only −0.90 kcal in tubulin subunits in microtubules. The near-zero change in standard free energy for GMPCPP hydrolysis in the microtubule indicates that the majority of the free energy potentially available from this reaction is stored in the microtubule lattice; this energy is available to do work, as in chromosome movement. The equilibrium constants described here were obtained from video microscopy measurements of the kinetics of assembly and disassembly of GMPCPP-microtubules and GMPCP-microtubules. It was possible to study GMPCPP-microtubules since GMPCPP is not hydrolyzed during assembly. Microtubules containing GMPCP were obtained by assembly of high concentrations of tubulin-GMPCP subunits, as well as by treating tubulin-GMPCPP-microtubules in sodium (but not potassium) Pipes buffer with glycerol, which reduced the half-time for GMPCPP hydrolysis from >10 h to ~10 min. The rate for tubulin-GMPCPP and tubulin-GMPCP subunit dissociation from microtubule ends were found to be about 0.65 and 128 s^{-1}, respectively. The much faster rate for tubulin-GMPCP subunit dissociation provides direct evidence that microtubule dynamics can be regulated by nucleotide triphosphate hydrolysis.

THE hallmark for energy-transducing systems such as myosin (Bagshaw and Trentham, 1973), ion-transporting ATPases (Taniguchi, and Post, 1975; Pickart and Jencks, 1984), the mitochondrial ATPase (Grubmeyer et al., 1982) and chloroplast coupling factor (Feldman and Sigman, 1982) is a near-zero free energy for hydrolysis of bound nucleotide triphosphate (NTP)[1]. Negligible free energy is released during NTP hydrolysis since this is stored in the protein conformation until useful work can be done. We have used the hydrolyzable GTP analogue GMPCPP, which contains a methylene linkage between the alpha and beta phosphates, to determine the free energy for hydrolysis of microtubule-bound NTP. We found that the majority of this free energy is stored in the microtubule lattice, so that the standard free energy for hydrolysis is near zero. This stored energy can do work, as in the NTP-independent movement of chromosomes in a reaction coupled to microtubule disassembly (Koshland et al., 1988; Coue et al., 1991). The retention of the energy of NTP hydrolysis by microtubules parallels the behavior of several energy-transducing systems.

In addition to these equilibrium studies, we have characterized the dynamics of microtubules formed with GMPCPP. The recent observation that this substance is not hydrolyzed in microtubules (Hyman et al., 1992) suggested its use in determining the role of the gamma phosphate moiety in microtubule dynamics. Our rationale was that if conditions could be found for forming microtubules containing GMPCP, it would be possible to determine the kinetic behavior of microtubules with a cognate pair of bound nucleotide tri- and diphosphates. Such a comparison was not possible with GTP analogues containing a nonhydrolyzable linkage between the beta and gamma phosphates (Weisenberg and Deery, 1976; Penningroth and Kirschner, 1978; Arai and Kaziro, 1976; Karr and Purich, 1978).

We found two routes for forming GMPCP-microtubules: by treating GMPCPP-microtubules with glycerol in sodium (but not potassium) Pipes buffer, which induces rapid hydrolysis of bound GMPCPP and stabilizes the resulting polymer; by assembling high concentrations of tubulin-GMPCP subunits. Our observation that subunits containing GMPCP dissociate much faster than subunits containing GMPCPP provides direct evidence that microtubule dynamics can be regulated by NTP hydrolysis. This conclusion was previously inferred from the requirement for GTP for dynamic instability behavior.

Materials and Methods

Materials

Pig and beef brain tubulin was purified by two cycles of thermal-induced assembly and disassembly, followed by chromatography on phosphocellulose (Weingarten et al., 1975). For some experiments the protein was further purified by a glutamate-induced polymerization step (Voter and Erickson, 1984). The small amount of glutamate that contaminated the resultant protein was removed by chromatography on Sephadex G-25. Some studies with calf brain tubulin were with protein provided by T. J. Mitchison (University of California, San Francisco, CA). We found no significant difference in the properties of beef and pig tubulin.

The amount of bound and free guanine nucleotide contained in purified tubulin was determined by an isotope dilution procedure. Microtubules were assembled with 0.5 mM ATP, a trace amount of [^{3}H]GDP, 0.17 U/ml of recombinant nucleoside diphosphate kinase (2500 U/mg, Nm23-1 expressed in *Escherichia coli* and purified essentially as described by Randazzo et al., 1991) and varying amounts of added GDP; polymer was isolated with an Airfuge (see below). Since the amount of label that is incorporated from radioactive nucleotide into polymer is proportional to the specific activity of the nucleotide, and the specific activity is inversely proportional to the nucleotide concentration, the endogenous guanine nucleotide contained in purified tubulin (E) is described by the relationship

$$\frac{\text{CPM in pellet (GDP added = 0)}}{\text{CPM in pellet (GDP added = N)}} = \frac{E + N}{E} \quad (1)$$

N in this equation corresponds to the concentration of added GDP. We found that the amount of radiolabel incorporated into polymer was reduced by two when N was equal to the tubulin concentration. This result indicates that the tubulin used here contained ~1.0 mol exchangeable guanine nucleotide/mol tubulin; the nucleotide was 30% GTP and 70% GDP.

[^{3}H]Guanylyl-(a,b)-methylene-diphosphonate ([^{3}H]GMPCPP) was obtained in 1984 from ICN Biomedicals, Inc. (Costa Mesa, CA); GMPCPP was also obtained in 1984 from ICN, or was synthesized as described (Hyman et al., 1984). The material obtained from ICN was repurified by chromatography on a 0.7 × 10 cm column containing Waters Protein-Pak DEAE 40HR, developing with a 50 ml 0.05–0.225 M triethylammonium bicarbonate gradient. Gamma-[^{32}P]GMPCPP was synthesized from GMPCP (provided by T. J. Mitchison or synthesized in this laboratory), using ATP-32 and nucleoside diphosphate kinase, as described previously (Hyman et al., 1992).

In preparing tubulin-GMPCP for studies of assembly it was necessary to deplete tubulin subunits of endogenous GTP and GDP. Removal of GTP was necessary since assembly might otherwise result from reaction with this nucleotide. Endogenous GDP could inhibit binding of GMPCP, which was found (see below) to have lower affinity for the E-site. Endogenous nucleotide was depleted by addition of alkaline phosphatase (P4252, 5 U/ml, 60 min, 10°; Sigma), including 1 mM GMPCP, which is not hydrolyzed by alkaline phosphatase, to stabilize the tubulin as the E-site nucleotide was hydrolyzed. To determine the extent of hydrolysis of endogenous GDP and GTP the pool of nucleotide was radiolabeled by a 10-min reaction with a trace amount of [^{3}H]GTP and nucleoside diphosphate kinase (0.7 μg/120 μl) before alkaline phosphatase addition. The nucleoside diphosphate kinase catalyzes isotopic equilibrium between GDP and GTP so that hydrolysis of these can be determined by measuring the radiolabel in GTP, GDP, GMP, and guanosine. Samples were quenched with perchloric acid and analyzed with HPLC. After a 60-min incubation only 0.1% of the initial E-site GTP and 21% of the initial GDP remained. The relatively slow digestion resulted because, as described previously for the reaction of added pyruvate kinase with E-site nucleotide (Brylawski and Caplow, 1983), the tubulin repeatedly recaptures most of the dissociated nucleotide before it can react with alkaline phosphatase. We did not extend the alkaline phosphatase digestion time to hydrolyze the 21% remaining GDP because we were concerned that this might result in loss of activity in the tubulin. Also, any observed assembly with tubulin-GMPCP subunits could not be attributed to tubulin-GDP subunits, since this material does not form microtubules under these conditions. In our calculation of the rate constant for microtubule assembly with GMPCP we have corrected for the presence of 21% tubulin-GDP.

Isolation and Characterization of GMPCPP-Microtubules

All reactions were in BRB80 buffer (80 mM Na Pipes, 1 mM $MgCl_2$, 1 mM EGTA, pH 6.8), at 37°, except for rates measured with video microscopy, where the temperature was 22–24°. Microtubules were made by two methods, in both the tubulin was incubated with GMPCPP for 20 min at 0° before a 30 min incubation at 37°. "5:1 microtubules" were generated with an ~92% yield of protein by assembly with 200 μM GMPCPP and 40 μM tubulin. The amount of GDP in this polymer was determined by including a trace amount of [^{3}H]GDP and [^{3}H]GTP in the assembly reaction; the specific activity of the added label was calculated from the amount of exchangeable GDP or GTP (see Eq. 1). "High-GMPCPP Tubes" were generated by an initial assembly at 25° with 1 mM GMPCPP and 10 μM tubulin, with a second assembly reaction using 10 μM tubulin (obtained by disassembling the initial pellet for 45 min in buffer at 0°) and 50 μM radiolabeled GMPCPP. The amount of GDP in these microtubules was determined by including a trace amount of alpha-[^{32}P]GTP and alpha-[^{32}P]GDP in the second assembly reaction.

Microtubules were isolated using an Airfuge (3–10 min, 37°, 30 psi), or by layering a 50-μl aliquot over a 2-ml cushion, made with 5% Ficoll 400 in BRB80 buffer, with centrifugation in a Beckman TLA100.3 rotor (100,000 rpm, 37°). After the supernatant was removed by suction and the pellet carefully rinsed with buffer, the portion of the tube near the pellet was wiped dry with a Kimwipe. The pellet was dissolved in 0.1 M NaOH for measurement of protein. For nucleotide analysis the pellet was treated with 1.4 M $HClO_4$ for 10 min at 0°, after which the perchloric acid was neutralized with K_2HPO_4. Precipitated salt was removed by a 30-s centrifugation in a microfuge and the nucleotide composition in the supernatant was determined using a SynChrompak AX100 column (Synchrom Inc., Lafayette, IN). GMPCP and GMPCPP eluted at 4.5 and 7.5 min (1 ml/min) when the column was developed with 0.15 M sodium phosphate buffer and 1.2 M sodium acetate, pH 7.3.

The rate of hydrolysis of GMPCPP in microtubules was determined by HPLC analysis of perchloric acid-quenched aliquots of resuspended polymer containing tritium-labeled nucleotide. Also, the rate was determined by measuring release of [^{32}P]Pi (Carlier, et al., 1987) from microtubules that had been assembled with gamma-labeled [^{32}P]GMPCPP.

Video Assay of Assembly and Disassembly at Microtubule Ends

Microtubule dynamics were analyzed using video microscopy, as described previously (Walker et al., 1988). Briefly, microtubules were assembled at the ends of sea urchin axonemes (kindly provided by E. D. Salmon) with tubulin subunits in BRB80 buffer. Disassembly was induced by displacement of subunits with buffer, using the flow cell described by Vale (1991), or, less frequently, with the cell described by Berg and Block (1984).

The rate of assembly of tubulin-GMPCPP was determined with 4 μM tubulin and 1 mM GMPCPP. It was not possible to vary significantly the tubulin subunit concentration since with 3 μM tubulin there was no nucleation at axoneme ends in 10 min and with 6 μM tubulin there was extensive nucleation of free microtubules that obscured observations of axoneme-associated tubes; formation of free microtubules also decreases the tubulin subunit concentration by an unknown amount. It is noted that the requirement for 3 μM tubulin for nucleation is not related to the critical concentration for assembly, which is much lower. Rather, as reported previously (Walker et al., 1988), there is a significant lag before axonemes are elongated with tubulin subunits and this lag was excessively long when the tubulin concentration was below 3 μM.

Tubulin-GMPCP subunits were assembled at axoneme ends by reacting 90–100 μM tubulin with 1 mM GMPCP and alkaline phosphatase. The lag for axoneme elongation was especially significant with tubulin-GMPCP, so that it was necessary to incubate the flow cell containing the reaction mixture for ~5 min at 37° (in a humidified chamber) before viewing samples at room temperature. Less frequently, axonemes were first incubated for about 5 min with 7.5 μM tubulin and 1 mM GMPCPP to generate short stubs at axoneme ends. After the tubulin-GMPCPP subunits had been washed out with buffer the stubs were elongated with the 100 μM tubulin, 1 mM GMPCP, alkaline phosphatase mixture. Electron microscopic images of elongated axonemes were obtained with samples that had been diluted 100-fold into BRB buffer containing 1% glutaraldehyde and pelleted on an electron microscope grid using a Beckman EM90 rotor.

Assays of the Rate of Disassembly of GMPCPP-Microtubules

The rate of disassembly of [^{32}P]GMPCPP-microtubules was determined by sedimenting polymer with an Airfuge (37°, 10 min, 30 psi) after a 30-fold dilution into BRB80 buffer. The radioactive nucleotide contained in the supernatant was measured. Either the microtubules were not fully sedi-

mented, or disassembly continued during a portion of the time required for centrifugation, so that an only 80% yield was obtained with microtubules that were centrifuged immediately after dilution.

The kinetics for dilution-induced disassembly were also measured with high-GMPCPP tubes containing gamma-[^{32}P]GMPCPP, from the rate of release of [^{32}P]Pi formed in the reactions in Eqs. 2 and 3:

$$[^{32}\text{P}]\text{GMPCPP-Microtubule} \xrightarrow{\text{200-fold dilution}} [^{32}\text{P}]\text{GMPCPP-tubulin subunits} \quad (2)$$

$$[^{32}\text{P}]\text{GMPCPP-tubulin subunit} \rightarrow [^{32}\text{P}]\text{GMPCPP} \xrightarrow{\text{alkaline phosphatase}} [^{32}\text{P}]\text{Pi} \quad (3)$$

With alkaline phosphatase at 1 U/ml the cleavage of GMPCPP was rapid (0.56 s^{-1}), so that the observed rate of Pi release closely tracked the rate of disassembly. The molecular rate constant for disassembly was obtained by multiplying the % microtubule disassembled/s times the mean number of tubulin subunits/microtubule. The microtubule length distribution was determined by diluting an aliquot from the reaction mixture 3,000-fold into 1% glutaraldehyde, before the microtubules were sedimented with an Airfuge EM90 rotor onto an electron microscope grid. Lengths were determined by measuring >300 microtubules.

Equilibrium Constants for Nucleotide Binding

The equilibrium constant for GMPCP and for GMPCPP binding to tubulin was determined by competition experiments in which these nucleotides displaced bound [^{3}H]GTP from the tubulin E-site. Tubulin-[^{3}H]GTP subunits were prepared by adding a trace amount of [^{3}H]GTP to the 14.2 μM tubulin that eluted in the void volume when a mixture of 40 μM tubulin and 200 μM GTP was chromatographed on a Sephadex G-25 column. It was necessary to determine the amount of GTP in this mixture, since this is required in calculating the nucleotide specific activity, used in deriving the stoichiometry for nucleotide binding. The amount of GTP was determined by adding a trace amount of [^{3}H]GTP with and without 10 μM GTP before the 14.2 μM tubulin was rechromatographed on Sephadex G-25. Since 10 μM added GTP reduced the amount of radioactive nucleotide that eluted with the protein by 42%, it was concluded that the 14.2 μM tubulin contained 13.8 μM GTP (see Eq. 1).

The K_d values for GMPCPP and GMPCP were determined by incubating these nucleotides with 14.2 μM tubulin-[^{3}H]GTP for 5 min before a 40-μl aliquot was chromatographed on a 1-ml Sephadex G-25 column. In a control reaction without added GMPCPP or GMPCP the tubulin eluted with 0.57 mol[^{3}H]GTP/mol tubulin; however, since 20% of E-site GTP dissociates from tubulin during chromatography under these conditions (see Fig. 1 in Zeeberg, 1980), the E-site stoichiometry was 0.57/0.8 = 0.71.

Results

Nucleotide Composition of Microtubules Assembled with GMPCPP

We were puzzled by the discrepancy between results showing that either GMPCPP (Hyman et al., 1992) or GMPCP (Sandoval et al., 1977) is found in microtubules assembled with GMPCPP. We reinvestigated this problem using [^{3}H]GMPCPP, rather than the gamma-[^{32}P]GMPCPP used by Hyman et al. (1992), so that both GMPCPP and GMPCP could be tracked by the tritium in the guanine moiety.

Table I. Nucleotide Composition of Isolated Microtubules

Isolation Procedure	Pelleted protein	Pelleted [^{3}H]	Pelleted [^{32}P]
	%	%	%
Cushion	85	28	2.7
No cushion	100	30	20

Microtubules were assembled with tubulin (51 μM) and gamma-[^{32}P], [^{3}H]GMPCPP (150 μM) and the resultant polymer was isolated by centrifugation in an Airfuge, or by centrifugation through a cushion containing 25% glycerol.

Microtubules assembled with [^{32}P], [^{3}H]GMPCPP and isolated through a glycerol cushion were found to contain very little radioactive phosphorus (Table I). The 10/1 ratio of [^{3}H] and [^{32}P] indicated that ~90% of the GMPCPP that had been incorporated was hydrolyzed in the pelleted microtubules. In contrast, microtubules that were isolated without using a glycerol cushion contained nearly equal amounts of [^{3}H] and [^{32}P] (Table I). The possibility that the presence of [^{32}P] in the product isolated without glycerol resulted from subunits containing [^{3}H]GMPCP and [^{32}P]Pi was ruled out by HPLC analysis of bound nucleotide: 83% of the tritium was in [^{3}H]GMPCP and 17% in [^{3}H]GMPCPP.

Rate of Hydrolysis of GMPCPP in Microtubules

To determine the basis for the dramatic difference in the extent of GMPCPP hydrolysis in microtubules isolated with or without glycerol (Table I), the rate of nucleotide hydrolysis was determined in microtubules that had been assembled with [^{3}H]GMPCPP and isolated with a Ficoll cushion. Hydrolysis was slow: the fraction of bound tritium as [^{3}H]GMPCP increased from 19.3% in the initially isolated polymer to 30.9% in 2 h and to 59% in 18 h. The rate constant calculated from results during the first 2 h of incubation is 2.1 × 10^{-5} s^{-1}; this is twice the value calculated from the longer incubation, where protein denaturation may have influenced the rate. The rate of release of [^{32}P]Pi from microtubule bound gamma-[^{32}P]GMPCPP was linear with time and an observed 2.4% release of label in 40 min corresponds to a rate constant equal to 1 × 10^{-5} s^{-1} (19 h half-life).

To confirm that glycerol affected the rate of hydrolysis of GMPCPP in microtubules parallel analyses were performed with glycerol added to microtubules in solution. The half-time of GMPCPP hydrolysis was reduced to ~10 min (Fig. 1). To test whether other commonly used chemicals affect the hydrolysis rate, we examined GMPCPP hydrolysis in the

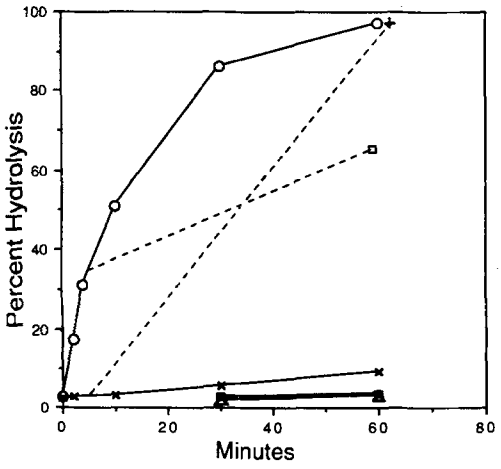

Figure 1. Effect of glycerol on the rate of hydrolysis of GMPCPP in microtubules. The rate of release of [^{32}P]Pi was determined when [^{32}P]GMPCPP-microtubules were diluted into buffer containing alkaline phosphatase and Na- (○) or K-Pipes (×) in glycerol, or in Na- (■) or K-Pipes (△) in the absence of glycerol. The dotted lines describe the reaction when GMPCPP-microtubules in either Na or K-Pipes and glycerol for 5 min were diluted 10-fold into glycerol buffer containing Na-Pipes (+) or K-Pipes (□). The rate in 1 M Na glutamate in Na-Pipes was indistinguishable from that in Na-Pipes and glycerol.

presence of glutamate or following substitution of Na-Pipes buffer with K-Pipes. The former was chosen because it is commonly used in tubulin purification; the latter was used because this had been used in a previous study (Hyman et al., 1992) which found intact GMPCPP. Like glycerol, glutamate stimulated hydrolysis, reducing the half-time to ~10 min. Most surprisingly, the switch from sodium to potassium cations strongly slowed hydrolysis, yielding a rate similar to that reported earlier (Hyman et al., 1992). The rate was also mildly stimulated by glycerol in Li-Pipes buffer: hydrolysis was increased from about 2% to 14% by glycerol, when gamma-[^{32}P]GMPCPP-microtubules that had been assembled in Li-Pipes buffer were incubated for 30 min. These cation effects are reversible, since a buffer change by a 10-fold dilution reduced hydrolysis in K-Pipes and increased it in Na-Pipes (Fig. 1).

Since both glycerol (Solomon, et al., 1973) and glutamate (Hamel and Lin, 1981) stabilize microtubules we examined whether taxol would also affect the hydrolysis rate. Isolated GMPCPP-microtubules were reacted with 25 μM taxol and the [^{3}H]GMPCPP remaining was analyzed by HPLC after a 5-, 45-, and 90-min incubation. This revealed that hydrolysis was essentially unaffected by taxol, as 82–84% of GMPCPP remained intact even at the latest time point.

To determine whether the presence of adjacent tubulin-GDP subunits could simulate the effect of glycerol on the rate of GMPCPP hydrolysis, microtubules were assembled under conditions where GMPCP and GMPCPP constituted only ~5% of the total bound nucleotide. Adjacent tubulin-GDP subunits did not simulate the effect of glycerol since there was no enhanced hydrolysis of GMPCPP in microtubules under these conditions (Table II).

Microtubules Containing GMPCPP Are Very Stable

The rate of microtubule disassembly upon dilution was sensitive to relatively small differences in the degree of substitution with analogue (Fig. 2). The sedimentation assay used here was not suited for determining the molecular rate constant for subunit dissociation, since in 30 min there was only a small increase in radiolabel that was not pelleted, over a relatively high (20%) background (lower curve in Fig. 2). To surmount this technical problem we assayed the rate of release of [^{32}P]Pi from [^{32}P]GMPCPP-microtubules after the polymer had been diluted into buffer containing alkaline phosphatase (see Eqs. 2 and 3). This revealed an initial rate

Table II. Effect of Coassembly of GMPCPP and GTP on GMPCPP Hydrolysis

GTP in assembly	μM Analogue in pellet*	% GMPCPP Hydrolyzed
50 μM	0.64 (3.9%)	25
200 μM	.54 (3.3%)	15
400 μM	.46 (2.8%)	6

Microtubules were assembled by a 30-min incubation of 40 μM tubulin, a GTP regenerating system (250 μM ATP and nucleoside diphosphate kinase) and 16 μM [^{3}H]GMPCPP and isolated by centrifugation in an Airfuge. A Ficoll cushion could not be used here since microtubules containing GDP are not stable to dilution in Ficoll. It was determined that 10.4 μM GDP was in microtubules, from measurement of the fraction of the label pelleted in an identical reaction with label in [^{3}H]GTP.

* The amount of nucleotide is expressed as concentration, after normalizing the volume of the resuspended pellet to the initial reaction volume. The value in parenthesis gives percent total [^{3}H]GMPCPP in the pellet; this exceeded the 0.5–.8% nonspecific entrapment of nucleotide under these conditions.

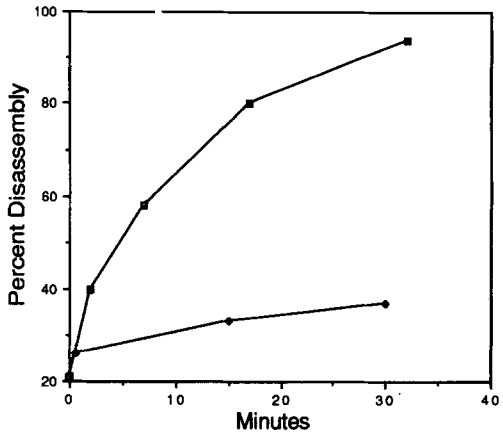

Figure 2. Rate of dilution-induced disassembly of GMPCPP-microtubules measured with a sedimentation assay. Rates with High GMPCPP Tubes (●) and 5:1 microtubules (□) are shown. High GMPCPP Tubes were generated by two cycles of assembly with GMPCPP; these contained 0.82 mol analogue/mol tubulin and <0.07 mol GDP/mol tubulin. 5:1 Tubes were assembled in a single cycle with GMPCPP/tubulin equal to 5. These contained 0.07 mol GMPCP, 0.46 mol GMPCPP, 0.05 mol GDP (from coassembly with tubulin-GDP subunits), and 0.11 mol GDP (from coassembly with tubulin-GTP subunits) per mol tubulin in polymer; this corresponds to 0.69 guanine nucleotide/tubulin, with 77% substitution with analogue.

of 1.7%/min (Fig. 3), and with a mean microtubule length equal to 2.8 μm, the molecular rate constant for subunit dissociation is 1.3 s^{-1}. Since the disassembly rates are about equal at the two ends (see below) the molecular rate constant is 0.65 s^{-1}. The rate of subunit dissociation was not significantly influenced by the identity of the monovalent cation: when microtubules assembled in Na-Pipes were diluted 100-fold the disassembly rate was 0.48%/min when dilution was in Na-Pipes and 0.33%/min in K-Pipes.

To confirm that microtubules were stabilized by GMPCPP, video measurements were made on individual microtu-

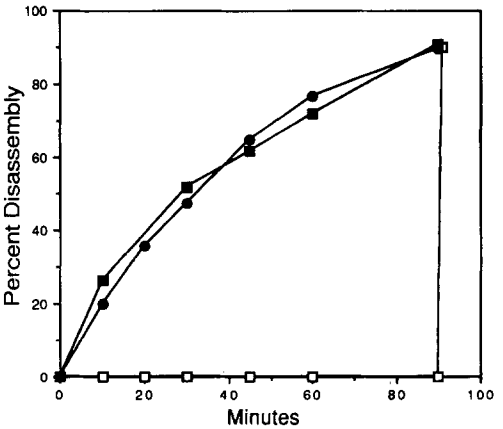

Figure 3. Rate of dilution-induced disassembly of GMPCPP-microtubules. Results from experiments run on consecutive days (●,■) and a reaction where alkaline phosphatase was not included in the diluent (□) are shown. In the latter reaction alkaline phosphatase was added at 90 min, and the quantitative release of Pi demonstrated that the microtubules had disassembled fully.

bules. High GMPCPP microtubules were very stable at both ends (Table III, Fig. 2). Subunit dissociation was extremely slow. Assuming that loss of fewer than 600 subunits (~2 mm on the video screen) would go undetected during a 30-min observation yielded a maximal rate constant for subunit loss of 0.4 s^{-1}, in agreement with the bulk measurements above (Fig. 3). About 15% of the microtubules were observed to disassemble at a rate of about 2 s^{-1}; we have no explanation for this faster rate. Microtubules assembled with a 5:1 GMPCPP/tubulin ratio so that they were 77% substituted with analogue (see legend to Fig. 2) had reduced stability. After dilution to remove tubulin subunits the majority of microtubules disassembled relatively slowly at one end (Table III), while a small fraction of these microtubules did not disassemble at a measurable rate.

To characterize further GMPCPP-microtubules, the rate of elongation from axonemes was determined for 4 μM tubulin-GMPCPP. This revealed a rate of 6.1 (n = 12, SD 1.8) s^{-1}, with no significant difference in the rate at the two microtubule ends. It was not possible to determine the elongation rate at widely varying concentrations of tubulin-GMPCPP because, as described in Materials and Methods, there is massive nucleation of microtubules that are not at axoneme ends when the tubulin concentration exceeds ~6 μM. Thus, the rate constant for elongation with tubulin-GMPCPP could not be determined from a linear plot of the concentration dependence of the rate. Instead, the observed rate with 4 μM tubulin, corrected for the rate for tubulin-GMPCPP subunit dissociation (0.65 s^{-1}, the average for the two ends from results in Fig. 3), was divided by the 4-μM subunit concentration used for assembly. The so-derived second-order rate constant was 1.36×10^6 M^{-1} s^{-1} (at 23°); the rate constant at 37° was reported to be 5×10^6 M^{-1} s^{-1} (Hyman et al., 1992). For comparison, rates equal to 1.2–5.3 $\times$ 10^6 M^{-1} s^{-1} have been reported for the reaction of tubulin-GTP subunits (Mitchison and Kirschner, 1984; Walker et al., 1988).

Table III. Kinetics for Disassembly of GMPCPP-microtubules Measured with Video Microscopy

Polymerization conditions	Glycerol treatment*	Rate end 1	Rate end 2
		s^{-1}	s^{-1}
High-GMPCPP Tubes	–	0.4‡ (41)	2.1 (11, 2)
High GMPCPP Tubes	+	146 (4, 39)	5.5 (6, 3)
5:1 Tubes‡	–	.5§ (19, .4)	10 (15, 7)

Rates were measured after microtubules assembled at axoneme ends were diluted with buffer. Values in parenthesis are number of microtubules analyzed and standard error. Results were from studies where both ends of an axoneme could be observed; however, numerous observations of microtubules on axonemes that could not be viewed at both ends confirmed the results reported here. The properties of High GMPCPP Tubes and 5:1 Tubes are described in the legend for Fig. 2.

* Microtubules that had been elongated at the end of axonemes were exposed to 60% glycerol for 40 min, after which the glycerol was displaced by excess buffer to induce disassembly.

‡ This is an upper limit for the rate since 16 of the 18 microtubules analyzed did not measurably shorten in 25 min of observation. The rate was calculated by assuming that a 2-mm shortening on the video screen would not be detected during the period of observation.

§ There was no measurable disassembly for 15 of 19 microtubules examined. An upper limit to the rate was calculated by assuming that a 1-mm change in length would not be detected in the 10 min of observation.

Stability of GMPCP-microtubules

The stability of GMPCP-microtubules was determined with microtubules that had been assembled with GMPCPP and then treated with glycerol to induce hydrolysis. On subsequent dilution these microtubules disassembled very rapidly, but only at one end (Table III). Microtubules containing GMPCP were also generated by assembling tubulin-GMPCP subunits at axoneme ends. This reaction could be induced with high concentrations of tubulin (91 μM) and GMPCP, using alkaline phosphatase to cleave excess endogenous nucleotides. The possibility that assembly resulted from reaction with residual tubulin-GTP subunits was ruled out since only 0.1% of the initial E-site GTP was found to survive the alkaline phosphatase treatment. Evidence that microtubules were formed was obtained by electron microscopy (Fig. 4). The previous failure to form microtubules in a reaction of purified tubulin with GMPCP (Sandoval, 1977) probably resulted from use of low protein concentrations.

Video microscopy was used to measure the elongation rate with GMPCP. A wide range of rates, much wider than that attributable to experimental error, was observed for elongation of a single axoneme end. For example, two microtubules at one axoneme end grew at rates of 5.7 s^{-1}, while another at the same end grew at 1.6 s^{-1}. A similarly wide range of rates of microtubule assembly (Gildersleeve et al., 1992; Toso et al., 1993) and disassembly (O'Brien et al., 1990) with GTP has also not been accounted for. Also, in agreement with previous reports (Gildersleeve et al., 1992; Toso et al., 1993), we occasionally observed periods during which microtubules temporarily stopped growing, as well as variable rates for both assembly and disassembly of a single microtubule. When results from experiments on three successive days were plotted the assembly rates clustered in two ranges, with rates equal to 16 s^{-1} (n = 16, SD 4) and 8 s^{-1} (n = 11, SD 1.7); two microtubules assembled at 1 s^{-1}. Since assembly with tubulin-GTP occurs more rapidly at the microtubule plus end we assume that the 16 s^{-1} rate is for reaction at this end.

The disassembly rate was more difficult to measure with GMPCP-microtubules since these were out of focus during the flow of buffer and moved violently for some time after the flow was stopped. Also, microtubules were frequently lost by shear and since disassembly is relatively rapid, it was not possible to select a new field or otherwise optimize observations after the flow of buffer. Rates again mainly fell into two categories: 128 s^{-1} (n = 12, SD 23) and 63 s^{-1} (n = 12, SD 15); six other microtubules had a mean rate of 26 (SD 6). Since the ratio of the assembly to disassembly rate is equal to the equilibrium constant for tubulin-GMPCP subunit addition, and this ratio must be equal at the two ends for a reaction where there is no NTP hydrolysis (Wegner, 1976), the rapid and slow assembly rates were coupled with the corresponding disassembly rates to calculate the second-order rate constant for assembly and the equilibrium constant for subunit addition (Table IV). The appropriateness of this coupling of rapid and slow rates was indicated by analysis of the rates for microtubules where both assembly and disassembly could be observed. For example, 12 out of 17 microtubules were found to have assembly and disassembly rates that were both either in the rapid or slow category. Generally, microtubules at opposite microtubule ends were

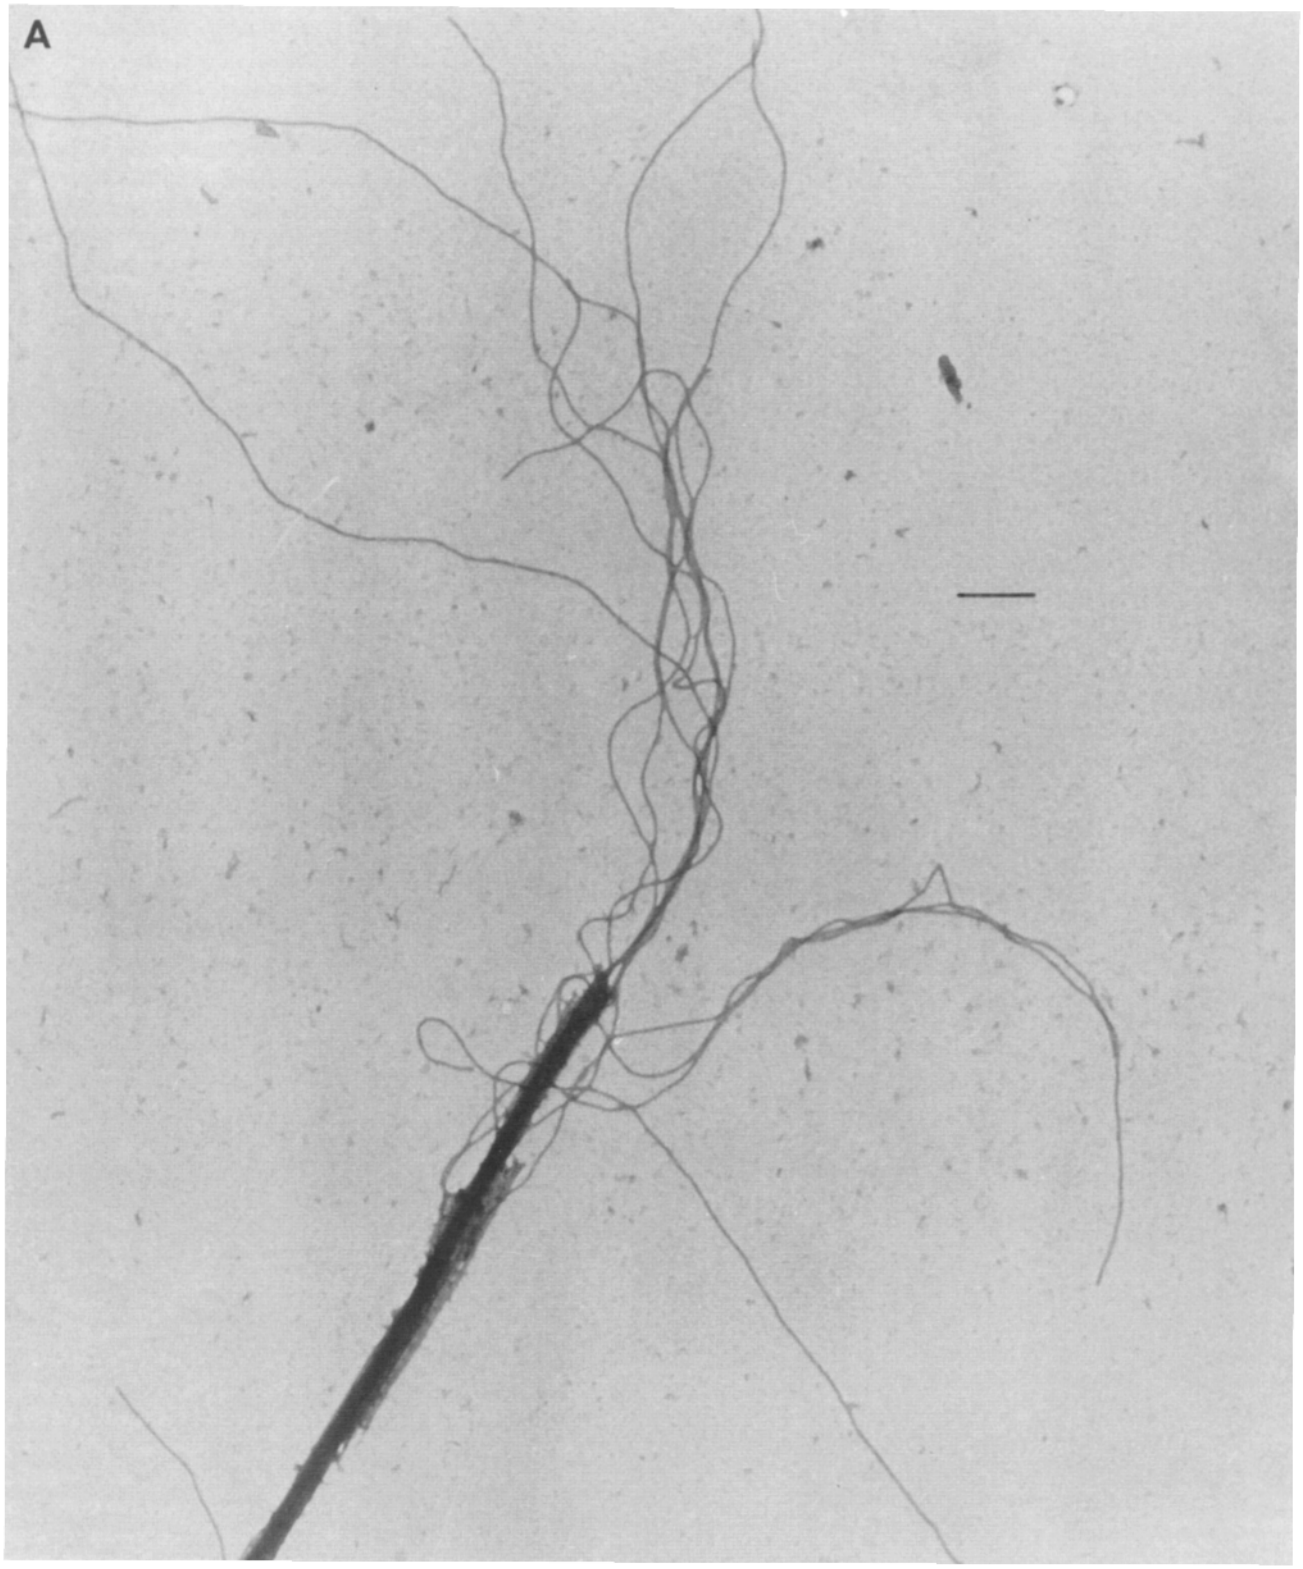

Figure 4. Structure of microtubule assembled with GMPCP. Bars, 0.5 μm.

either in the fast or slow range for assembly or disassembly. Deviation from the rule that either rapid or slow assembly and disassembly must occur at a given end may have resulted because some of the microtubules originated from axonemes with opposite polarity that were stuck together, or because microtubules grew from defects in the axoneme structure and then folded back on the axoneme so that their site of origin was mistaken. The frayed character of the axonemes is apparent in Fig. 4.

The second-order rate constant for assembly with tubulin-

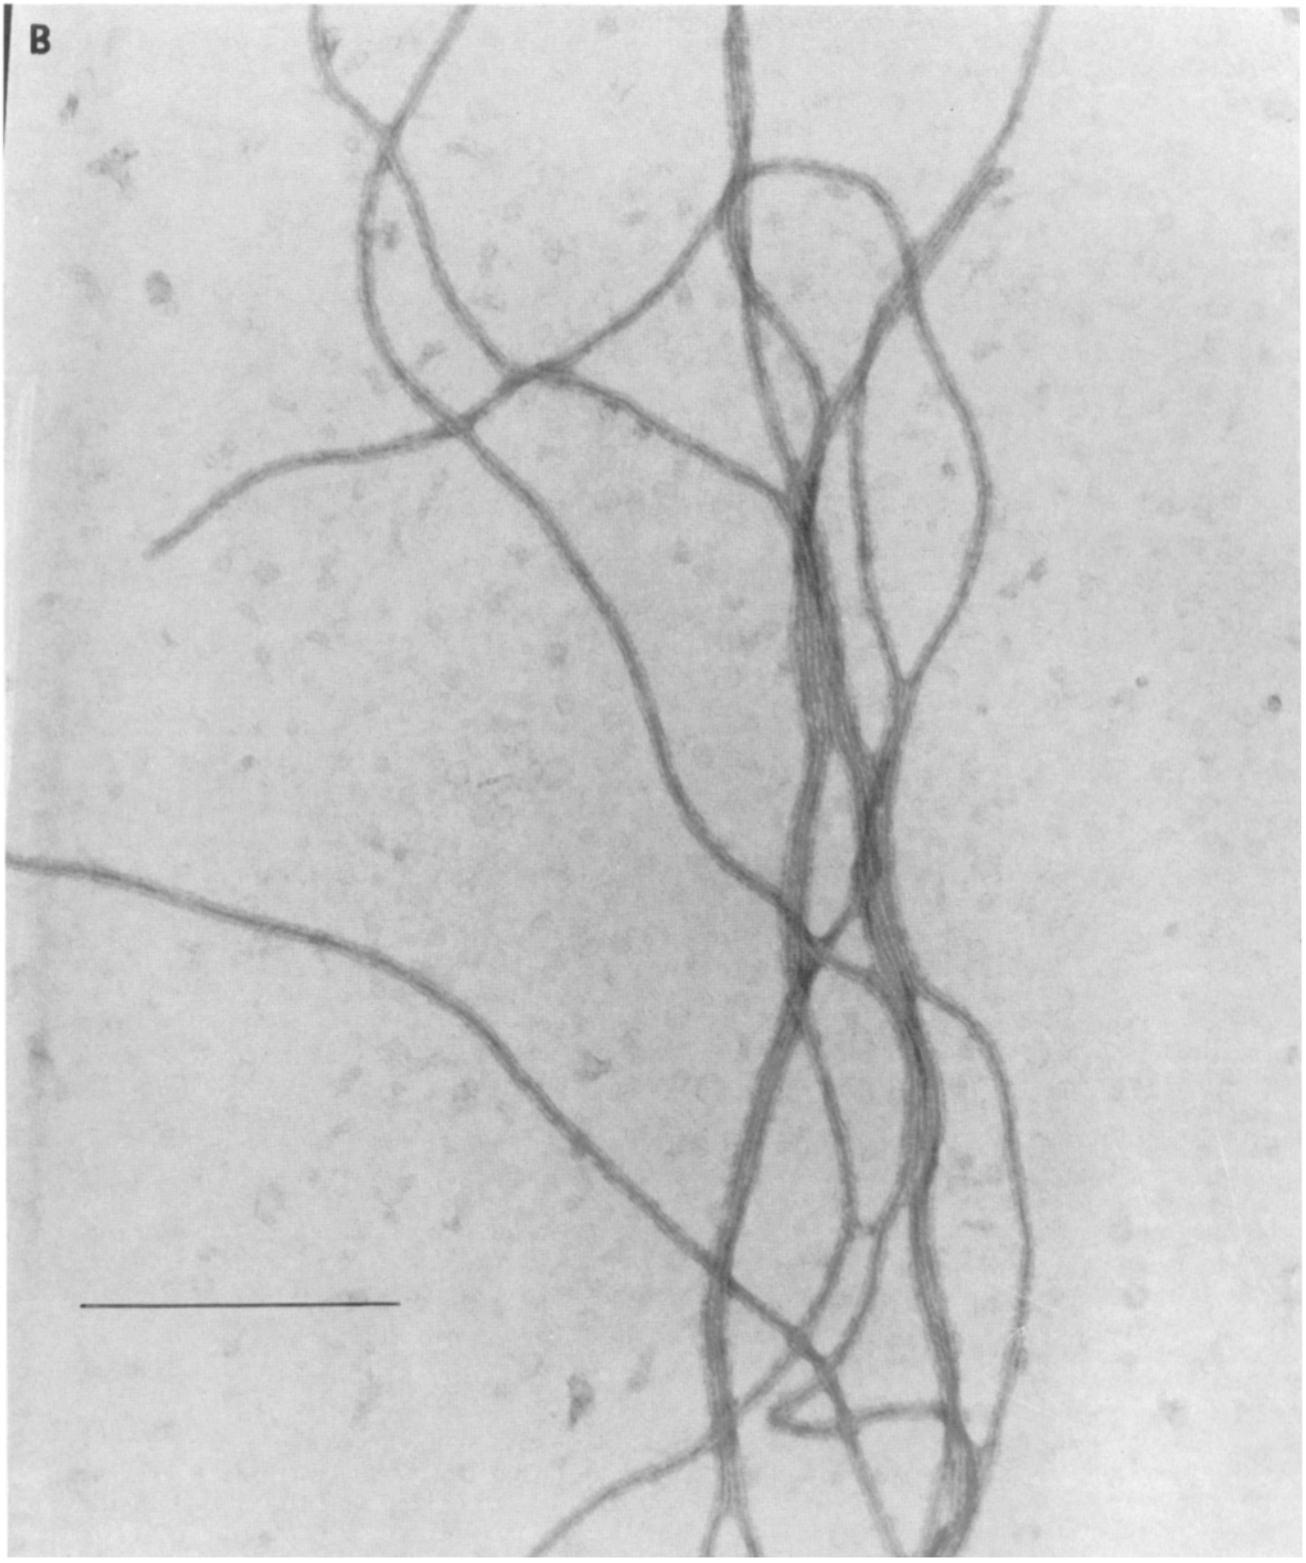

Figure 4.

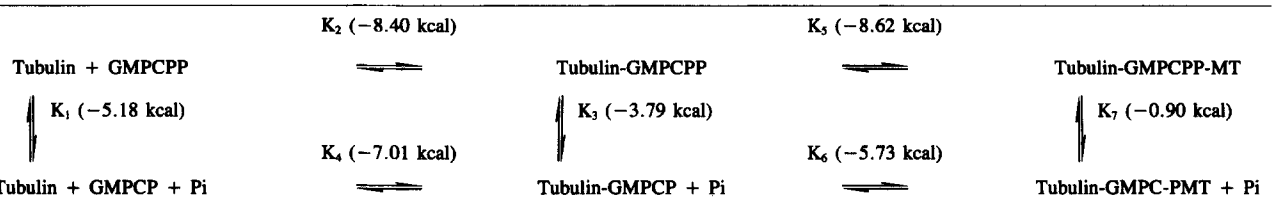
GMPCP was determined by dividing the sum of the observed elongation and disassembly rates by the tubulin-GMPCP subunit concentration (73 μM, after correcting for the 21% occupancy of the E-site with GDP). The calculated second order-rate constants were 2×10^6 M^{-1} s^{-1} at one end and 1×10^6 M^{-1} s^{-1} at the other end.

Equilibrium for GMPCP and GMPCPP Binding to Tubulin Subunits

The binding affinity of GMPCPP and GMPCP to tubulin subunits was measured by their ability to displace GTP (Table V). The affinity is quite high, with K_d equal to 7.25 μM

Table IV. Equilibrium Constants for Reactions of GMPCPP and GMPCP with Tubulin



Parameter	K_{eq}	How determined
K_1	6.30×10^3	Assumed to be identical to AMPCPP*
K_2	1.45×10^6	See Table V
K_4	1.38×10^5	See Table V
K_3	3.50×10^2	$K_1 K_4 = K_2 K_3$
K_5	2.09×10^6‡	Rate constant assembly/rate constant disassembly§
K_6	1.58×10^4	See K_5‖
K_7	2.65	$K_5 K_7 = K_3 K_6$

* Milner-White and Rycroft, 1983. Since this value was determined by comparison with ATP, we use a free energy for ATP hydrolysis equal to −8.8 kcal/mol (Jencks, 1968), corrected for pH 6.8.
‡ This is equal to 5×10^7, using the rate constants derived by Hyman et al. (1992). The difference is mainly in the rate for subunit dissociation, which was found to be 0.1 s^{-1} for both ends, compared to 1.35 s^{-1} found here. A larger value for K_5 would make the free energy change for K_7 more positive, reinforcing the conclusions we have derived.
§ k(tubulin-GMPCPP subunit addition)/k (tubulin-GMPCPP subunit dissociation) = 1.36×10^6 $m^{-1}/0.65$ s^{-1}. The subunit dissociation rate was derived from the 1.3 s^{-1} measured for both ends, taking into account the fact that the rate must be equal at the two ends. This equality is required because the rate of addition of tubulin-GMPCPP subunits was the same at the two ends, and because K_5, which is equal to the ratio of the rate constants, must be identical at the two microtubule ends when there is no NTP hydrolysis in the reaction (Wegner, 1976).
‖ As with K_5, with rates equal to 2.0×10^6 M^{-1} s^{-1} and 128 s^{-1}, or 1.0×10^6 M^{-1} s^{-1} and 63 s^{-1}.

with GMPCP and 0.69 μM with GMPCPP (at 23°); this corresponds to a free energy for binding equal to −7.01 and −8.04 kcal, respectively.

Discussion

Regulation of Microtubule Dynamics by Controlled Hydrolysis of a GTP Analogue

Although the GTP-cap model for microtubule dynamic instability is generally accepted and even made its way into textbooks, there is conflicting evidence for the presence of tubulin-GTP subunits in microtubules (reviewed by Caplow, 1992). The most convincing evidence that GTP hydrolysis modulates microtubule dynamics has come from comparison of the behavior of microtubules containing nonhydrolyzable GTP analogues and GDP.

The GTP analogue GMPCPP, which is susceptible to hydrolysis because the methylene bridge links the alpha and beta phosphate residues, is unique in binding relatively tightly to the tubulin E-site and in being more effective than GTP in promoting assembly (Sandoval et al., 1977; Hyman et al., 1992).

Table V. Equilibrium Constant for GMPCPP and GMPCP Binding to Tubulin

Nucleotide	% cpm bound	K_d
		(μM)*
1 mM GMPCP	74.5-80.2	4.7, 6.5
2.5 mM GMPCP	66.7-71.0	8.0, 9.8
1 mM GMPCPP	29.6	0.67
2.5 mM GMPCPP	14.6-15.1	0.71, .69

* The equilibrium constant was determined from the relationship: eluted [Tubulin-GMPCPP/Tubulin-GTP] = K_{GTP} $(GMPCPP)_{free}/K_{GMPCPP}$ $(GTP)_{free}$, where K_{GTP} is equal to 2.2×10^{-8} (Zeeberg and Caplow, 1979).

It is of special interest that the rate of tubulin subunit dissociation from microtubules is dramatically increased when the gamma phosphate moiety of a bound NTP has been lost by hydrolysis. The more than 100-fold greater rate for dissociation of tubulin-GMPCP subunits compared to tubulin-GMPCPP subunits provides direct evidence that microtubule dynamics can be regulated by NTP hydrolysis. This conclusion was previously derived from considering the requirement for GTP for dynamic instability, as well as from comparison of the properties of microtubules assembled with nonhydrolyzable GTP analogues that were presumed to exactly mimic GTP, with the properties of GDP-microtubules.

Free Energy for Hydrolysis of Microtubule-bound GMPCPP

The equilibrium constant for hydrolysis of GMPCPP bound to the E-site of tubulin subunits and microtubules was determined from experimental measurements of five of the equilibrium constants in Scheme I (Table IV). The most striking result is the decrease in the free energy for GMPCPP hydrolysis from −5.18 kcal in solution, to −3.79 kcal in subunits, to −0.90 kcal in microtubules. The near zero free energy for hydrolysis of microtubule-bound GMPCPP is of singular interest.

It must be noted that the products for hydrolysis of microtubule-bound GMPCPP (K_7 in Table IV) are the binary complex of GMPCP and tubulin subunits in the microtubule, and free Pi at a 1 M standard state. To estimate the free energy change to form the ternary complex contain-

ing both GMPCP and Pi in the microtubule requires correcting the −0.9 kcal value for K_7 for the free energy expended for Pi dissociation at the 1 M standard state concentration; this depends on the K_d for Pi dissociation. Pi binding to GDP-subunits in microtubules is weak (Carlier, et al., 1988; Caplow et al., 1989; Melki et al., 1990; Stewart et al., 1990; Trinczek et al., 1993) and a K_d equal to 25 mM was previously estimated from the effect of Pi on the disassembly rate in glycerol buffer (Carlier, et al., 1988). Based on this value for K_d, the free energy expended for Pi dissociation at the 1 M standard state concentration is +2.18 kcal ($-RT\ln 1/K_d$). Therefore, the standard free energy for forming the GMPCP-Pi-microtubule ternary complex would be +1.28 kcal (i.e., 2.18 − 0.9), corresponding to an equilibrium constant equal to 0.114. For comparison, the free energy change is −1.3 kcal for conversion of the myosin-ATP to the myosin-ADP-Pi ternary complex (Bagshaw and Trentham, 1973).

It is emphasized that the observed free energy change for NTP hydrolysis under physiological conditions will be more negative than +2.18 kcal, since the position of the equilibrium depends on the Pi concentration. With Pi buffered in cells at 1 mM, the apparent free energy change for NTP hydrolysis in the microtubule would be 4.08 kcal more negative ($-RT\ln 0.001$) than the +1.28 kcal; ie., equal to −2.8 kcal.

The relatively small free energy change for NTP hydrolysis (even at physiological Pi concentrations) indicates that much of the free energy potentially available from this reaction is stored in the microtubule lattice, presumably as a repulsive force between subunits. This repulsive force is manifested in the enormous rate for dissociation of subunits containing GMPCP or GDP. The energy stored in the microtubule lattice can do work, by coupling disassembly to vesicle or chromosome movement (Koshland et al., 1988; Coue et al., 1991). Finally, it is noted that calculation of the free energy for hydrolysis of microtubule-bound GTP is not possible since the equilibrium constant for addition of tubulin-GDP subunits to the microtubule (K_6 in Table IV) is not available.

Glycerol and Glutamate-Induced Hydrolysis

Our observation that glycerol induces hydrolysis of microtubule bound GMPCPP in Na Pipes buffer means that glycerol binds to microtubules. Although this would appear to be a reasonable conclusion, since glycerol is used to stabilize microtubules (Solomon, et al., 1973), the effect of glycerol has primarily been taken to involve destabilization of tubulin subunits. That is, results from studies of the effect of glycerol on the apparent specific volume of tubulin (Na and Timasheff, 1981) were interpreted as proving that glycerol is preferentially excluded from the solvation sphere of tubulin dimers. This increase in the chemical potential of tubulin (and glycerol) is presumably relieved by a shift of tubulin from dimer to microtubule. According to this model, the dramatic reduction by glycerol of the rate of dilution-induced disassembly (Caplow et al., 1986; O'Brien and Erickson, 1989) results because glycerol destabilizes the transition state for disassembly, since this transition state resembles tubulin subunits. However, equally likely is the possibility that glycerol binds to and stabilizes microtubules.

As to the mechanism through which glycerol and glutamate accelerate hydrolysis of GMPCPP in microtubules, we propose that interaction of these compounds with the microtubule induces a protein conformation change. It is suggested GMPCPP is ordinarily stable because the different stereochemistry of the methylene linkage between the alpha and beta phosphate groups alters the position of the gamma phosphate, so it is remote from the residues responsible for catalysis. A protein conformation change may move the phosphate group to the active site for catalysis. The different rates of glycerol-induced hydrolysis with Na and K-Pipes is unaccounted for.

It is noted that GMPCP-microtubules formed by glycerol-induced hydrolysis in GMPCPP-microtubules did not have identical kinetic properties as microtubules formed with GMPCP. The disassembly rates at the two ends were 146 s^{-1} rate and 5 s^{-1} after glycerol treatment (Table III), compared to 128 s^{-1} and 63 s^{-1} with microtubules that had been assembled with tubulin-GMPCP. This difference may result from the ~17% of the GMPCPP that remained after treating GMPCPP-microtubules with glycerol (see discussion of results in Table I). We suggest that the slower rate at one end with glycerol-treated microtubules results because the residual sticky tubulin-GMPCPP subunits that escape hydrolysis slow down the rate. The effect of these tubulin-GMPCPP subunits may be different at the two ends because the unhydrolyzed nucleotide interfaces with the solution at the plus end and with the core of the microtubule at the minus end (Mitchison, 1993).

We are grateful to Harold Erickson for helpful comments on the manuscript and to Tim Mitchison, who used his tubulin and our reagents to repeat our study of the effect of glycerol on GMPCPP hydrolysis. These experiments allowed us to identify the role of sodium and potassium in hydrolysis of GMPCPP in microtubules. Don Cleveland's editorial assistance is greatly appreciated.

This work was supported by the National Institutes of Health (GM46773).

Dedicated to Gian Fausto Dell'Antonio on his sixtieth birthday

Abstract

The Hubbard model of interacting electrons, like the Ising model of spin-spin interactions, is the simplest possible model displaying many "real world" features, but it is much more difficult to analyze qualitatively than the Ising model. After a third of a century of research, we are still not sure about many of its basic properties. This mini-review will explore what is known rigorously about the model and it will attempt to describe some open problems that are possibly within the range of rigorous mathematical analysis.

0. Introduction

The Hubbard model is to the problem of electron correlations as the Ising model is to the problem of spin-spin interactions; it is the simplest possible model displaying many "real world" features. It is, however, much more difficult to analyze qualitatively than the Ising model. After a third of a century of research, we are still not sure about many of its basic features. It is believed, for example, to have something to do with high temperature superconductivity, and it would be nice to validate this.

One of the most intriguing questions concerns magnetism — particularly the magnetic properties of the ground state. The familiar models of interacting spins, such as the Ising or Heisenberg models, posit an underlying spin Hamiltonian that ultimately comes from a model of itinerant electrons. The mystery here is that neither the electronic kinetic nor the electronic potential energies favor ferromagnetism, but together they sometimes do so. Ferromagnetic spin models, for example, are popular, but the truth is that the antiferromagnetic preference of the kinetic energy usually seems to dominate. In fact the only known examples of saturated itinerant electron ferromagnetism come from the

Hubbard model in a special limit (infinite repulsion and one hole) devised by Nagaoka [NY] or from the Hubbard model with finite repulsion but on special lattices devised by Mielke and Tasaki [Mi1, TH2, MT] for which the kinetic energy spectrum is macroscopically degenerate. No doubt, further study of the Hubbard model will eventually lead to a better understanding of the way in which the Pauli exclusion principle leads to magnetism.

These notes will explore what is known rigorously about the model and it will attempt to describe some open problems that are possibly within the range of rigorous mathematical analysis. The notes are not a complete review in the sense that every contribution is covered, but an attempt has been made to mention, at least, most topics that can be treated rigorously. I apologize to those authors whose works have been omitted and I hope this will be attributed to my ignorance rather than intent. Given more space I would have liked to discuss the closely related Falicov-Kimball model, for which many rigorous results are known, but which is not a Hubbard model because it does not have $SU(2)$ symmetry. Another interesting chapter would be the infinite dimensional Hubbard model—pioneered by Metzner and Vollhardt [MV]—and which opens exciting mathematical and physical avenues. It has led to a large literature, but much remains to be added in the way of mathematical rigor.

I thank Peter Eckle, Walter Metzner and Hal Tasaki for critically reading this manuscript and I thank Bálint Tóth for considerable help with the bibliography.

1. Definition of the Model

Only the original short-range Hubbard model will be considered here. Like the Ising model, the Hubbard model is defined on a graph, i.e., a collection of vertices or sites (denoted by Λ and whose number is $|\Lambda|$) and (unordered) edges or bonds connecting certain distinct pairs of vertices. The word graph instead of lattice is used to avoid any possible implication of translation invariance because most of the results stated here do not depend on such invariance. One is given a **hopping matrix** T, with elements t_{xy}, with x and $y \in \Lambda$, and we assume, as a convention, that $t_{xy} = 0$ if x, y are not connected by an edge. Note that $t_{xx} = 0$. t_{xy} might be complex, signaling the presence of a magnetic field, the line integral of whose vector potential from x to y (thought of now as points in $\mathbf{R}^3$) is $\arg(t_{xy})$. However, T is always self adjoint, $t_{xy} = t^*_{yx}$, with $*$ denoting complex conjugate.

The **bipartite** graphs form an important sub-class; here $\Lambda = A \cup B$, with A and B disjoint, and such that there is no edge between x, y if $x \in A$ and $y \in A$ or if $x \in B$ and $y \in B$. The square lattice is bipartite, the triangular is not.

Electrons, i.e., spin $\frac{1}{2}$ fermions, move on Λ with kinetic energy given in second quantized form by $K = K_\uparrow + K_\downarrow$ with

$$K_\sigma = -\sum_{x,y\in\Lambda} t_{xy} c^\dagger_{x\sigma} c_{y\sigma}. \tag{1.1}$$

Here $\sigma = \pm 1$ denote the two spin states $\uparrow$ and $\downarrow$ while $c^\dagger_{x\sigma}$ is the creation operator for an electron at x with spin σ. We have $c^\dagger_{x\sigma}c_{y\tau} + c_{y\tau}c^\dagger_{x\sigma} = \delta_{xy}\delta_{\sigma\tau}$ and $c_{x\sigma}c_{y\tau} + c_{y\tau}c_{x\sigma} = 0$. The number operator is defined by $n_{x\sigma} = c^\dagger_{x\sigma}c_{x\sigma}$ and has eigenvalues 0 and 1. The total number of each spin species

$$N_\sigma = \sum_{x\in\Lambda} n_{x\sigma}$$

is a conserved quantity. The total particle number is $N = N_\uparrow + N_\downarrow$ which satisfies $0 \leq N \leq 2|\Lambda|$. The **half-filled band**, $N = |\Lambda|$ is especially important and especially amenable to analysis.

In the physics literature it is often assumed that $t_{xy} = \text{constant} = t > 0$ on all edges of Λ, in which case T is a discrete version of the Laplacian, but without the diagonal terms. This assumption will not generally be made here.

At each site x there is also given a number U_x which governs the on-site electron-electron interaction at x. We usually assume all $U_x \geq 0$ (repulsive case) or all $U_x \leq 0$ (attractive case). The total potential energy is[†]

$$W = \sum_{x\in\Lambda} U_x(n_{x\uparrow} - \tfrac{1}{2})(n_{x\downarrow} - \tfrac{1}{2}). \tag{1.2}$$

The total Hubbard Hamiltonian of our system is then

$$H = K + W, \tag{1.3}$$

and most of the results discussed here are about the ground state of this H. In fact, many of the results do not require a point interaction as in (1.2); instead, terms like $U_{xy}(n_{x\uparrow} - \frac{1}{2})(n_{y\downarrow} - \frac{1}{2})$, with the matrix U_{xy} being positive semidefinite, are also allowed.

The interaction in (1.2) includes a one-body term $-\frac{1}{2}\sum_x U_x(n_{x\uparrow} + n_{x\downarrow})$ plus a trivial constant term $\frac{1}{4}\sum_x U_x$. If U_x is independent of x, as is normally assumed in almost all papers on the subject, then this one-body term is trivially a constant proportional to the fixed particle number. It is interesting to consider $U_x \neq$ constant, and the one-body term is included in (1.2) in order to be able to exploit **hole-particle symmetry**: The unitary transformation that maps $c_{x\downarrow} \to c^\dagger_{x\downarrow}$ and $c^\dagger_{x\downarrow} \to c_{x\downarrow}$ (but $c_{x\uparrow} \to c_{x\uparrow}$) is the hole-particle transformation on the down-spins and it maps $(n_{x\downarrow} - \frac{1}{2})$ into $-(n_{x\downarrow} - \frac{1}{2})$. Thus, this transformation maps the repulsive W into the attractive W and vice versa, but it changes the down-spin number from $N_\downarrow$ to $|\Lambda| - N_\downarrow$.

This hole-particle transformation may or may not map $K_\downarrow$ into $K_\downarrow$. It does map $K_\downarrow$ into $\widehat{K}_\downarrow$, defined by $\widehat{t}_{xy} = -t^*_{yx}$.

[†] The usual formulation is $n_\uparrow n_\downarrow$ instead of our $(n_\uparrow - \frac{1}{2})(n_\downarrow - \frac{1}{2})$. If U_x varies with x the two formulations are obviously inequivalent. The formulation here is not without a physical foundation because a neutral atom (with $n_\uparrow + n_\downarrow = 1$) is locally the most stable configuration and adding or removing an electron produces a net local charge that raises the energy roughly equally.

In the special, but important case that T is real and Λ is bipartite we can make a further unitary transformation that will take $\widehat{K}_\downarrow$ into $K_\downarrow$ and $n_{x\downarrow}$ into $n_{x\downarrow}$. This unitary transformation maps $c_{x\downarrow}$ into $(-1)^x c_{x\downarrow}$ (and, of course, $c_{x\uparrow}$ into $c_{x\uparrow}$), where $(-1)^x$ denotes the function on the vertices of Λ which is $+1$ for $x \in A$ and -1 for $x \in B$. Effectively, t_{xy} is mapped into $(-1)^x(-1)^y t_{xy} = -t_{xy}$ for the down-spins. Henceforth, the hole-particle transformation on bipartite lattice is always meant to include this additional unitary $(-1)^x$, so that $K_\downarrow$ is mapped into $K_\downarrow$.

Thus, in the special real, bipartite case we can analyze the repulsive case by analyzing the attractive case. But we have to remember that $N_\downarrow \leftrightarrow |\Lambda| - N_\downarrow$ so that the particle number for one is related to the magnetization of the other. This is a non-trivial distinction and is similar to the relation between the ferromagnetic and antiferromagnetic Ising models on a bipartite graph.

The hole-particle transformation also induces a conservation law in the real, bipartite case that has no classical analogue. Like any electron system this model has an $SU(2)$, i.e., angular momentum, invariance. The generators are

$$J^3 = \tfrac{1}{2}(N_\uparrow - N_\downarrow), \qquad J^+ = \sum_{x\in\Lambda} c^\dagger_{x\uparrow} c_{x\downarrow}, \qquad J^- = (J^+)^\dagger. \tag{1.4}$$

However, the Hamiltonian H in (1.3) is the unitary transform (described above) of another H' (with U_x replaced by $-U_x$) which also has an $SU(2)$ symmetry with generators given by (1.4) in the *transformed* basis. By transforming back we obtain a different set of $SU(2)$ generators

$$\widehat{J}^3 = \tfrac{1}{2}(N_\uparrow + N_\downarrow - |\Lambda|), \qquad \widehat{J}^+ = \sum_{x\in\Lambda} (-1)^x c^\dagger_{x\uparrow} c^\dagger_{x\downarrow}, \qquad \widehat{J}^- = (\widehat{J}^+)^\dagger \tag{1.5}$$

that also commute with H and with the J's in (1.4). We call this the **pseudospin**. This special model thus has an $SU(2)\times SU(2)$ symmetry group,[§] but it must be emphasized that real T is *essential* (zero magnetic field). These operators change the quantum numbers $N_\uparrow$ and $N_\downarrow$. The operators $J^\pm$ change J^3 by one unit while $\widehat{J}^\pm$ change $\widehat{J}^3$ by one unit. The four operators together thus permit us to move around inside rectangles in $(N_\uparrow, N_\downarrow)$ space whose four vertices have the form $(n,m), (m,n), (|\Lambda|-n, |\Lambda|-m), (|\Lambda|-m, |\Lambda|-n)$. This means that to each eigenstate for $N_\uparrow = n$, $N_\downarrow = m$ there is a corresponding eigenstate with the same energy at each point in the rectangle (there are also additional eigenstates, of course). Thus, the usual operators $J^\pm$ permit us to infer all the states of our Hamiltonian from knowledge of the states on the line $N_\uparrow - N_\downarrow = 0$ or the line $N_\uparrow - N_\downarrow = 1$. The pseudospin

[§] Actually, the group is $SO(4) = SU(2)\times SU(2)/Z_2$, as pointed out by Yang and Zhang [YZ]. The reason is that the two operators $w = -\mathbf{1}$ in each $SU(2)$ corresponds to only *one* operator on our Hilbert space, i.e., $w \otimes \mathbf{1} = \mathbf{1} \otimes w$. This reduction to $SO(4)$ coincides with the observation that in every state the spin and pseudospin are either both integral or both half-integral.

operators $\widehat{J}^{\pm}$ permit us to infer everything from knowledge of the line $N_\uparrow + N_\downarrow = |\Lambda|$ (half-filled band) or the line $N_\uparrow + N_\downarrow = |\Lambda| + 1$. But we repeat that this property of $\widehat{J}^{\pm}$ holds *only* for the real, bipartite case.

We note, for future use, that the hole-particle transformation (*without* $(-1)^x$) applied to *both* spins (namely $c_{x\sigma} \leftrightarrow c^\dagger_{x\sigma}$). does not preserve $\vec{J}$. Indeed, $J^3 \to -J^3, J^\pm \to -J^\mp$, but $\mathbf{J}^2 \to \mathbf{J}^2$.

The Hubbard model describes — in the simplest possible fashion — an interacting fermion system. It can be viewed this way, as a toy model, or it can be viewed, a bit more realistically in the repulsive case, as a serious model of π-electrons hopping between localized Wannier orbitals in some molecule such as benzene (with $|\Lambda| = 6$); the half-filled band, $N = |\Lambda|$, is then especially important because it corresponds to neutrality. The ultra-short range interaction is supposed to mimic a highly screened Coulomb potential. From the latter viewpoint it was known first in the chemistry literature as the Pariser-Parr [PP]-Pople [PJ] model; molecules having a bipartite structure are called "alternant molecules". It was a decade later that Hubbard [HJ], Gutzwiller [GMC] and Kanamori [KJ] realized its importance for bulk matter.

2. One-Dimensional Exactly Solvable Model

In 1968 the ground state of H was solved for the translation invariant one-dimensional ring by Lieb and Wu [LW] using the extension of the "Bethe ansatz" technique [BH, LL1] to fermions [MJ, FL1, YC, GM]. Shortly thereafter, Ovchinnikov [OA] used these results to calculate the elementary excitation spectrum at half filling. Recently, Essler and Korepin [ES] obtained a new and illuminating derivation. Coll [CC] extended Ovchinnikov's results to arbitrary filling, as did Woynarovich [WF]. Takahashi [TM] evaluated the magnetism curve at half filling and Shiba [SH] evaluated the magnetic susceptibility for all filling. Koma [KO] has formulated a sequence of approximations to the positive temperature free energy and correlation length (obtained by using the Trotter product formula for the partition function) which converge to the exact answer and such that each approximation can be calculated using the Bethe ansatz without any assumptions, such as the "string hypothesis".

These results were obtained in the thermodynamic limit, in which sums could be replaced by integrals. Woynarovich and Eckle [WE] evaluated the asymptotics of finite size effects on the ground state energy. For small chains the general "Bethe ansatz" solution, while correct, is too complicated for numerical evaluation. Heilmann and Lieb [HL] undertook to evaluate *all* the energy levels for *all* $U > 0$ for the benzene molecule ($N = 6, |\Lambda| = 6$). To our surprise we found many instances of both level crossings and of permanent degeneracy — as a function of U — and which were not accounted for on the basis of the known invariance groups (spin, pseudospin and symmetries of the hexagon). This means that the system has *non-abelian* symmetry groups and these *are dependent on* U (i.e., the group operations commute with H but *not* with K and W separately; a

well known example of this phenomenon, for the hydrogen atom, is the Runge-Lenz vector whose definition depends on the value of the electron's charge).

What are these invariants? Sixteen years later Shastry [SB] (unaware of [HL]) found many invariants and also a two-dimensional classical statistical mechanics vertex model whose transfer matrix commutes with our H. In fact he found a whole commuting family of such transfer matrices — which means that the one-dimensional model can be called "integrable". It is not clear whether all invariants of H are of Shastry's form. A few years later, Grosse [GH] (motivated by [HL]) published another derivation of some of the invariants.

Another interesting question is whether all the eigenstates of H are of the "Bethe ansatz" form. This was answered in the negative by Essler, Korepin and Schoutens [EKS] who went on to demonstrate that when the ring is bipartite (i.e., even length) the $SU(2) \times SU(2)$ generators J^+ and $\widehat{J}^+$ save the day. The lowest weight states (the ones that are annihilated by J^- and $\widehat{J}^-$) are claimed to be *all* of the "Bethe ansatz" type. All the remaining states are then obtained by application of J^+, and $\widehat{J}^+$.

Many of the "Bethe Ansatz" results rely on a "string" hypothesis. Moreover, some assertions in [EKS], notably the linear independence of the solutions, rely on an appeal to some properties of Shastry's invariants that have not been verified. It is desirable to put these matters on a more rigorous basis.

The literature about this one-dimensional solution is vast and the above remarks do not reflect everything that is known about the subject.

3. Magnetism

A. One-Dimension.

It is convenient, now, to take an open chain instead of a ring. Then, by a general theorem of Lieb and Mattis [LM1], whose proof also works for lattice systems with nearest neighbors hopping and a *completely arbitrary* many-body potential, $E^N(S)$, the ground state energy of H, as a function of total spin $S \leq \frac{1}{2}N$ and for N particles, satisfies

$$E^N(\tfrac{1}{2}N) > E^N(\tfrac{1}{2}N-1) > E^N(\tfrac{1}{2}N-2) > \ldots > E^N(0) \text{ or } E^N(\tfrac{1}{2}). \tag{3.1}$$

The numbers U_x are now totally arbitrary and not necessarily of one sign. [Note: The original theorem [LM1] uses a Perron-Frobenius positivity argument, which a-priori requires $t_{xy} > 0$. However, any T can be reduced to this form in one-dimension by the simple unitary gauge transformation $c_{x\sigma} \to \exp[-i\theta(x)]c_{x\sigma}$, which carries t_{xy} into $\widehat{t}_{xy} := t_{xy}\exp[i\theta(x) - i\theta(y)]$, where $\theta(x)$ is an arbitrary real number, selected so that $\widehat{t}_{xy} > 0$ for all x and y.] Since we can then take T to be real, our H is then the (down-spin) hole-particle transform of some other $\widehat{H}$, in which U_x is replaced by $-U_x$. Assuming N to be even, (3.1) says that the ground state of H has $N_\uparrow = N_\downarrow = N/2$. The transformed $\widehat{H}$ system has $\widehat{N}_\uparrow = N_\uparrow$, $\widehat{N}_\downarrow = |\Lambda| - N_\downarrow$, whence $\widehat{S}^3 = \frac{1}{2}(\widehat{N}_\uparrow - \widehat{N}_\downarrow)$ is the predetermined

number $\frac{1}{2}(N - |\Lambda|)$. The $\widehat{H}$ system also satisfies (3.1) since it is one-dimensional, and the spin of the ground state of the $\widehat{H}$ system is therefore

$$\widehat{S} = \tfrac{1}{2}\big|N - |\Lambda|\big|.$$

This number, $\widehat{S}$, is *the pseudospin of our ground state* — a curious result whose physical significance is not entirely obvious. (Note the logic here. Both systems, H and $\widehat{H}$ must be in their respective ground states, consistent with the given conditions on each; for H it is $N_\uparrow + N_\downarrow = N$ and for $\widehat{H}$ it is $N_\uparrow - N_\downarrow = N - |\Lambda|$.)

This theorem was extended many years later by Aizenman and Lieb [AL] to positive temperatures. The main theorem, applicable to any many-body potential in a one-dimensional system, expresses the fact that the free energy is a monotone increasing function of the spin. This is done in terms of total spin S or 3-component s, as follows; neither inequality implies the other.

Classify the eigenstates by the 3-component of spin, $J^3 = s = \frac{1}{2}(N_\uparrow - N_\downarrow)$, and by S, the total spin angular momentum (recall $\mathbf{J}^2 = S(S+1)$). For a given N and inverse temperature β, let $Z_3(s) = \mathrm{Tr}_s e^{-\beta H}$ be the partition function in which only states of a given s value are included. Likewise, let $Z_J(S) = \mathrm{Tr}_S e^{-\beta H}$ be the partition function for a given S. We have the relation $Z_3(S) - Z_3(S+1) = (2S+1)^{-1} Z_J(S)$, which is obvious from the theory of angular momentum. Correspondingly, we have the combinatorial quantities $Y_3(s) := \binom{N}{\frac{N}{2}+s}$ and $Y_J(S) := (2S+1)[Y_3(S) - Y_3(S+1)]$, which are essentially the partition functions of free particles with $H = 0$, and which serve to normalize the Z's. The two theorems are then that

$$\frac{Z_3(s)}{Y_3(s)} \quad \textit{and} \quad \frac{Z_J(S)}{Y_J(S)}$$

are *both strictly monotone decreasing functions of their arguments* (s or S). A corollary of this is that the magnetization is less than its value in the **atomic limit** (or what I prefer to call the pure paramagnetic value). I.e., for all β and magnetic field h

$$M(\beta, h) = \frac{1}{\beta}\frac{\mathrm{d}}{\mathrm{d}h}\ln Z(h) < N\tanh(\beta h). \tag{3.2}$$

Here $Z(h) = \sum_{s=-N/2}^{N/2} Z_3(s)\exp[2\beta s h]$ is the total partition function (recall that the g-factor of an electron is 2).

It is noteworthy that all this holds for *completely arbitrary*, Hermitian t_{xy} and (real) U_x. Indeed, it holds even if we add an arbitrary real one body potential

$$V = \sum_{x\in\Lambda} V_x(n_{x\uparrow} + n_{x\downarrow}).$$

An amusing fact about one-dimension concerns the $U = +\infty$ case. For an open chain the ground state is highly degenerate—indeed, it can have any value of S. For a closed

chain the situation is quite different and the S of the ground state depends on the sign of the t_{xy}'s and whether N is even or odd; S can be $N/2$ in some cases [AL]. The situation is discussed in detail by Mielke [Mi2] who finds that the "average" S is $\sqrt{N}$. Some interesting facts about the closed one-dimensional chain with $U = 0$, but with a magnetic field, can be found in [LL2]. The $U \neq 0$ case is discussed by Fujimoto and Kawakami [FK1].

B. Half-Filled Band.

The hole-particle symmetry notwithstanding, the repulsive case (all $U_x \geq 0$) and the attractive case (all $U_x \leq 0$) are quite different, even for a bipartite lattice. The physical spin of one is the pseudospin of the other.

In the limit $U \to +\infty$ (by which I mean all $U_x \to +\infty$), the energy and wave functions have nice limits. The electrons become hard-core particles. When $N = |\Lambda|$ we just have one electron per site and, since motion is impossible, each electron can be, independently, spin-up or spin-down. This gives us the atomic limit whose partition function is Y_3 or Y_J given above. First order perturbation theory in t/U vanishes, but in second order we have to diagonalize our H among all the $2^{|\Lambda|}$ degenerate ground states just described. This yields an effective Hamiltonian H' that can be written in terms of the three Pauli spin operators $\mathbf{S}$ at each site. It turns out [AP] that for any graph

$$H' = \sum_{x,y \in \Lambda} J_{xy}(\mathbf{S}_x \cdot \mathbf{S}_y - \tfrac{1}{4}) \tag{3.3}$$

with $J_{xy} = |t_{xy}|^2(U_x^{-1} + U_y^{-1})$. This is the spin 1/2 antiferromagnetic Heisenberg Hamiltonian and it is known [LE1, LM2] that its ground state has total spin

$$S = \big||A| - |B|\big| \tag{3.4}$$

on a bipartite graph. It is also known [DLS, KLS] that in the **translation invariant case** (i.e., our graph is a D-dimensional hypercube with periodic boundary conditions and $t_{xy} = \text{constant} = t$ and $U_{xy} = \text{constant} = U$) there is long range order when $D \geq 3$.

The obvious question is whether the results just stated (i.e., (3.4) and the long range order) hold non-perturbatively in the repulsive case. One would also guess that in the attractive case the total spin should be zero in the ground state because when $U_x = -\infty$ for all x the ground state consists simply of bound pairs of electrons sitting on selected sites. These questions about the spin are answered in the following [LE1].

Theorem 1: *Assume t_{xy} is real for all $x, y \in \Lambda$. If $U_x < 0$ for all x, the ground state on any connected graph is unique and has spin $S = 0$* for any even electron number, N, not just $N = |\Lambda|$. *If $U_x > 0$ for all x, if Λ is connected and bipartite and if $N = |\Lambda|$ is even, the ground state is unique (except for the $(2S+1)$-fold degeneracy) and has spin $S = \frac{1}{2}\big||A| - |B|\big|$.*

We can easily have $|A| - |B|$ of the order of $|\Lambda|$ itself. As an example, take a square lattice and add a site at the center of each bond of this square lattice. The original sites

are then B sites and the new sites are A sites. Then $|A| = 2|B|$ and the ground state has a bulk magnetization per site of 1/3. This is really more like ferrimagnetism than ferromagnetism but, in any case, it is one of the few examples known in which the system has a bulk magnetization without an external magnetic field.

There is an interesting corollary of this theorem if Λ is bipartite and if $|A| \geq |B|$. Suppose we ask for the absolute minimum energy, without fixing N. Starting with $U_x > 0$ we find that an optimum N is $N = |\Lambda|$ (by the $SU(2) \times SU(2)$ symmetry mentioned in Sec. 1). But $J^3 = (N_\uparrow - N_\downarrow)/2$ can be anywhere in the interval $(|B|-|A|)/2$ to $(|A|-|B|)/2$ since $S = (|A|-|B|)/2$. Now using hole-particle symmetry to obtain the $U_x < 0$ model, we find that the optimum N is any integer satisfying $2|B| \leq N \leq 2|A|$. (E.g., starting with $N_\uparrow = |A|, N_\downarrow = |B|$, the transformed values are $N_\uparrow = |A|, N_\downarrow = |\Lambda| - |B|$, which yields $N = 2|A|$.) Thus, *there can be a large degeneracy in the attractive case!* (For $U = 0$ this is easily seen from the remark that T has at least $|A| - |B|$ zero eigenvalues.)

This theorem was extended to positive temperature by Kubo and Kishi [KK] who found upper bounds on certain two-point functions. They discuss only the translation invariant case on a hypercubic lattice with $U_x = U =$ constant, but their method easily extends to the general case. For $U < 0$ they bound the spin susceptibility at wave vector q by

$$\chi_q \leq \frac{1}{4|U|} \tag{3.5}$$

for all temperatures and all filling fraction $N/|\Lambda|$ (more precisely, they use the grand canonical ensemble and prove (3.5) for all chemical potentials μ). This result precludes magnetic long range order. In the repulsive case $U > 0$, and with μ adjusted to the half-filled band case $N = |\Lambda|$, namely $\mu = 0$, they bound the charge susceptibility as

$$(\delta\widehat{n}_q, \delta\widehat{n}_{-q}) \leq (\beta U)^{-1} \tag{3.6}$$

and the pairing susceptibility as

$$(\widehat{p}_q, \widehat{p}_{-q}) \leq (\beta U)^{-1}. \tag{3.7}$$

Here (A, B) is the Duhamel two-point function $(A, B) = \int_0^1 \mathrm{Tr}[A^\dagger e^{t\beta H} B e^{(1-t)\beta H}]\, dt$ and $\delta\widehat{n}_q = \widehat{n}_q - \langle\widehat{n}_q\rangle$ and $p_x = c^\dagger_{x\uparrow} c_{x\downarrow}$ and $\widehat{\ }$ denotes spatial Fourier transform. Charge long range order is precluded by (3.6) while Cooper pairing is precluded by (3.7).

Although I am restricting this review to the Hubbard model, I cannot resist the temptation to mention that Theorem 1 has recently been extended [FL2] to another model—the Holstein model—in which electrons interact with a quantized phonon field instead of with each other. Again, the finite system ground state for any even number of electrons is unique and has zero spin. The method of proof of Theorem 1 has also been used by Ueda, Tsunetsugu and Sigrist [UTS] to show that the periodic Anderson model at half-filling has a singlet ground state.

This close connection between the half-filled band, repulsive Hubbard model and the antiferromagnetic Heisenberg model points to the first of our spin problems. The antiferromagnetic Heisenberg model on a hypercubic lattice, in the thermodynamic limit, has no long range order (LRO) at positive temperature in dimensions $D = 1$ or 2. This is a consequence of the Hohenberg-Mermin-Wagner theorem. The same is true for the Hubbard model as first shown by Walker and Ruijgrok [WR], then by Ghosh [GD]. Later, Koma and Tasaki [KT]proved it by a different method—that of McBryan and Spencer [MS]. As far as the ground state is concerned, the Heisenberg model has LRO for $D = 2$ and spin 1 or more per site [KLS] (i.e. $|\mathbf{S}_x|^2 = S(S+1)$ and $S \geq 1$) and it is believed to have LRO also when $S = 1/2$, which is the case of interest for us. The $D = 1$ case is believed to have no LRO in the ground state. For $D \geq 3$ there is LRO in the ground state for all $S \geq 1/2$ [KLS] and at positive temperature [DLS, KLS] for $S \geq 1$ (presumably, also for all $S \geq 1/2$). The obvious conjecture is the following.

Problem 1: *Prove that there is antiferromagnetic LRO in the half-filled band, repulsive Hubbard model on the hypercubic lattice (with $t_{xy} = 1$ for $|x - y| = 1$ and $U_x =$ positive, finite constant) in the ground state when $D = 2$ and for positive temperature when $D \geq 3$. For which values of N will the attractive model have LRO?*

The Falicov-Kimball [FK2] model poses an analogous problem that *can be solved* affirmatively. In this model, one kinetic energy term, $K_\downarrow$, is omitted from the Hamiltonian. Although the down spins are not dynamic their locations are left arbitrary. After "integrating out" the movable particles (up-spins), an effective interaction among the fixed particles (down-spins) is left. This, then, is a classical lattice gas with a complicated interaction. It resembles an Ising (not Heisenberg) model when U is large and it can be shown [KL] to have long range order at low temperatures (and no long range order at high temperatures) in two or more dimensions—as does the Ising model.

C. The Surprising Hole.

In the previous subsection we considered the half-filled band and showed a strong tendency to antiferromagnetism. The only important requirement on T was that it was real (i.e., no magnetic field acts on the orbital motion). Nagaoka [NY] made a surprising discovery about the case $U = +\infty$, but *with one hole* (i.e., $N = |\Lambda| - 1$). Thouless [TD] had a similar result a bit earlier (cf. note 7 in [NY] and the discussion on p. 47 in [LE2]) but there is little doubt that Nagaoka's presentation of this particular result is clearer, more precise and applicable to certain non-bipartite lattices such as *bcc* and *fcc*. The Thouless approach uses a Perron-Frobenius argument that appears to be restricted to bipartite lattices; for such lattices it is true that fermions behave like bosons when $U = +\infty$ and there is one hole. Nagaoka, on the other hand seems to require a regular Bravais lattice, but this is not really necessary provided *all* t_{xy} are nonpositive. The fully general result with a considerably simplified proof, was given by Tasaki [TH1].

It is usually assumed in the condensed matter literature that the t_{xy}'s are nonnegative, but there seems to be neither a compelling reason for this assumption nor many examples

in which it can be verified (S. Kivelson, private communication). (For a bipartite lattice, however, one can have either sign with the help of the unitary operator $(-1)^x$ applied to *both* spin $\uparrow$ and $\downarrow$.) Notice that $t_{xy} > 0$ puts the lowest kinetic energy at one point, namely $k = 0$, in Fourier space. The condition $t_{xy} < 0$ puts it at the edge of the Brillouin zone, and thus the lowest kinetic energy can be highly degenerate. The physical intuition is then quite different in the two cases—a fact that should not be lost sight of because of the hole-particle symmetry that holds for bipartite graphs. The proof in [TH1] shows that negative, not positive t_{xy} is the *natural mathematical assumption* for this theorem. If this upsets anyone's physical proclivity, that is a pity.

Theorem 2: *If $N = |\Lambda| - 1$, if $U_x = +\infty$ for all $x \epsilon \Lambda$, and if $t_{xy} \leq 0$ for all x, y, then the ground state has total spin $S = N/2$. This state is unique up to the trivial $(N+1)$–fold degeneracy if Λ satisfies a certain connectivity condition [TH1].*

The connectivity condition mentioned above is not stringent and it holds for all regular lattices in dimension greater than one (see also [AL]). Essentially it means that there are loops that permit nontrivial permutations of the particles.

In the case that Λ is completely translation invariant, i.e., that all vertices of Λ are equivalent, as is the case on a hypercubic lattice on a torus, a different proof of the theorem, very similar to Nagaoka's, was given by Tian [TG1] and by Trugman [TS].

The obvious next question to ask is this: *If there is more than one hole $(N < |\Lambda| - 1)$ and $U = +\infty$, is the ground state totally ferromagnetic, i.e., is $S = N/2$?* There can be no simple general theorem because numerical calculation on small systems show that the answer seems to be "no" and, at the same time, no simple pattern seems to emerge. Yet there are a few theoretical results, as follows.

(i) The Nagaoka-Tian-Trugman method can be generalized for $\Lambda =$ the D-dimensional hypercubic lattice with periodic boundary conditions and with $t_{xy} = t =$ nonpositive constant to show [TG2, TG3, TS, SQT] that the completely magnetized state energy, $E(S = N/2; \Lambda)$, when compared to the actual ground state energy, $E(\Lambda)$, satisfies

$$\lim_{\Lambda \to \infty} E(S = N/2; \Lambda) - E(\Lambda) = 0 \tag{3.8}$$

in the thermodynamic limit, $\Lambda \to \infty$, when the number of holes $N_h = |\Lambda| - N$ is not too large. The best result is by Shen, Qiu and Tian [SQT], which gives (3.8) when $N_h < |\Lambda|^\alpha$ with $0 < \alpha < 2/(D+2)$. Note that we do not divide by $|\Lambda|$ in (3.8), which thus truly represents the vanishing of a gap. The proof here is elegant and simple. However, one would expect (3.8) to hold as long as $N_h/|\Lambda| \to 0$ as $|\Lambda| \to 0$.

(ii) If there are many holes, $N_h/|\Lambda| > 0.49$ for the $D = 2$ or $N_h/|\Lambda| > 0.32$ for the $D = 3$ hypercubic lattices, and $\Lambda \to \infty$ as in (i) then

$$E(S = N/2; \Lambda) - E(S = N/2 - 1; \Lambda) \not\to 0. \tag{3.9}$$

There really is an instability of the $S = N/2$ state with respect to one spin flip. This was proved by Shastry, Krishnamurthy and Anderson [SKA]; see also [SA1]. The estimate was

improved to $N_h/|\Lambda| > 0.29$ by von der Linden and Edwards [LvE]; Hanisch and Müller-Hartmann [HM] simplified the calculation (but not the estimate of 0.29).

(iii) Several authors [DW, FRDS, SA1, TB] were able to prove, for a translation invariant hypercubic lattice model, that when there are two holes the ground state energies satisfy $E(S = N/2-1; \Lambda) < E(S = N/2; \Lambda)$. However, assumptions have to be made about the relative lengths of the sides. Sütő [SA1] extended this to $2, \ldots, 6$ holes for a bcc lattice.

(iv) Sütő [SA2] shows, as expected, that the energy splitting needed for demagnetization is, in any case, negligible. He proves that $M(\beta, h, \rho)$, the magnetization per site in field h at density $\rho = N/|\Lambda|$ satisfies (in the thermodynamic limit) $M(\beta, h, \rho) \to \tanh(\beta h)$ as $\rho \to 1$.

The results in (ii) and (iii) are achieved with a variational calculation. The value of $E(S = N/2; \Lambda)$ is easy to find exactly because it equals the energy of spinless electrons, i.e.,

$$E(S = N/2; \Lambda) = \sum_{j=1}^{N} \lambda_j(T) \tag{3.10}$$

for any Λ and hopping matrix, T, and in which $\lambda_1(T) \leq \lambda_2(T) \leq \cdots$ are the eigenvalues of T. Thus, the hard problem is to find a good variational function with $S = N/2 - 1$, and this appears to be extraordinarily difficult. Why? No one seems to know! And why is it so difficult to treat $S = N/2 - 2$?

These results, (i)–(iii), show that one cannot expect $S = N/2$ except when $N = |\Lambda|-1$, but one can ask the following.

Problem 2: *With $U = +\infty$, for which $\rho := N/|\Lambda|$ is it true that some (if there is more than one) ground state has $S/|\Lambda| > 0$ in the thermodynamic limit $\Lambda \to \infty$?*

This brings us to two more open problems about the $U = +\infty$ case; the first is a corollary of the second. We take a large Λ and N particles and suppose that the thermodynamic limit $\Lambda \to \infty$ with $\rho = N/|\Lambda|$ fixed is well defined. We set $S =$ spin of the ground state (the maximum such spin if there is more than one ground state) and we set $S_{\max} = N/2$. We also assume that $t_{xy} \geq 0$ for all x and y. Then

Problem 3: *Prove or disprove that*

$$\lim_{\rho \to 0} \lim_{\Lambda \to \infty} \quad S/S_{\max} = 0. \tag{3.11}$$

Problem 4: *Does there exist some number $\rho_c > 0$ such that*

$$\lim_{\Lambda \to \infty} \; S/S_{\max} = 0 \;\; \textit{for all } \rho < \rho_c \,? \tag{3.12}$$

The requirement that $t_{xy} \geq 0$ is important. As we shall see in Sect. D, Mielke's work shows that there can be nice, periodic lattices in any dimension (such as the kagome lattice in two-dimensions) for which $S = S_{\max}$ for all $\rho < \rho_c$ with $\rho_c > 0$, thereby contradicting (3.11) and (3.12). To achieve this, however, one needs $t_{xy} \leq 0$. Perhaps (3.11) and (3.12)

hold in the case $t_{xy} \leq 0$ if we replace "maximum such spin" by "average of such spins", because Mielke's and Tasaki's examples have highly degenerate ground states with spins ranging from 0 to $N/2$.

Closely related in spirit to Theorem 2, but with an interesting, different proof, is the result of Chakravarty, Chayes and Kivelson [CCK]. They start with a half-filled band, $N = |\Lambda|$, and U large. Then they add or subtract one or two particles, and define $E_n := E(N = |\Lambda| + n)$ for $-2 \leq n \leq +2$. They then define

$$\Delta_e = 2E_1 - E_2 - E_0$$

$$\Delta_h = 2E_{-1} - E_{-2} - E_0. \tag{3.13}$$

The interpretation of Δ_e is as a 2-particle binding energy, while that of Δ_h is as a 2-hole binding energy. The picture of Δ_e, for example, is that given two very large systems at half-filling, and given two extra electrons, is it energetically favorable to add the two electrons to one system ($\Delta_e > 0$), or is it favorable to add one electron to each system ($\Delta_e < 0$)? The former, $\Delta_e > 0$, connotes **pair binding**.

It is pointed out in [CCK] that $\Delta_e \leq 0$ and $\Delta_h \leq 0$ when $U = 0$, but they quote numerical studies showing that $\Delta_e > 0$ and $\Delta_h > 0$ for some U and some Λ. They prove, however, that in the limit $U \to \infty$, $\Delta_e \leq 0$ if all t_{xy} are nonnegative and $\Delta_h \leq 0$ if all t_{xy} are nonpositive. For a bipartite graph the sign does not matter (as long as all t_{xy} are positive or all are negative), and thus $\Delta_e \leq 0$ and $\Delta_h \leq 0$ in this case. They interpret this result to mean that the numerical positive binding results are only an intermediate U phenomenon but, strictly speaking, the (unlikely) alternatives $\Delta_e = 0$ and $\Delta_h = 0$ in their theorems would first have to be eliminated.

D. Another Path to Ferromagnetism.

The one-hole, $U = +\infty$ model is not the only one known to have *saturated* ferromagnetism (i.e., $S = N/2$). Mielke [Mi1] and later Tasaki [TH2] and then both [MT] found interesting, but very special models with this property.

The basic idea is to find a graph Λ and a hopping matrix T such that the lowest eigenvalue of T (call it λ_0) is highly degenerate; in fact we want the degeneracy to be at least N and, to be interesting, we want that to be of the order of $|\Lambda|$. Let N_0 denote the degeneracy of this lowest eigenvalue and denote the space of these eigenfunctions by $\mathcal{H}_0$. If $U_x \geq 0$ for all $x \in \Lambda$, it is easy to see that if $N = N_0$ then

(i) There is a ground state having $S = N_0/2$.

(ii) The state is simply a determinant formed from the N_0 vectors in $\mathcal{H}_0$ and its energy is $N_0\lambda_0$.

(iii) The ground state is unique if certain additional conditions (known to be optimal) are met [Mi1].

If $N < N_0$ the ground state manifold will contain at least one state with $S = N/2$, but perhaps others as well (see [Mi1]).

A comparison with Theorem 1 is interesting, but it is not clear whether or not it is misleading. Note that the $S = \big||A| - |B|\big|/2$ result there for a bipartite graph and a half-filled band was somehow related to the $\big||A| - |B|\big|$-fold degeneracy of the zero-mode of T. Thus, a common feature is degeneracy, and it is often said that itinerant ferromagnetism is associated with atomic or kinetic energy degeneracy. But there are also important differences:

(i) The spin in Theorem 1, while it might be proportional to $|\Lambda|$, is not $N/2 = |\Lambda|/2$.

(ii) No fine tuning of T or of Λ was needed for Theorem 1. All that was needed was the bipartite structure, the positivity of the U_x's and the reality of the t_{xy}'s.

Mielke's way of achieving the degeneracy N_0 is to start with some graph G and then to set $\Lambda = L(G)$, the **line graph of G**, which is defined as follows. Make a mark in the center of every edge of G; those marks will be the sites of $L(G)$. Two sites are connected by an edge in $L(G)$ if the two edges of G on which they reside have a G-site in common. Note that $L(G)$ is never bipartite, except for the trivial case of a ring. A well known example of a line graph is the kagome lattice. (Incidentally, kagome is not a person—it is a pattern of woven bamboo.)

The hopping matrix T is defined to be $-t < 0$ on every edge of $\Lambda = L(G)$. Not only is there a restriction on the magnitude of t_{xy} but we see, once again, that negative t_{xy} is the natural sign—as it is for Theorem 2.

Of course, as Mielke and Tasaki note, and as is also true in Theorem 2, one can convert positive t_{xy} into negative t_{xy} by a hole-particle transformation on both spin $\uparrow$ and spin $\downarrow$. This does not alter the interaction or the total spin, S, but it changes N into $N' = 2|\Lambda| - N$. For positive, t_{xy}, then, we can transform to the negative t_{xy} situation and conclude that $S = N'/2$ when $N' \leq N_0$. This translates into $S = |\Lambda| - N/2$ when $N \geq 2|\Lambda| - N_0$ (and not $\leq$). This construction would yield saturated ferromagnetism, $S = N/2$, only at $N = |\Lambda|$ (half-filled band), provided it were possible to achieve $N_0 \geq |\Lambda|$; this is clearly impossible (unless $T = 0$), so the positive t_{xy} choice does *not* yield the desired saturated ferromagnetism. However, it is still possible to have unsaturated ferromagnetism, i.e. $1 > 2S/N \neq 0$ in the thermodynamic limit. By taking $N = 2|\Lambda| - N_0$ and $S = |\Lambda| - N/2$ we have $2S/N = N_0/(2|\Lambda| - N_0)$. (One *can* reasonably argue, however, that the condition $S = |\Lambda| - N/2$ *is indeed* saturated ferromagnetism because this value of the spin is the maximum possible one when $N > |\Lambda|$, given the constraints of the sytem and given the Pauli principle. The system is constrained by allowing only a limited number of states for the electrons, i.e., two per site. I leave the semantic resolution to the reader.)

The homology of G determines $\mathcal{H}_0$ in a simple way. Pick any closed, self avoiding path in G of even length. This path corresponds, in an obvious way, to a closed path, P, of the same length in $L(G)$. If, now, we take the vector $\phi(x) = 0$ for x not a vertex of P and $\phi(x) =$ alternately $+1$ and -1 as we traverse the vertices of P, we see at once that ϕ is an eigenvector with eigenvalue $-2t$. It is also not hard to prove that $-2t$ cannot be improved, i.e., $\lambda_0 = -2t$. Moreover, this construction yields all of $\mathcal{H}_0$.

In [TH2, MT] essentially the same result as Mielke's (with similar requirements on T) is achieved, but with certain decorated lattices with next nearest neighbor hoppings. The ferromagnetism of [TH2, MT] is shown to be stable under small change of the electron density, by using a "grand canonical ensemble" with a fixed electron density. It is also proved that there is a transition to a paramagnetic phase as one decreases the electron density. Thus (3.11) and (3.12) (with S replaced by its grand canonical average) are proved for these special graphs.

In all cases, the eigenvectors in $\mathcal{H}_0$ can all be taken to have compact support, i.e., each $\phi(x)$ vanishes except on a finite set of sites of Λ, and each such set is independent of Λ once Λ is large enough to include the set. This property leads to the result [MT] that the effective Hamiltonian, in a suitable subspace of states that includes the ground states, can be written exactly as a Heisenberg Hamiltonian.

4. The Flux Phase Problem

Very little seems to be known rigorously about the effect of a magnetic field on the orbital motion, that is, if we set

$$t_{xy} = |t_{xy}| \exp[i\theta_{xy}], \qquad \theta_{xy} = \int_x^y A \cdot ds \tag{4.1}$$

for some vector potential A. The spin of the ground state might well change. The known proofs of Theorems 1 and 2 fail when $A \neq 0$. If, indeed, the spin of the ground state changes then we have a new kind of "magnetic field—spin" interaction, brought about by the Pauli exclusion principle. Indeed, something similar is discussed in the one-dimensional context in [FK1].

The energy certainly does change, and it is by now well known that when $U = 0$ the zero flux state does *not* give the lowest ground state energy. When Λ is a square lattice and when $N = |\Lambda|$, it is conjectured that the *maximum* (!) possible flux, namely π in each square ($t_{12}t_{23}t_{34}t_{41} = -1$ around a square), is optimum. (For a survey of this question and for some rigorous results about it see [LL2].) The same conjecture has been made for $U \neq 0$.

Problem 5: *Solve the flux phase problem for $U \neq 0$ (or even for $U = 0$) for a half-filled band on a square lattice.*

The moral of this story is that the Pauli exclusion principle can really upset our ideas about diamagnetism. For one solitary electron, the imposition of a magnetic field raises the ground state energy. For many electrons it can and does lower the energy. It is trivially true, for example, that when $U = +\infty$ and $N = |\Lambda|$, or $U =$ anything and $N = 2|\Lambda|$, a magnetic field has absolutely no effect on the energy.

5. Uniform Density Theorem

The hole-particle transformation has remarkable consequences for the Hubbard model on a bipartite graph with a half-filled band, $N = |\Lambda|$. The ideas given below are well known to chemists—less so to physicists. They go back to Coulson and Rushbrooke [CR] for the $U = 0$ case, and to MacLachlan [MA] who generalized them to many interacting models—including the Hubbard model as a special case. A simplified proof together with an extension to models involving explicity spin-spin interactions (such as the $t-J$ model), and to the Falicov-Kimball model, is given in [LLM].

The results apply equally to three cases: (a) The canonical Gibbs state with $N = |\Lambda|$; (b) The grand-canonical Gibbs state with zero chemical potential; (c) The ground state with $N = |\Lambda|$ and which is defined, in case of degeneracy, to be the $\beta \to \infty$ limit of the canonical Gibbs state. The one-body density matrix $\rho_\sigma(x, y)$ is the expectation value of $c^\dagger_{x\sigma} c_{y\sigma}$ in the state in question.

Theorem 4: *For a half-filled band on a bipartite lattice, the one-body density matrix for each of the above states satisfies (for each* $\sigma =\uparrow$ or $\downarrow$*).*

$$\rho_\sigma(x, y) = \tfrac{1}{2}\delta_{xy} \qquad \textit{if } x, y \epsilon A \textit{ or } x, y \epsilon B. \tag{5.1}$$

If $x\epsilon A$ and $y\epsilon B$, nothing simple can be said. Note that the theorem does *not* require T to be real, and is thus one of the few theorems that applies to complex t_{xy}. However, a true, physical magnetic field would also act on the electron spins and thereby vitiate the hole-particle symmetry needed for the proof.

The complex case is a bit subtle, for it uses more than just a hole-particle transformation (call it W). It also utilizes the nonlinear antiunitary map J that maps a vector ψ, considered as a polynomial in the $c^\dagger_{x\sigma}$'s applied to the vacuum, into the vector ψ^* corresponding to the polynomial with complex conjugate coefficients. While J is nonlinear, JKJ is linear when K is any linear operator, and $TrJKJ = (TrK)^*$. The antiunitary $Y = JW$ satisfies $Y = JW = WJ$ (and hence $Y^2 = \mathbf{1}$) and $Yc_{x\sigma}Y = Wc_{x\sigma}W$. Most important is the invariance of the Hamiltonian, $YHY = H$, which replaces the hole particle invariance, $WHW = H$, which fails for complex T.

What is the significance of this result? It seems to contradict the conjecture in Problem 1 that there can be antiferromagnetic, i.e., staggered, LRO. Such an ordering can occur only in the thermodynamic limit and it has the property that for every state with ordering $\uparrow\downarrow\uparrow\downarrow\cdots$ there is a state with ordering $\downarrow\uparrow\downarrow\uparrow\cdots$. The point about Theorem 4, applied to the thermodynamic limit, is that for every state with ordering there is an equally good state (obtained by changing boundary conditions) with the opposite ordering, and on the average each site will have the same density for each spin value. In other words, *there is no way to adjust the potentials* U_x *or the hopping matrix* t_{xy} *in a clever way so as to enhance the occupation of certain sites* — in a manner independent of boundary conditions. This stability is remarkable and, although it is not true for real materials, the theorem hints

at some kind of remnant stability that might transcend the overly idealized assumptions needed for its proof.

Problem 6: *Is there any residue of (5.1) when* $N \neq |\Lambda|$?

I. Introduction

Although the importance of the polyelectrolyte character of DNA has been recognized for some time (Felsenfeld & Miles 1967), few of the implications have been explored, primarily because of a lag in translating the breakthroughs in polyelectrolyte theory of the last decade into a form that is well adapted to the analysis of the specialized problems of biophysical chemistry. Perhaps an analogous situation existed in the field of protein chemistry during the period after the formulation and confirmation of the Debye–Hückel theory of ionic solutions but before Scatchard's incorporation of the theory into his analysis of the binding properties of proteins. An achievement for polynucleotide solutions parallel to Scatchard's was recently presented by Record, Lohman, & de Haseth (1976) and further developed and reviewed by Record, Anderson & Lohman (1978). Record and his colleagues have succeeded in the self-consistent incorporation of the central result of the theory of polyelectrolyte solutions – counterion condensation – into the thermodynamic description of multiligate binding. A general conclusion of major importance arising in a systematic way from their analysis is that the release of counterions is a substantial contribution to the driving force for the binding of cationic substances to polynucleotides. A limitation of the thermodynamic approach, however, is a sharply reduced capacity for numerical prediction.

Indeed, polyelectrolyte theory has been a successful example of statistical mechanical methodology, whereby assumptions are made on the molecular level, a molecular model is constructed on the basis of these assumptions, and quantitative information about the behaviour of the model is then derived from well-known computational rules. In optimal cases – and polyelectrolytes present such a case – the parameters of the model are independently known, and then the results of the computation provide *a priori* numerical predictions that may be directly compared with the results of measurement. Good agreement strengthens the belief that the model is an accurate representation of reality; the experimentally observed behaviour has been successfully explained in terms of intermolecular forces and molecular movements. Systematic discrepancy between prediction and observation may also be of value, in so far as specific aspects of physical reality that may have been omitted from the model may be revealed. In this paper I have attempted to extend the theory of polyelectrolyte solutions to cases of

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

interest in polynucleotide chemistry. Its statistical mechanical character, and hence its full predictive and explanatory capability, is retained.

I shall begin with a detailed discussion of the ionic state of an extended polynucleotide structure in an aqueous environment of simple counterions, such as the alkali metal and alkaline earth cations. I shall then develop the concept that in such an environment the polynucleotide is 'potentiated' by its counterions for the spontaneous occurrence of any process that results in the relief of the electrostatic stress on the polynucleotide set up by the repulsive interactions among the phosphate groups. Binding of multivalent cationic substances is only one process of this type. Others include transitions to conformation of lower charge density – the DNA helix–coil transition being the prototypical example – and the tendency of DNA to straighten spontaneously from a locally bent configuration (a thermodynamic consequence of its very long persistence length).

To varying degrees of detail, but always on a molecular, as distinct from thermodynamic, level, I will be able to discuss the binding to polynucleotides of cationic substances as diverse as sodium and magnesium ions, spermine, polylysine, and *lac* repressor. At this stage perhaps it will be forgiven if the variation in mathematical detail is inversely related to the structural complexity of the cation. The analysis of ionic effects on conformational transitions includes those induced by strong electric fields as well as by temperature increases. I have also treated the local bending of DNA as a differential conformational transition to a state of higher charge density. The result suggests that DNA would not be a stiff molecule (on the scale of its persistence length) in the absence of the phosphate repulsions. An obvious corollary is that DNA will collapse, or condense, if sufficient charge neutralization by bound cationic substances occurs.

II. The molecular basis of polyelectrolyte behaviour

A. *Counterion condensation – a directly observable property of polyelectrolytes in solution*

Except for cases involving binding to the bases, the interaction of extended polynucleotide configurations with small ions is governed by the general laws of polyelectrolyte solutions. Indeed, the commonly heard dogma that a polyelectrolyte solution of low normality belongs

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

nevertheless, because of the high counterion concentration in the immediate vicinity of the polymeric chain, to the realm of concentrated salt solutions – about which little or nothing of a general nature can be quantified – has turned out not to be true. All particular effects in the locally concentrated region are subsumed by the general phenomenon of counterion condensation, which, together with ionic screening interactions at long range, familiar from the classical theory of dilute small-electrolyte solutions, provides a framework for polyelectrolyte solutions (Manning, 1969, 1972*a*, 1974, 1977*a*, 1978; Bailey, 1973; Iwasa, 1977) capable of predicting with remarkable accuracy a large variety of measurable properties. The concept of counterion condensation is a radical departure from the ideas that have traditionally dominated the biochemical literature in this field. When first introduced as the basis for polyelectrolyte theory (Manning, 1969), its status as a physically sharp phenomenon, as opposed to a convenient mathematical device, was uncertain. Experimental progress has been rapid, however, and has established condensation as a fundamental physical property of polyelectrolyte solutions. It has become easy, therefore, to avoid all possibility of investing the definition of counterion condensation with an abstract quality, simply by describing its measurement.

Consider therefore the following ultrasonic absorption experiment (Zana *et al.* 1971). NaOH is added to an aqueous solution of carboxymethylcellulose (CMC), initially in its completely protonated form. No differential ultrasonic absorption (with respect to titration with tetramethylammonium hydroxide) can be detected until the titration has proceeded to a critical extent of neutralization; whereupon, with continuing titration, absorption increases up to complete neutralization of the polyacid. Addition of more Na^+ in the form of its chloride salt has no further effect on the ultrasonic absorption. The explanation is without ambiguity (Zana *et al.* 1971). In the initial stages of the titration the Na^+ counterions are not in close interaction with the CMC polyion. At a critical degree of neutralization, however, further addition of OH^- results not only in chemical neutralization of carboxyl protons but also their replacement near the CMC chain by Na^+ counterions added simultaneously. The volume fluctuations due to interpenetration of the electrostricted hydration layers surrounding both the Na^+ ion and the CMC polyion are detected by the ultrasonic probe. Sodium ions continue to 'condense' on the polyacid as added until the titration end-point is reached. All carboxyl groups are now deprotonated, but

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

the charge fraction of the polymer – that is, the charge per carboxylate group – is less than unity if one counts the condensed Na^+ ions as part of the polymeric molecular unit. The charge fraction is then equal to α_{crit}, the critical degree of neutralization for the onset of differential ultrasonic absorption. Further addition of Na^+ as its chloride salt does not lead to increased Na^+ binding; the charge fraction is stable to increases of ionic strength. Conceptually similar experiments have been reviewed elsewhere (Manning, 1977*a*).

For the case of DNA volume effects are so small (an important point that will be expanded in subsequent discussion) that direct 'tracking' of the counterion itself appears to be necessary. Sodium-23 NMR linewidth measurements have established that the charge fraction of DNA in an environment of excess Na^+ is invariant to variations of ionic strength at least up to 0·5 M (Anderson, Record & Hart, 1978). Under these conditions there remain many electrostatically uncompensated phosphate groups, as demonstrated by NMR-monitored titration of tetrabutylammonium DNA by Na^+ ions; association of Na^+ with the DNA polyion is indicated up to $75 \pm 10\%$ compensation of the phosphate charge but no further (Anderson *et al.* 1978). NMR charge-fraction experiments on a variety of other polyelectrolytes have been reviewed (Manning, 1977*a*).

Similar results are obtained for the interaction of Mg^{2+} with DNA. Dialysis-monitored titration of DNA by Mg^{2+} in excess 1 : 1 salt yielded about 85–86% maximum DNA charge neutralization by bound Mg^{2+} (Skerjanc & Strauss, 1968; Bhat, 1974). Over a limited range of added counterion, a minimum non-zero charge fraction independent of counterion concentration has also been confirmed by direct NMR measurement for the cobalt and manganese polyphosphate systems (Spegt & Weill, 1976).

Thus, as a matter of physical observation, polyelectrolytes in general, and DNA in particular, in an environment containing only one species of small cation like Na^+ and Mg^{2+}, possess a saturated charge fraction less than unity but well above zero. The data reveal a further, more restrictive generalization; in each case the value of the charge fraction depends only on the valence of the counterion and the *axial charge density* of the polyelectrolyte. The charge fractions of fully deprotonated sodium polyacrylate (carboxylate groups), sodium polystyrenesulphonate and sodium polyphosphate are equal (Manning, 1975; Kielman, van der Hoeven & Leyte, 1976). If b is the average axial charge spacing

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

(along the helical axis for DNA, along the contour axis for more flexible polymers) and if a dimensionless structural parameter ξ is defined as proportional to the charge density,

$$\xi = q^2/\epsilon kTb, \tag{1}$$

where q is the protonic charge, ϵ the bulk dielectric constant of solvent, k Boltzmann's constant, and T the Kelvin temperature, then a quantitative formulation of the physical observation is that the saturated charge fraction is close to $(N\xi)^{-1}$, where N is the valence (without sign) of the counterion. For water at 25 °C, $\xi = (7{\cdot}1/b)$ if b is expressed in Å (the temperature dependence is small and may be neglected for most purposes). The B form of DNA has step height 3·4 Å between base pairs, i.e. between phosphate pairs, so its value of b is 1·7 Å and $\xi_{\mathrm{DNA}} = 4{\cdot}2$. Then the charge fractions of DNA in aqueous Na^+ and Mg^{2+} environments are, respectively, 0·24 and 0·12.

The operational definition of counterion condensation can therefore be formulated thus: *the mode of binding of counterions of valence N to a polyelectrolyte is called condensation if, in an environment containing only the single counterion species, the charge fraction of the polyelectrolyte equals the constant value* $(N\xi)^{-1}$ *over a broad concentration range.*

B. *Nature of the condensed state; delocalized binding*

The extent to which condensed counterions are dehydrated and localized near discrete groups, that is, the 'tightness' of binding, may be expected to vary both with the nature of the charged groups and the counterion species (Strauss, 1974). At one extreme the counterion may be fully dehydrated and directly coordinated to several neighbouring charged groups. About half of the Mn^{2+} and Co^{2+} ions condensed on the polyphosphate chain are bound in this fashion (Spegt & Weill, 1976). At the other extreme the condensed counterion is said to be 'delocalized'. It retains the fully hydrated state characteristic of a pure aqueous environment while moving in an unrestricted and random way along the length of the polyion chain. If, for example, about half of the Mn^{2+} and Co^{2+} population condensed on polyphosphate is, as mentioned, completely dehydrated, the other half has been shown to retain at least a complete inner hydration layer (Spegt & Weill, 1976). NMR relaxation measurements have demonstrated the nearly unrestricted movement of possibly the entire population of Na^+ and Rb^+ condensed on DNA (Reuben, Shporer & Gabbay, 1975). The extremely small

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

specificities observed in differential dialysis experiments among alkali metal ions bound to DNA (J. Span & U. P. Strauss, unpublished) indicates the delocalized binding mode for condensed Li^+ and K^+ as well. Relaxation kinetic studies on the binding of Mg^{2+} and Ca^{2+} to poly A and poly C reveal diffusion control of the binding process, a result consistent with delocalized movement of these alkaline earth cations when bound and inconsistent with tight dehydrated binding to localized sites on the polynucleotide (Pörschke, 1976*a*). There is no reason to anticipate dissimilar behaviour for DNA, and the very small dilatometric effects exhibited by the binding of Mg^{2+} to DNA (in contrast to much larger effects for a number of synthetic polyelectrolytes) is indeed direct evidence that Mg^{2+} binds to DNA with almost no dehydration (Skerjanc & Strauss, 1968).

That alkali metal and alkaline earth cations condensed on extended polynucleotide conformations are almost fully hydrated and delocalized on the polyion surface is in fact their *expected* behaviour. Each fixed phosphate group is monovalent and rigidly held (Olson, 1975) at a great distance, about 7 Å, from its nearest-neighbour phosphate groups. Singly charged phosphate monomers do not interact strongly with cations. Activity coefficients of aqueous MH_2PO_4 solutions decrease (i.e. the ionic interactions become stronger) in the order of decreasing *hydrated* radius of the alkali metal ion M^+ (Li^+ interacts more weakly than K^+) (Robinson & Stokes, 1959). No ion-pair formation between Mg^{2+} and $H_2PO_4^-$, monovalent glucose 1-phosphate, or monovalent glycerol 2-phosphate could be detected by sensitive electrochemical measurements (Greenwald, Redish & Kibrick, 1940; Clarke, Cusworth & Datta, 1954). It should be realized that, even if ion-pairing with the monomer is present to a slight extent, delocalization on the polymer would still be likely to occur because of the long-range overlap of coulomb fields. Tight localized binding (site binding) is expected to occur for a polyelectrolyte with monovalent charged groups only if the chain is sufficiently flexible or the nearest-neighbour charge spacing is sufficiently close that two or more groups can co-operate in holding the cation, i.e. when the 'monomer' is effectively multivalent (Strauss & Siegel, 1963). Extended polynucleotide conformations do not satisfy this requirement (Skerjanc & Strauss, 1968; Olson, 1975). Significant binding of alkali metal or alkaline earth cations to the bases in aqueous solution has been ruled out by differential dialysis studies (Shapiro, Stannard & Felsenfeld, 1969*b*).

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

The qualitative difference, *as a matter of physical observation*, between polyelectrolyte–counterion binding and association reactions of oppositely charged small ions cannot be overemphasized. The latter is governed by mass action. The *extent* of ion pairing and the *tightness* of the complex are inseparable; the greater the association constant, the greater will be both the extent of reaction (number of ion pairs) and the tightness (stability) of each pair. For a polyelectrolyte in an environment of a single counterion species, however, the extent and tightness of binding are uncorrelated. Polyphosphate and DNA, which possess, roughly, about the same axial charge densities ($\xi_{PP} = 2{\cdot}8$, $\xi_{DNA} = 4{\cdot}2$), bind about the same number of Na^+ ions in accordance with the condensation principle; but condensed Na^+ ions are bound loosely to DNA with little or no dehydration and localization, while Na^+ ions condensed on polyphosphate are extensively dehydrated (Strauss, 1974), although probably still not strongly localized (Kielman *et al.* 1976). In accordance with its higher valence, more Mg^{2+} than Na^+ is bound on an equivalent basis to the synthetic polyelectrolyte PVS (with weakly binding sulphonate groups that are comparable to the monovalent phosphates on polynucleotides), but Na^+ is actually the more *tightly* bound of the two if extent of dehydration per equivalent is used as the criterion (Hen & Strauss, 1974).

Of course if the affinity of a counterionic species for sites on the polyion contains an appreciable covalent, or other non-ionic, component, then the situation is different. The binding of protons to nucleotide bases or to carboxylate groups on polyacrylate, for example, does not conform to the condensation requirement, but rather obeys a mass-action law with an association constant dependent on the extent of binding. There is also a formal similarity to a mass-action binding distribution when a multivalent species (Mg^{2+} or small oligolysines, for example) equilibrates by purely electrostatic interaction with DNA in the presence of excess univalent salt, although important qualitative differences remain. This situation, which is of the greatest practical interest for the biologist, will be discussed subsequently.

C. *Molecular theory of counterion condensation; the counterion diffusion potential*

It has been proved (Manning, 1977*a*, 1978) that condensation of counterions is a simple consequence of the spatial correlation of fixed charge centres along a single axis characteristic of all linear polyelectro-

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

lytes (even flexible chains can be expected to be fairly 'straight' over distances of the order of a Debye length because of electrostatic repulsion among the fixed charges). Thus, condensation is a manifestation of long-range electrostatic forces, and its general occurrence regardless of the specific nature of the polyelectrolyte charges is thereby explained.

To investigate the consequences of long-range overlap of the spherical coulomb fields generated by each charged group (assumed univalent) on the polyion, the actual spatial distribution of groups with average axial spacing b may be replaced by a regular linear array of fixed univalent point charges of magnitude q and spacing b (Manning & Zimm, 1965; Manning, 1977*a*). Let θ_N be the number of associated counterions per fixed charge, with the understanding that all counterions M^{N+} in the system have the same valence N. Then the *effective* charge q_{net} on each element of the linear array is lowered from q by the factor $1-N\theta_N$,

$$q_{\text{net}}/q = 1-N\theta_N. \tag{2}$$

Each pair of effective charges is then assumed to contribute a repulsive term to the overall free energy of the form

$$(q_{\text{net}}^2/\epsilon)\,(|i-j|\,b)^{-1}\exp(-\kappa|i-j|\,b), \tag{3}$$

a Debye–Hückel screened coulomb potential between the ith and jth charges in the array, $|i-j|\,b$ being their fixed distance of separation. The Debye screening parameter κ is proportional to the square root of ionic strength (if simple electrolyte is present in excess over polyelectrolyte):

$$\kappa^2 = (8\pi)\times 10^{-3}L_{\text{AV}}(q^2/\epsilon kT)\,I, \tag{4}$$

where L_{AV} is Avogadro's number and I is the ionic strength. For excess 1 : 1 salt in water at 25 °C,

$$\kappa = (3{\cdot}29\times 10^7)\,c_1^{\frac{1}{2}}\ [\text{cm}^{-1}], \tag{5}$$

where c_1 is the molarity of excess univalent counterion (ionic strength of the salt). The theoretical extent of association θ_N will therefore be dictated by the deviation of the actual electrostatic free energy from the Debye–Hückel approximation to it, or, again, the departure from diffuse Debye–Hückel screening interactions (ion atmosphere) is theoretically attributed entirely to counterion association. Thus determined, the theoretical extent of counterion association satisfies the requirements for counterion condensation (see Section IIA).

The total free energy of the system is the sum of contributions G_i from various sources, of which screened repulsions of the form of equation

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

(3) are one. In general I shall define

$$\bar{g}_i = G_i/n_P RT, \tag{6}$$

where n_P is the total number of moles of charged groups on the polyions (number of moles of phosphate groups in a polynucleotide system) and R is the gas constant. I shall also assume that

$$I \gg c_P, \tag{7}$$

where c_P is the polyion equivalent concentration (molarity of phosphate groups for a polynucleotide), so that equations (4) and (5) may be used.

The work of charging the phosphate groups against their mutual electrostatic repulsion is obtained by summing equation (3) over all pairs (i, j) of effective charges in the linear array,

$$\bar{g}_{\mathrm{el}} = -(1 - N\theta_N)^2 \, \xi \ln (1 - e^{-\kappa b}), \tag{8}$$

where ξ has been defined by equation (1). Note that the summation, the mathematical device for making the 'overlap' of coulomb fields a quantitative concept, has drastically transformed the qualitative nature of the individual spherical screened coulomb fields; the exponential screening, equation (3), has become logarithmic.

Other contributions to the free energy that depend on θ_N are given by the mixing of free M^{N+} cations, bound M^{N+} cations, and solvent molecules. Lumped together, these terms can be written as

$$\bar{g}_{\mathrm{mix}} = \theta_N \ln (10^3 \theta_N \, V_P^{-1}/c_N), \tag{9}$$

where terms independent of θ_N have been omitted. The argument of the logarithm in equation (9) is the ratio of the local concentration of bound M^{N+} cations to their molarity c_N in free solution. The quantity V_P is the volume of the region surrounding the polynucleotide within which M^{N+} cations are said to be 'bound'. The units of V_P are cm^3/mole P, so that the local concentration $10^3 \theta_N \, V_P^{-1}$ is expressed in molarity units, and the argument of the logarithm is dimensionless. The assertion that there are no other θ_N-dependent contributions to the free energy is equivalent to the assumption that the interaction of bound and free M^{N+} ions with the solvent is the same, and that the 'bound' M^{N+} ions may translate freely within the volume V_P centred along the long axis of the polynucleotide. This assumption is the natural way to incorporate the discussion in II B into a model.

Turning to the qualitative features of the dependence of $\bar{g}_{\mathrm{el}}$ and

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

$\bar{g}_{\mathrm{mix}}$ on θ_N, one sees that $\bar{g}_{\mathrm{el}}$ is positive and decreases as θ_N increases, the expected behaviour for the contribution of phosphate–phosphate repulsions, which decrease in magnitude as more counterions bind and effectively lower the phosphate charge. This term alone, then, would lead to complete binding, $N\theta_N = 1$, or minimum electrostatic work of charging the polynucleotide, as the equilibrium state.

However, increased binding of M^{N+} cations lowers the entropy of the system, as expressed by $\bar{g}_{\mathrm{mix}}$, which increases as θ_N increases if, as will be seen to be true for cases of interest here, the local concentration of bound M^{N+} is greater than the concentration of free M^{N+},

$$10^3\theta_N V_P^{-1} > c_N. \tag{10}$$

By itself, $\bar{g}_{\mathrm{mix}}$ would lead to $\theta_N = 0$ as the equilibrium state; that is, complete dissociation. The actual equilibrium state, determined from minimization of the sum $\bar{g}_{\mathrm{el}}+\bar{g}_{\mathrm{mix}}$, is a value of $N\theta_N$ intermediate between 0 and 1, a state of incomplete dissociation and incomplete binding.

The discussion thus far has held no surprises; *any* system of interacting molecules possessing binding capacity behaves similarly, the equilibrium state of incomplete binding representing the balance between maximization of entropy by dissociation and minimization of energy by binding. Polyelectrolyte binding is qualitatively distinctive, however. For a typical binding system dissociation tends to completion as the concentration tends to zero, because the entropy increase becomes infinite while the energy increase is essentially independent of concentration and remains finite. But for the polyelectrolyte case it can be verified from equations (8) and (4) that $\bar{g}_{\mathrm{el}}$ increases without bound as c_N tends to zero. Moreover, the concentration variation is logarithmic, just as for $\bar{g}_{\mathrm{mix}}$. The consequence is that θ_N does not tend to zero with c_N but remains positive. The implications of this distinctive behaviour are far-reaching. (It should be noted that the validity of equation (8) requires neglect of end-effects, an excellent approximation for ionic strengths of practical interest and *poly*nucleotides, as opposed to *oligo*nucleotides.)

To proceed quantitatively, the operation of minimization of $\bar{g}_{\mathrm{el}}+\bar{g}_{\mathrm{mix}}$ with respect to θ_N is performed, with the result that θ_N satisfies the following transcendental relation at the free energy minimum,

$$1+\ln\left(10^3\theta_N V_P^{-1}/c_N\right) = -2N\xi(1-N\theta_N)\ln\left(1-e^{-\kappa b}\right). \tag{11}$$

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

In the limit $c_N \to 0$ the only value of θ_N that satisfies the equation is

$$N\theta_N = 1 - (N\xi)^{-1} \tag{12}$$

because only for this value will the right-hand side produce a term $-\ln c_N$ to cancel exactly the singular $-\ln c_N$ term on the left-hand side (see equation (4)). The value of V_P that corresponds to equation (12) in the low-concentration limit is

$$V_P = 4\pi e L_{\Delta V} N' \nu^{-1}(\nu + \nu')(\xi - N^{-1}) b^3, \tag{13}$$

where e is the base of natural logarithms, ν and ν' are the number of counterions and coions, respectively, in the formula for the small electrolyte that is present in excess and hence determines the ionic strength, and N and N' are the valences (without sign) of the counterion and coion, respectively. Note that the only polyelectrolyte parameter on which V_P depends is the axial charge spacing b. Equation (13) is obtained by substituting equation (12) into (11) along with (4) for κ, while linearizing the exponential in accord with the stipulation $c_N \to 0$. For a 1 : 1 salt

$$\theta_1 = 1 - \xi^{-1} \tag{14}$$

and

$$V_P = 41{\cdot}1(\xi - 1) b^3, \tag{15}$$

where V_P has the units cm^3/mole P if b is expressed in ångströms. Clearly, equation (12) and (13) are physically meaningful only for polyelectrolytes of structures such that $\xi \geqslant N^{-1}$, a condition satisfied by all known polynucleotide conformations. Thus, a polyelectrolyte molecule with $\xi > 1$, immersed in 1 : 1 salt of vanishingly small bulk concentration c_1, is nevertheless surrounded by a local concentration c_1^{loc} of counterions

$$c_1^{loc} = 10^3 \theta_1 V_P^{-1} = 24{\cdot}3(\xi b^3)^{-1}, \tag{16}$$

where c_1^{loc} has molarity units if b is expressed in ångströms. Table 1 lists these local concentrations of bound univalent counterions for several polynucleotide structures. Also listed in Table 1 are the values Δx of the thickness of cylindrical shells of volume V_P about the polynucleotide; to calculate Δx it was assumed that the double- and triple-stranded structures are cylinders of radius 10 Å, while the single-stranded structures all have 5 Å radii. As an example from Table 1 the charge fraction of native DNA in excess 1 : 1 salt is 0·24 (76% of the phosphate charge is compensated by bound M^+), and the bound cations

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

TABLE 1. *Parameters for bound univalent cations in the limit* $c_1 \to 0$

Polynucleotide	b (Å)†	ξ	θ_1	V_P (cm³/mole P)	Δx (Å)	c_1^{loc} (M)

translate freely within about 7 Å of the DNA surface (of course, there is rapid exchange between ions in the bound region and bulk solution), where their local concentration is about 1·2 M, even though their bulk concentration c_1 may approach zero. *The local concentration is not governed by the law of mass action; it does not tend to zero with the bulk concentration* c_1.

It is now natural to wonder whether an approximate ionic strength c_1 can be specified below which, for practical purposes, the system has reached the mathematical limit $c_1 \to 0$. That is, over what range of ionic strengths c_1 are the parameters in Table 1 practically applicable? It may be verified that if the condition $\kappa b \ll 1$ is fulfilled, so that the exponential term on the right hand side of equation (11) can be linearized, then equations (14) and (15) for θ_1 and V_P satisfy the free-energy minimization condition equation (11). Thus, for concentrations c_1 such that the Debye screening length κ^{-1} is appreciably larger than the axial phosphate spacing b, Table 1 is applicable. For double- and triple-stranded structures, this requirement is not very restrictive, since the corresponding values of b are so small. For example, κ^{-1} equals 3·0 Å at 1 M according to equation (5), which may be compared to the value $b = 1{\cdot}7$ Å for native DNA. It is expected, then, that Table 1 is applicable to native DNA for ionic strengths in 1 : 1 salt approaching 1 M. For the single-stranded structures anticipation of the applicability of Table 1 would be restricted to concentrations below about 0·1 M, for which $\kappa^{-1} = 9{\cdot}6$ Å.

An equivalent and most appealing criterion for the applicability of Table 1 is $c_1 \ll c_1^{loc}$. It may in fact be verified from equations (5) and (16) that $c_1/c_1^{loc} = 2{\cdot}7\kappa^2 b^2$ (use of the general expressions rather than

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

TABLE 2. *Number of bound counterions per phosphate (θ_1) as a function of ionic strength*

$\xi = 4{\cdot}2$		$\xi = 1{\cdot}5$	
c_1 (M)	θ_1	c_1 (M)	θ_1

1·0	0·83		

the numerical ones identifies the factor 2·7 as e, the base of natural logarithms), so that the conditions $c_1 \ll c_1^{loc}$ and $\kappa b \ll 1$ are indeed equivalent. Thus, Table 1 applies for ionic strengths approaching the listed values of the local concentrations of bound counterions.

In Table 2 these qualitative remarks are validated. Equation (15) for V_P is used in (11) with $N = 1$ and θ_1 is then evaluated by numerical iteration as a function of c_1. For $\xi = 4{\cdot}2$ (native DNA) Table 1 indicates that c_1^{loc} equals 1·2 M, while Table 2 shows that θ_1 retains its limiting value 0·76 up to $c_1 = 0{\cdot}1$ M and does not deviate much from this value even at $c_1 = 1$ M. For $\xi = 1{\cdot}5$ (~poly U) Table 1 lists c_1^{loc} as about 0·2 M, and Table 2 shows that θ_1 remains at its zero-concentration limit up to $c_1 = 0{\cdot}01$ M and is not immoderately different for concentrations five times higher.

The significance of the trend in θ_1 as a function of c_1 exhibited in Table 2 is obscure at the present time. The theory contains inconsistencies that become significant at the same concentrations at which θ_1 begins to deviate from its limiting value (Manning, 1977*a*). From the experimental side no variations of polyelectrolyte charge fractions with ionic strength have been reported; the charge fraction of DNA in NaCl is invariant up to 0·5 M, the highest ionic strength investigated by Anderson *et al.* (1978). The point to emphasize from Table 2 at present is the theoretical *invariance* of θ_1 up to ionic strengths c_1 approaching c_1^{loc}, not the variation of θ_1 at higher ionic strengths.

I can now formulate an evocative description of the ionic state of an extended polynucleotide structure in a solution environment of excess 1 : 1 salt of concentration (ionic strength) $c_1 \ll c_1^{loc}$. The structure is 'potentiated', in the sense that a large entropy increase $nR \ln (c_1^{loc}/c_1)$

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

would accompany the diffusion of n M^+ cations from the bound region of locally high concentration to the lower concentration in free solution. This statement is implicit in equation (9), since $c_1^{loc} = 10^3\theta_1 V_P^{-1}$. The process of local diffusion of M^+ into bulk solution does not occur spontaneously only because its presence at high concentration near the polynucleotide is required to offset the repulsive electrostatic free energy of interaction among the phosphate groups, as described by equation (8). However, if the system can avail itself of another mechanism for relieving the stress of phosphate–phosphate repulsion, then M^+ will diffuse spontaneously into free solution as the alternate mechanism is implemented. Conversely and equivalently, the counterion diffusion potential $RT \ln (c_1/c_1^{loc})$ constitutes a thermodynamic driving force for the spontaneous implementation of the alternate mechanism of phosphate charge compensation. As the ionic strength c_1 approaches c_1^{loc}, or 1·2 M for DNA, the polyelectrolyte is no longer potentiated in this sense, and, to the extent that a given process consists of the relief of long-range electrostatic stress, that process will have lost its ability to occur spontaneously.

III. Binding of metal ions in the aqueous DNA/MCl_N system

A. *Charge fraction of DNA and mode of binding*

This subject has already been covered in Section II. The theoretical charge fraction r of DNA in excess MCl_N (fraction of phosphate charge uncompensated by bound M^{N+}) is given by (12):

$$r = 1 - N\theta_N = (N\xi)^{-1} \tag{17}$$

or 0·24 and 0·12 for $N = 1$ and $N = 2$, respectively. These values have been closely confirmed by direct measurement for Na^+ and Mg^{2+} in DNA solutions over wide ranges of ionic strength, and (17) has also been confirmed for Mn^{2+} and Co^{2+} in polyphosphate solutions; see Section II for references. There exists no reason at the present time to doubt the essential validity of (17) for all small univalent and divalent cations except those that may interact strongly with the nucleotide bases in native DNA, like Ag^+ and Cu^{2+}.

Good experimental evidence exists that Na^+, Rb^+, Mg^{2+} and Ca^{2+} are bound loosely to DNA, to the molecule as a whole rather than to discrete sites on it, and are in a state of essentially complete hydration

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

and free translational and rotational mobility (see Section II for references). This information has been incorporated into the theoretical model leading to the successful equation (17). The similarity in behaviour among all the alkali metal ions, as well as the nearly identical binding constants to native DNA of Mg^{2+}, Ca^{2+}, Mn^{2+} and Zn^{2+} (Daune, 1970; Clement, Sturm & Daune, 1973) suggests that *all* small cations, except those that can actually penetrate the native DNA structure and enter into strong interaction with the bases, are more or less associated with DNA in this delocalized mode. The burden of proof has now clearly shifted to those who would support a contrary position. As I shall point out in Section III F, the undisputed existence of small specific ionic effects does not constitute such proof.

B. *The free energy of binding*

Binding of M^{N+} cations to DNA in the system DNA/MCl_N/H_2O can be formulated as a chemical reaction (Manning, 1978),

$$M^{N+}\text{ (free)} \rightarrow M^{N+}\text{ (bound)}. \tag{18}$$

Note carefully that this reaction does *not* imply that free M^{N+} combines with a 'site' to form a cation–site complex; it states simply that M^{N+} is transferred from free solution into the spatial region V_P, where it is defined as bound. Application of the standard thermodynamic treatment of chemical reactions to equation (18) is fully equivalent to the treatment in II C and yields the same results as (12) and (13). The integral free energy of reaction (18) – that is, the free energy when DNA is combined with its equilibrium number of counterions (and hence has charge fraction r given by (17)), relative to the non-equilibrium state of complete dissociation ($r = 1$) – is $\Delta\bar{g} = -5{\cdot}3$ for $N = 1$ at ionic strength 0·1 M. That is, condensation of Na^+ ions at 0·1 M stabilizes DNA by 3·2 kcal/mole P at 25 °C. At 10^{-3} M the corresponding stabilization is twice as great.

C. *Colligative properties*

Since, as described in II, the free energy of a polyelectrolyte solution is theoretically calculable, expressions may also be obtained for all the observables associated with classical equilibrium electrochemistry such as activity coefficients, osmotic coefficients, Donnan effects and heats of solution and mixing (Manning, 1972*a*, 1974; Devore & Manning, 1974; Boyd, Wilson & Manning, 1976; Manning, 1976*a*). As an example let

‡ Calculated from equation (19) of text.

us consider the activity coefficient γ_{Mg} of the Mg^{2+} ion in the ternary solution MgDNA/$MgCl_2$/H_2O. Theoretical activity coefficients are easily obtained, since the number of associated counterions, which do not contribute to the apparent activity, is known, while unassociated counterions contribute to simple Debye–Hückel screening interactions. The theoretical formula for γ_{Mg} is (Kwak, O'Brien & MacLean, 1975),

$$\ln(\gamma_{Mg}/\gamma^0_{Mg}) = -\tfrac{1}{4}\xi^{-1}X(\tfrac{1}{2}\xi^{-1}X+\tfrac{3}{2})^{-1} + \ln[(\tfrac{1}{2}\xi^{-1}X+1)(X+1)^{-1}]. \quad (19)$$

In this formula γ^0_{Mg} is the activity coefficient of Mg^{2+} in the binary solution $MgCl_2$/H_2O at the same $MgCl_2$ concentration as in the polyelectrolyte solution, X is the ratio of polyelectrolyte equivalent concentration (normality) to $MgCl_2$ equivalent concentration, and ξ is the charge density parameter defined by equation (1) and equal to 4·2 for DNA in an aqueous environment.

Table 3 presents a comparison of observed values of γ_{Mg} with values calculated from equation (19). X has been defined above, c_P is the DNA normality (molarity of phosphate groups) and $MgCl_2$ normalities are equal to $c_P X^{-1}$. The last entry in the table, $X=\infty$, refers to a pure MgDNA solution in the absence of added $MgCl_2$. Note the remarkably good agreement between observed and theoretical values of $\gamma_{Mg}/\gamma^0_{Mg}$ over the entire composition range, $1 < X < \infty$ and $MgCl_2$ normalities up to 0·01 N. Underlying the predicted values is the concentration-

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

invariant theoretical charge fraction $(2\xi)^{-1} = 0{\cdot}12$; Table 3 adds to the evidence for its physical reality.

D. *Transport properties*

It is an easy matter to calculate the electrophoretic mobility U expected for the polyelectrolyte model under discussion, namely a linear array of effective point charges of magnitude $N^{-1}\xi^{-1}q$ and spacing b. The starting point is Kirkwood's theory of the translational friction coefficient for macromolecules composed of identical subunits (Bloomfield, Crothers & Tinoco, 1974). It need only be recognized that the hydrodynamic interaction between each pair of subunits (in this case, point charges) is attenuated, not only by the familiar inverse dependence on distance but also by the oppositely charged Debye–Hückel atmosphere that surrounds each fixed charge and moves in the opposite direction, dragging the solvent with it, under the action of an applied electric field. The quantitative expression of this added attenuation is the appearance of a Debye screening factor $\exp(-\kappa b|i-j|)$ in the hydrodynamic interaction between fixed charges i and j. The summation over all pairs is then exactly the same operation as summing the Debye–Hückel pair potentials of equation (3), and the final result is

$$U = N^{-1}(\epsilon kT/900\pi\eta q)\,|\ln \kappa b|, \tag{20}$$

where η is the viscosity and all other quantities have been previously defined. At 0 °C in water the numerical value of the factor in parentheses is $1{\cdot}37 \times 10^{-4}$; the units of U are standard, $cm^2\ sec^{-1}\ V^{-1}$.

Mobilities predicted from equation (20) are compared in Table 4 with values measured for DNA ($b = 1{\cdot}7 \times 10^{-8}$ cm) in excess $MgCl_2$ ($N = 2$) at 0 °C. It should be noted that, although prediction consistently overestimates observation, the ratio of calculated to observed values is almost constant over a range of $MgCl_2$ normalities n_{MgCl_2} that cover more than two orders of magnitude. The data are therefore in reasonable agreement with the predicted linear dependence on the logarithm of ionic strength, and the discrepancy in absolute values can probably be ascribed to the obviously oversimplified description of the hydrodynamic particle as a linear array of points. Nevertheless, the *electrostatic* contribution to the mobility is apparently, as anticipated, accurately contained in this model. The theoretical mobility explicitly rests on a concentration-invariant charge fraction $(N\xi)^{-1}$, which therefore is supported by the mobility data in Table 4.

E. *The dissociation–field effect*

The extent of counterion condensation, $N^{-1}(1 - N^{-1}\xi^{-1})$ moles condensed counterion of valence N per polyelectrolyte equivalent, is invariant to changes of ionic strength. Application of a strong electric field E, however, can cause partial dissociation of the condensed counterions, thereby increasing the charge fraction of the polyelectrolyte. The dissociation–field effect is well known in the area of partially associated simple electrolyte solutions, since the linear increase with E of the conductance of such solutions is accepted as a direct measure of an increased dissociation constant (Onsager, 1934; Onsager & Liu, 1965). The conductance of polyelectrolyte solutions also increases linearly with E, but it is not clear at present that the field–dissociation effect is the dominant factor in this behaviour. It is conceivable that charge fractions can be directly measured in the presence of a field, as they have been in its absence, but no attempt in this direction has yet been undertaken. Therefore the field–dissociation effect for polyelectrolytes cannot yet be said to have been directly observed. The great current interest in the effect is due rather to observations that sufficiently strong electric fields can induce conformational changes in ordered polynucleotide structures (Pörschke, 1976*b*; Revzin & Neumann, 1974).

The theory for polyelectrolytes (Manning, 1977*c*) is surprisingly easy, in view of the almost legendary difficulty of Onsager's 1934 paper on small electrolytes. At zero field the contribution to the free energy from condensed counterions is, aside from the effective decreased charge on the polyion, an ideal mixing entropy. When the field E (in e.s.u.) is turned on, the free energy is supplemented by a work term proportional

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

to $NqaE$, where Nq is the charge of a counterion and a is a distance. That is, in order to remain condensed, a counterion must do work against the field which tends to tear it from the polyion. The key to the derivation is the unambiguous knowledge of a, which is simply the cylindrical radius of the free volume V_P determined by equation (13). The average position of a counterion, if condensed, is on the cylindrical axis of the free volume; to remain there, the counterion must work against the field over the distance a, past which it is no longer condensed. Values of a have been tabulated as a function of ξ (Manning, 1977*a*); for DNA, $\xi = 4{\cdot}2$ and $a = 14{\cdot}2$ Å for univalent counterions.

With this added work term condensed counterions have higher energy; hence at the free energy minimum there will be fewer condensed counterions than for the field-free case. Define a degree of dissociation α by

$$\theta_N(E)/\theta_N(0) = 1-\alpha, \tag{21}$$

where $\theta_N(E)$ is the fraction of a condensed counterion per polyelectrolyte charge at field E; $\theta_N(0)$, the corresponding field-free quantity, has already been found and is given by equation (12). The relation between α and E at the free energy minimum is

$$\bar{E} = \alpha[1-2(N\xi-1)\ln \kappa b], \tag{22}$$

where

$$\bar{E} = (\tfrac{1}{4}\pi)(NqaE/kT). \tag{23}$$

For an aqueous polyelectrolyte solution at 25 °C containing excess 1 : 1 salt of ionic strength 10^{-2} M, a very high applied field of 402 kV/cm produces only 10% dissociation ($\alpha = 0{\cdot}1$) if $\xi = 4$ (the approximate value for DNA). At the higher ionic strength 10^{-1} M, dissociation requires less work because the dissociated ions enter a more effective screening atmosphere; the field corresponding to $\alpha = 0{\cdot}1$, however, is still 262 kV/cm for $\xi = 4$. Although the extent of counterion condensation is the *same* at 0·01 and 0·1 M in the absence of a field, it may be said that the condensed counterions are held more loosely at the higher ionic strength, in the sense that the field required to tear some of them away is then not as high as in the more dilute solution. In Section VD the theory is applied to the effect of a strong field on the melting of DNA.

F. *Specific ionic effects*

To a slight extent, DNA in aqueous solution has been observed to

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

discriminate among cations of the alkali metal series, preferentially selecting Li^+ over Na^+ and K^+ in differential dialysis experiments (Span & Strauss, unpublished) and exhibiting higher T_m's in Li^+ solution relative to Na^+ and K^+ (Gruenwedel, Hsu & Lu, 1971). Since these ions are unable to discriminate between A·T-rich and G·C-rich DNA (Shapiro *et al.* 1969*b*) there is no reason to suspect groove binding, and the almost unrestricted movement of bound Na^+ and Rb^+ (Reuben *et al.* 1975) suggests that varying degrees of 'tightness' of localized binding to phosphate groups is not an appropriate explanation. We have seen that the local concentration of condensed univalent cations in the immediate neighbourhood of DNA is about 1·2 M, regardless of the bulk ionic strength. Moreover, Li^+ is more highly hydrated (i.e. binds *water* more tightly) than Na^+ or K^+ (Robinson & Stokes, 1959). Given the sensitivity of DNA structure to solvent effects, it would be surprising if DNA in a local environment of 1 M aqueous M^+ did *not* exhibit at least small differential effects depending on the species M^+. By the same token circular dichroism variations upon addition of Mg^{2+} (Clement *et al.* 1973) are perhaps also not an unexpected consequence of changes in local solvent properties, since Mg^{2+} binds *water* extremely tightly (Eigen, 1963).

For one such effect a quantitative estimate can be made. If it is assumed that the electrophoretic mobility of DNA is inversely proportional to the *local* solvent viscosity (Abramson, Moyer & Gorin, 1942), then one would predict that mobilities at any ionic strength in aqueous MCl should vary in inverse proportion to the viscosities of 1 M-MCl (the Cl^- ion contributes little to the ionic effect on viscosity). On this basis DNA mobilities would be expected to vary in the proportion 1·23 : 1·13 : 1·00 in aqueous K^+, Na^+ and Li^+, respectively, at 0 °C. The observed variation (Ross & Scruggs, 1964) is 1·37 : 1·16 : 1·00.

A recent development of possibly great importance is the discovery that half of the Na^+ counterions are coordinated to $O_{(2)}$ of uracil and thymine in *crystalline* ApU and pTpT, respectively (Seeman *et al.* 1976; Camerman, Fawcett & Camerman, 1976). The $O_{(2)}$ atom of thymine and uracil is a carbonyl oxygen exposed in the minor groove of double helical structures and not involved in base pair hydrogen binding. Although all current evidence *in solution* points to the absence of groove binding for Na^+ (presumably because its electric field intensity is more easily compensated by complete hydration in solution than in even a relatively highly hydrated crystal), the $O_{(2)}$ atom could be an

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

important factor in the apparent ability of the A · T base pair to bind more water in solution than the G · C pair (Tunis & Hearst, 1968) as well as in the small selective affinity of the tetramethyl- and tetraethylammonium cations for A · T-rich regions of DNA relative to G · C-rich regions (Shapiro *et al.* 1969; Melchior & von Hippel, 1973).

Another interesting result is the charge reversal of DNA in aqueous $MgCl_2$ if the concentration is in excess of 1 N-$MgCl_2$ (Papon & Strauss, unpublished). DNA then behaves like a cation in an electrophoresis experiment. It would be of great interest to know if a conformational change, possibly to a compact form, is associated with this phenomenon. The constant anionic charge fraction 0·12 mentioned repeatedly in previous sections, of course, refers to an apparently much simpler situation at lower Mg^{2+} concentrations.

IV. Theory of delocalized binding of N-valent cationic substances to polynucleotides in aqueous excess 1 : 1 salt

A. *Introduction*

The subject of this section is a statistical mechanical analysis of binding constants obtained under typical experimental conditions. The goal is the *a priori* prediction of binding constants, properly defined, under the assumption that the bound cationic substance is delocalized (free translation near the polynucleotide surface). Comparison with measured values will then provide suggestive information about the molecular structure of the cation/polynucleotide complex. The central role of the counterion diffusion potential will be stressed, and the reader may wish to refer to the last paragraph of Section II C before proceeding.

B. *One-variable theory*

1. *Minimization of the free energy.* I shall begin with a discussion of binding relations obtained by treating the free energy as a function of the single variable θ_N, the number of M^{N+} cations bound per phosphate group. As in Section II C, the excess salt condition, equation (7), is assumed. In addition the inequality

$$c_1 \gg c_N, \tag{24}$$

where c_N is the molarity of *free* N-valent cations and c_1 the molarity of supporting 1 : 1 salt, proves useful without imposing a severe restriction

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

on applications to commonly employed binding conditions. It allows us to retain equation (5) for the Debye screening constant κ, since c_1 is then effectively equal to the ionic strength I. It also motivates the modelling specification that V_P as given by equation (15) for 1 : 1 salts, defines the region of binding for both univalent and N-valent cations. The numerical values of V_P for several polynucleotides may be found in Table 1.

The one-variable approach turns out to require two separate cases, low binding levels (small θ_N) and high levels (θ_N approaching saturation). The two-variable theory developed subsequently enables one to avoid this separation and also to assess the approximations inherent in one-variable minimization. On the other hand the one-variable theory will provide a simple and attractive interpretation for the otherwise physically obscure two-variable results.

For low θ_N Table 1 motivates the assumption that θ_1, the number of bound M^+ cations per phosphate, is fixed at the value

$$\theta_1 = 1 - \xi^{-1} - N\theta_N, \tag{25}$$

that is, the binding of one M^{N+} ion results in the release of N bound M^+ ions, so that the charge fraction of the polynucleotide (fraction of phosphate charge uncompensated by bound cations) remains invariant at $1 - \theta_1 - N\theta_N = \xi^{-1}$. It is this restriction on θ_1 that allows reduction of the problem to the minimization of the free energy with respect to the single variable θ_N. From equation (25) it follows that the calculation for low θ_N is mathematically applicable to the range

$$0 \leqslant \theta_N \leqslant N^{-1}(1 - \xi^{-1}). \tag{26}$$

With the notation of equation (6) the electrostatic free energy required to charge the phosphate groups is

$$\bar{g}_{el} = -\xi^{-1} \ln (1 - e^{-\kappa b}), \tag{27}$$

obtained by replacing the charge fraction $1 - N\theta_N$ in equation (8) by ξ^{-1}, in accordance with the discussion of equation (25). This contribution to the free energy is independent of θ_N; hence the electrostatic repulsion does not determine, even partially, the extent of binding of the M^{N+} ions, at least in the binding range (26) and subject to the constraint equation (25).

The only other contributions to the free energy of the system are

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

assumed to be from the ideal mixing of the various species,

$$\bar{g}_{\mathrm{mix}} = N\theta_N \ln (10^{-3}c_1) + \theta_1 \ln (\theta_1/V_P) + (c_N/c_P) \ln (10^{-3}c_N) + \theta_N \ln (\theta_N/V_P) + \theta_N, \quad (28)$$

where terms independent of θ_N have not been included. The first term on the right-hand side of equation (28) is the free energy of mixing of the free univalent cations M^+, with recognition that $N\theta_N$ M^+ ions per phosphate have been freed from the bound state if the extent of binding of the N-valent molecule is θ_N. The second term is the mixing contribution of the θ_1 M^+ ions remaining bound; θ_1 is given by equation (25) as a function of θ_N. The third term is contributed by free M^{N+} ions of concentration c_N, which satisfies the condition $dc_N/d\theta_N = -c_P$ if the *total* amount of M^{N+} ions is specified as fixed (corresponding to the typical experiment of adding a given amount of M^{N+} to the system, measuring the amount bound or free, and obtaining the amount free or bound by difference). The fourth term is the free energy of mixing of bound M^{N+} ions, assumed delocalized just like the univalent ions. The fifth term combines the mixing entropy of solvent with a higher-order term from the mixing of free M^+. Further detail for the case $N = 2$ may be found in Manning (1977*b*). Minimization of $\bar{g}_{\mathrm{mix}}$ as a function of θ_N yields the equilibrium binding relation

$$\log K_N = \log (V_P/1000e) + N \log [(1000e/V_P)(1 - \xi^{-1} - N\theta_N) c_1^{-1}], \quad (29)$$

where

$$K_N = \theta_N/c_N. \quad (30)$$

The quantity K_N is proportional to the equilibrium constant for the transfer of an M^{N+} ion from free solution to the 'bound' region V_P, and, as such, serves as the 'association constant' for the binding of M^{N+}. Recall also that K_N as defined by equation (30) is the ordinate in the usual Scatchard plot and is a directly accessible experimental quantity. The ionic strength dependence of K_N is given by the coefficient

$$d \log K_N / d \log c_1 = -N, \quad (31)$$

while, as a function of the extent of prior binding θ_N, K_N is a monotone decreasing Nth order polynomial with a single zero at $\theta_N = N^{-1}(1 - \xi^{-1})$.

In Fig. 1 K_2 is represented by a Scatchard plot; the dashed curve for $\theta_2 \leqslant 0{\cdot}38$, a number corresponding to $\xi_{\mathrm{DNA}} = 4{\cdot}2$, is equation (29) in the range specified by (26). The additional information in Fig. 1 and the other figures to which reference is made at this point pertain to calcula-

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

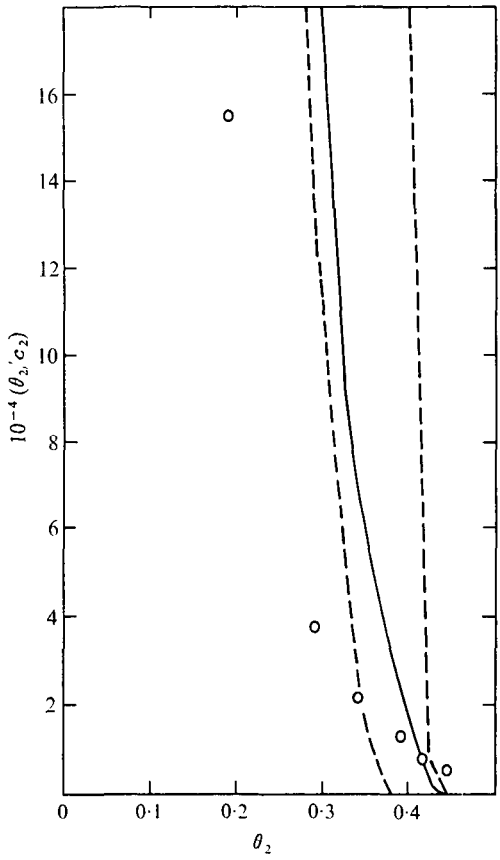

Fig. 1. Scatchard representation of divalent ion binding. Dashed curve for low θ_2, equation (29); dashed curve for high θ_2, equation (36); solid curve, equations (53) and (54). Data points from Clement *et al.* (1973). Ionic strength, 0·001 M.

tions and data that are discussed subsequently. In each of these figures only the dashed curves for $\theta_2 \leqslant 0{\cdot}38$ are germane to the present case. Fig. 2 gives a logarithmic representation of K_2. Fig. 3 shows the ionic strength dependence of K_2, equation (31). Fig. 4 shows how the bound fraction of M^+ cations decreases as M^{2+} is progressively bound, in this case following equation (25). Finally, Fig. 5 gives the total fraction of the phosphate charge compensated by bound cations of both species M^+ and M^{2+} as a function of θ_2; for the present case, as mentioned in connection with equation (25), this number is given by $1-\xi^{-1}$ (equal to 0·76 for DNA) for $\theta_2 \leqslant \frac{1}{2}(1-\xi^{-1})$.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

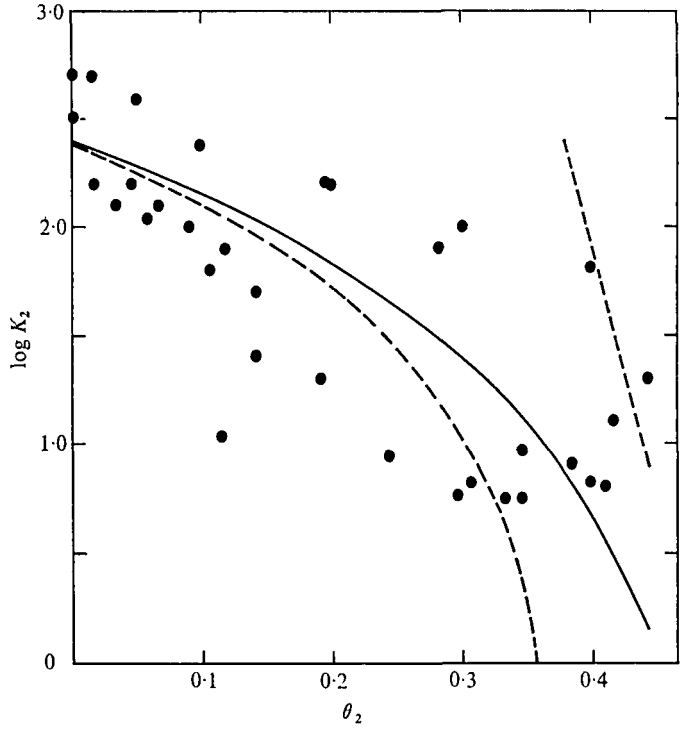

Fig. 2. Logarithmic representation of divalent ion binding. Curves as for Fig. 1; data from Archer *et al.* (1972), Clement *et al.* (1973), Bhat (1974), Skerjanc & Strauss (1968), and Zubay & Doty (1958). Curves are drawn for 0·1 M ionic strength; points represent ionic strengths in the range 0·001–0·2 M but are normalized to 0·1 M according to procedure described in text.

For the binding region

$$\theta_N \geqslant N^{-1}(1-\xi^{-1}) \tag{32}$$

a separate calculation is required. In this region the constraint that reduces the problem to one variable is

$$\theta_1 = 0, \tag{33}$$

that is, all bound M^+ cations have been displaced by M^{N+}. Note that equation (33) is continuous with equation (25) at the mutually included point $\theta_N = N^{-1}(1-\xi^{-1})$. Now

$$\bar{g}_{\mathrm{el}} = -(1-N\theta_N)^2\,\xi \ln (1-\mathrm{e}^{-\kappa b}), \tag{34}$$

in analogy to equation (8), while

$$\bar{g}_{\mathrm{mix}} = (c_N/c_P)\ln (10^{-3}c_N)+\theta_N \ln (\theta_N/V_P)+\theta_N, \tag{35}$$

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

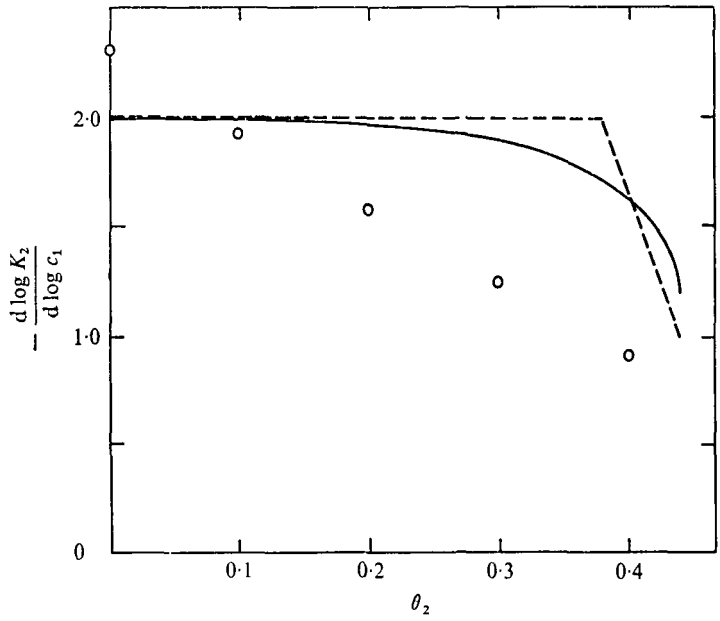

Fig. 3. Ionic strength dependence of divalent ion binding. Dashed curve for low θ_2, equation (31); dashed curve for high θ_2 (after break), equation (37); solid curve computed from equations (53) and (54). Data from Krakauer (1974) based on measurements in the range 0·01–0·1 M.

since only the mixing of free M^{N+}, bound M^{N+}, and solvent depend on θ_N. Minimization of $\bar{g}_{el}+\bar{g}_{mix}$ with respect to θ_N, with recognition that $dc_N/d_{\theta N} = -c_P$, produces the following relation for the value of θ_N at equilibrium:

$$\log K_N = \log (V_P/1000e) - 2N\xi(1-N\theta_N) \log \kappa b, \qquad (36)$$

where K_N is defined by equation (30) and κ is conveniently given by equation (5). The approximation $1-e^{-\kappa b} \approx \kappa b$ has been incorporated into (36) because (35), with which (33) is continuous, is motivated by the behaviour at low concentration illustrated in Tables 1 and 2. For the ionic strength dependence of K_N, it follows from (5) and (36) that

$$d \log K_N/d \log c_1 = -N\xi(1-N\theta_N), \qquad (37)$$

a relation that preserves continuity with (31) at $\theta_N = N^{-1}(1-\xi^{-1})$. As a function of θ_N, K_N decreases exponentially like $\exp [2N^2\xi \ln (\kappa b)\, \theta_N]$.

These relations are illustrated for K_2 and DNA by the dashed curves in Figs. 1–5 corresponding to $\theta_2 \geqslant 0{\cdot}38$. In Fig. 4, of course, the dashed

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

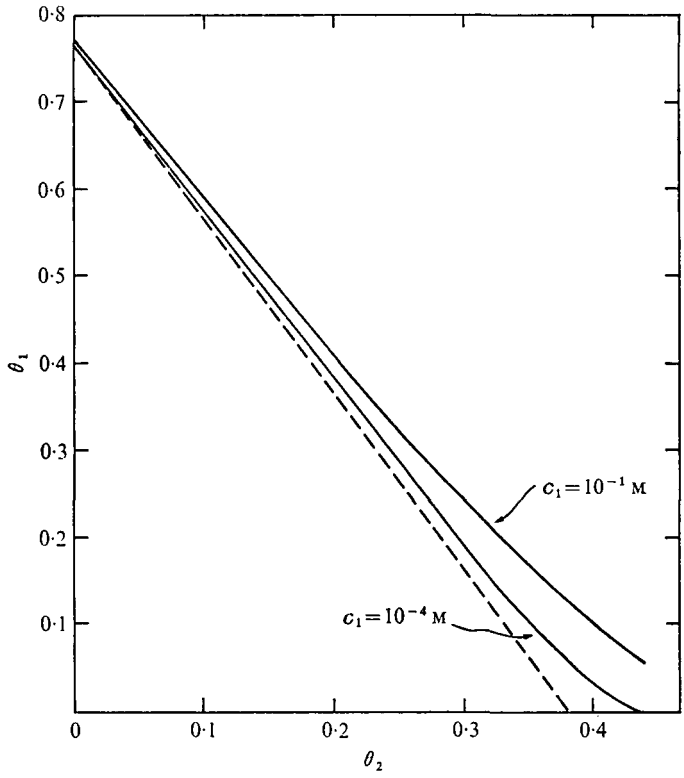

Fig. 4. Fractional number (per phosphate) of bound univalent counterions as a function of fractional number of bound divalent ions. Dashed curve, equation (25). Solid curves computed from equations (53) and (54) for the indicated ionic strengths.

curve in this range coincides with the abscissa, in accordance with (33). An important feature of the figures not yet mentioned is the existence of a maximum value $\theta_N^{\max}$. Due to the constraint imposed by inequality (24), $\theta_N^{\max}$ cannot be obtained from (36), which yields a positive value of K_N for any value of θ_N. However, as M^{N+} continues to be added to the system, so that inequality (24) becomes invalid and then reversed, the case that eventually presents itself is that of the polynucleotide in an aqueous environment of M^{N+} cations with negligible amounts of M^+. This situation is the same as that discussed in Sections II and III. According to (17), then,

$$\theta_N^{\max} = N^{-1}(1 - N^{-1}\xi^{-1}) \tag{38}$$

and the binding range to which (36) is restricted is defined by inequality

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

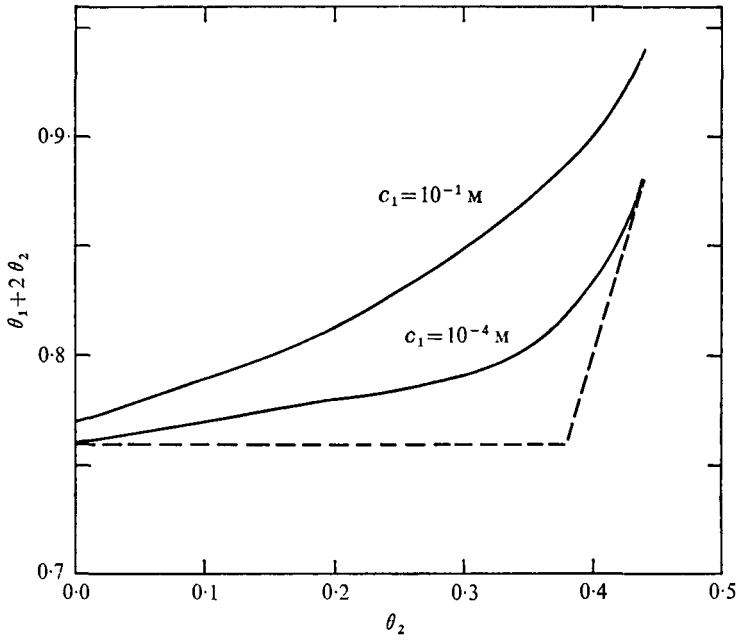

Fig. 5. Fraction of phosphate charge compensated by the combined charge of bound univalent and divalent ions, i.e. $\theta_1+2\theta_2$. Dashed curve for low θ_2 from equation (25); dashed curve for high θ_2 from equation (33) (i.e. this curve is merely $2\theta_2$ *v.* θ_2); solid curves computed from equations (53) and (54) for the indicated ionic strengths.

(32) and (38). For DNA, $\theta_2^{\max} = 0{\cdot}44$, a value that has been closely confirmed by measurement for Mg^{2+}, as discussed in Sections II and III. Recall from III F that this value is not an absolute upper limit; rather, it may represent a saturation plateau that is eventually exceeded, but not before concentrations of about 1 M free Mg^{2+}_f have been attained and factors other than electrostatic may become dominant.

2. *Chemical model.* Additional insights may be obtained by formulating the binding process as a chemical reaction,

$$M^{N+}\,(\text{free}) \rightarrow M^{N+}\,(\text{bound}), \tag{39}$$

and applying to it the standard thermodynamic analysis of chemical reactions. The reaction affinity (Kirkwood & Oppenheim, 1961) $\widetilde{\Delta}\mu_N$ for (39) is

$$\widetilde{\Delta}\mu_N = \mu_{N,b} - \mu_{N,f}, \tag{40}$$

where $\mu_{N,b}$ and $\mu_{N,f}$ are the chemical potentials of bound and free M^{N+}, respectively. By appropriate differentiation of the free energy of

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

the system for low binding levels, (28), the required chemical potentials, in units of RT, may be obtained as

$$\mu_{N,f} = \ln 10^{-3} c_N, \tag{41}$$

$$\mu_{N,b} = -(N-1) + N \ln [10^{-3} c_1 V_P (1 - \xi^{-1} - N\theta_N)^{-1}] + \ln (\theta_N / V_P). \tag{42}$$

Note that the local and free concentrations of univalent M^+ are 'hidden variables' relative to reaction (39) and appear in the 'standard state' component of $\mu_{N,b}$ (first two terms in r.h.s. of (42)). From (40), (41), (42), (16) and (25) one has

$$\tilde{\Delta}\mu_N = \tilde{\Delta}\mu_N^0 + \ln (c_N^{\infty} / c_N), \tag{43}$$

where

$$\tilde{\Delta}\mu_N^0 = -(N-1) + N \ln (c_1 / c_1^{\mathrm{loc}}). \tag{44}$$

In (43) the local molarity c_N^{loc} of bound M^{N+} is given in analogy to (16),

$$c_N^{\mathrm{loc}} = 10^3 \theta_N / V_P. \tag{45}$$

It is easily verified that the equilibrium condition $\tilde{\Delta}\mu_N = 0$ yields the equilibrium binding relation, (29).

The equilibrium constant for reaction (39) is conventionally defined by

$$\bar{K}_N = (c_N^{\mathrm{loc}} / c_N)_{\mathrm{equil}} = \exp (-\tilde{\Delta}\mu^0), \tag{46}$$

where the 'bar' on $\bar{K}_N$ distinguishes it from the quantity K_N of (30), to which it is proportional. Then, with (44),

$$\bar{K}_N = e^{N-1} (c_1^{\mathrm{loc}} / c_1)^N. \tag{47}$$

The association constant $\bar{K}_N$ for binding of M^{N+} is large if the concentration c_1 of free M^+ (ionic strength) is appreciably less than the local concentration c_1^{loc} of bound M^+. This conclusion is in complete agreement with the concept of the 'potentiated' polyelectrolyte discussed in II C; reaction (39) is driven by the diffusional entropy of the 'hidden' process $NM^+(c_1^{\mathrm{loc}}) \rightarrow NM^+(c_1)$. The constant contribution $(N-1)$ to $\ln \bar{K}_N$ arises from the osmotic inactivity of the bound cations, which, although free to move on the surface of the polyion, travel with the polyion and hence do not independently lower the activity of the solvent.

Note that, when $N = 1$, the equilibrium condition $\tilde{\Delta}\mu = 0$ reduces to

$$c_N^{\mathrm{loc}} / c_N = c_1^{\mathrm{loc}} / c_1 \quad (N = 1), \tag{48}$$

a relation that underscores the complete absence of specific effects in the model; selectivity is on the basis of valence alone.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

The chemical thermodynamical model allows a systematic calculation of the free energy ΔG stabilizing the M^{N+}/polynucleotide complex,

$$\Delta G/RT = \int_0^{\lambda_{eq}} \tilde{\Delta}\mu_N \, d\lambda. \tag{49}$$

In this equation ΔG is the free energy of the system at equilibrium relative to its free energy at the moment before commencement of reaction (39), when all M^{N+} ions are present and mixed uniformly but none are yet bound. The quantity λ is the progress variable, or degree of advancement of the reaction, and λ_{eq} is its value after the reaction has proceeded to equilibrium (Kirkwood & Oppenheim, 1961). For reaction (39), λ is the number of moles of bound M^{N+}

$$\lambda = \theta_N n_P, \tag{50}$$

where n_P is the number of moles of phosphate groups in the system. After the integration in (49) is carried through, extensive cancellation may be achieved by application of the relation $\tilde{\Delta}\mu(\lambda_{eq}) = 0$ (equivalent to equation (29)), and the final result is

$$\begin{aligned}\Delta\bar{g} = {} & \theta_N^t \ln [1-(\theta_N/\theta_N^t)] \\ & + N\theta_N + (1-\xi^{-1}) \ln [(1-\xi^{-1}-N\theta_N)/(1-\xi^{-1})],\end{aligned} \tag{51}$$

where it is understood that θ_N is the equilibrium value determined by (29) and (30), θ_N^t is the total number of moles of M^{N+} present in the system per mole phosphate, and $\bar{g}$ was defined by (6).

To illustrate this relation, suppose that the phosphate (base) molarity is 10^{-4} M at an ionic strength $c_1 = 0{\cdot}1$ M. For the equilibrium extent of binding $\theta_2 = 0{\cdot}25$ (50% phosphate charge compensation), (29) yields $\theta_2^t = 87$ or a total divalent cation molarity $8{\cdot}7 \times 10^{-3}$ M. One then calculates the value $\Delta\bar{g} = -0{\cdot}56$ from (51) for the B DNA value $\xi = 4{\cdot}2$. At 25 °C, then, the loss of 0·33 kcal free energy/mole phosphate accompanies the binding of 0·25 mole divalent cation/mole phosphate under these conditions. An interesting comparison is that, at the same ionic strength in the absence of divalent metal ion, formation of the bound layer of univalent cations is stabilized by the much larger amount 3·2 kcal/mole phosphate, as discussed in III B.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

C. *Two-variable theory*†

The constraints on θ_1, equation (25) for low binding levels and (33) for high, may be relaxed in a straightforward manner. The electrostatic free energy is taken as

$$\bar{g}_{\mathrm{el}} = -(1-\theta_1-N\theta_N)^2\,\xi \ln (1-\mathrm{e}^{-\kappa b}), \tag{52}$$

that is, both θ_1 and θ_N are variable and the net charge density after binding of univalent and N-valent cations is reduced from the stoichiometric value based on the phosphates alone by the factor $(1-\theta_1-N\theta_N)$. The mixing free energy is identical to equation (28), except that the coefficient $N\theta_N$ in the first term of the r.h.s. of (28) must be replaced by $-\theta_1$ to account for variable θ_1. Minimization of $\bar{g}_{\mathrm{el}}+\bar{g}_{\mathrm{mix}}$ with respect both to θ_1 and θ_N leads to the following two equations for the equilibrium values of θ_1 and θ_N:

$$1+\ln (10^3\theta_1\, V_P^{-1}/c_1) = -2\xi(1-\theta_1-N\theta_N)\ln (1-\mathrm{e}^{-\kappa b}), \tag{53}$$

$$\ln (\theta_N/c_N) = \ln (V_P/10000\mathrm{e})+N\ln [(10000/V_P)\, c_1^{-1}\theta_1]. \tag{54}$$

It is instructive to use these equations first to regain the results of the one-variable theory. Following the analysis of (11), one sees that (25) is indeed an approximate solution of (53) for small θ_N. Substitution of (25) into (54) yields a binding relation for M^{N+} identical to (29). Thus, the one-variable result for low levels of binding, (25) and (29), is an approximate solution of (53) and (54) for small θ_N.

For values of θ_N near saturation, an approximate solution of (53) and (54) is obtained as follows. First, note that

$$V_P = 10000\mathrm{e}\,(1-\xi^{-1})\,(\kappa b)^2\, c_1^{-1} \tag{55}$$

as a consequence of (11) with $N = 1$ and (14). Equation (55) is simply another form of (15). Now, anticipating that θ_1 is small near saturation of M^{N+} binding, substitute $\theta_1 = 0$ into the r.h.s. of (53), along with the approximation $1-\mathrm{e}^{-\kappa b} \approx \kappa b$. With (55) the result is an improved approximation for θ_1,

$$\theta_1 \approx (1-\xi^{-1})\,(\kappa b)^{2[1-\xi(1-N\theta_N)]}. \tag{56}$$

Substitution of this expression for θ_1 into (54), followed by a second application of (55), yields a result identical to (36), the prediction of one-variable theory for high levels of binding. Thus, (33) and (36)

† This section represents work done in collaboration with Nancy de Marky.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

constitute an approximate solution of equations (53) and (54) for high binding levels of M^{N+}.

Equations (53) and (54) can be solved exactly by numerical iteration. It is convenient to fix θ_N, obtain θ_1 from equation (53) by iteration, and then substitute θ_1 into (54) to get $K_N = \theta_N/c_N$ corresponding to the fixed value for θ_N. (An nth iterate for θ_1 may be obtained by substituting the $(n-1)$st into either the left- or right-hand side of (53); the scheme that converges depends on the value of θ_N. For small θ_N, a convenient zeroth-order trial for θ_1 is obtained from (25); for large θ_N, an appropriate starting point is $\theta_1 = 0$.)

The numerical results for DNA ($\xi = 4{\cdot}2$, $V_P = 646$ cm^3; see Table 1) are presented as the full curves in Figs. 1–5, the meanings of which were discussed above in connexion with the one-variable theory (dashed lines). At this point it can be remarked that the one-variable theory has provided useful approximations. Equation (29) is fairly accurate over a broad part of the low-binding end of the range (and nearly exact at $\theta_N = 0$), and (36) is reasonably good right at saturation (it is appreciably better at saturation than indicated by Fig. 2 if ionic strengths lower than 0·1 M are considered). More important than the degree of numerical accuracy of the approximations, since (53) and (54) are easily solved exactly, is the physical insight provided by the one-variable theory and discussed in detail above. The exact solution of (53) and (54) validates that discussion and sets limits to its applicability.

D. *Divalent metal ion binding*

1. *Summary of results for* $N = 2$. A summary of the main theoretical results obtained here must begin with the definition of the association constant K_2 (see equation (30)) as proportional to the equilibrium constant for the transfer of a divalent metal ion from free solution to a local volume region surrounding the polynucleotide, within which the metal cations move freely. For a duplex helix the 'association region' or 'free volume' V_P extends about 7 Å out from the surface of the helix (see Table 1). Thus defined, log K_2 is a linear function of the logarithm of the ionic strength (i.e. concentration of univalent cations from the excess 1 : 1 supporting electrolyte) with slope nearly equal to -2 over most of the binding range but dropping off rapidly to -1 as saturation is approached.

The association is anticooperative; K_2 decreases as the binding level increases. Over most of the binding range the functional dependence of

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

K_2 on extent of prior binding θ_2 is intrinsically quadratic (see equation (29)), becoming exponential only at the extremity near saturation. The origin of the anticooperativity is entropic; c_1^{loc} is decreased when divalent cation binds, in accordance with (25), so that the driving force decreases with θ_2; see (47). The repulsive interactions among bound divalent metal ions usually invoked to account for anticooperative behaviour are assumed here to contribute negligibly to the free energy and are not present in the model.

Equation (47), valid over most of the binding range, states that nearly the entire thermodynamic force that drives divalent cation binding is entropic, consisting of the positive concentration difference between bound but delocalized univalent counterions and univalent counterions free in the solution bulk. Binding of a divalent ion is accompanied by the net flow of two bound univalent counterions along this gradient, out into free solution. Only near the saturation end of the binding range does the decrease of electrostatic free energy (predominately still an entropy term, incidentally, since ϵT is nearly independent of temperature for water) become a source of binding free energy.

Substitution of the numerical values $\xi_{\text{DNA}} = 4{\cdot}2$ and $V_P^{\text{DNA}} = 646\ \text{cm}^3$ from Table 1 into equation (29) gives a good numerical approximation for K_2^{DNA} for θ_2 less than about 0·30,

$$\log K_2^{\text{DNA}} = 0{\cdot}39 + 2\log(1 - 2{\cdot}63\theta_2) - 2\log c_1. \qquad (57)$$

The exact equations (53) and (54) may be solved numerically, however, over the entire binding range.

2. *Comparison of theory with Mg^{2+} binding data.* Table 5 presents a comparison of values of $-\text{p}K_2$ calculated from (57) at $\theta_2 = 0$ (where (57) is essentially exact) with published measurements of $-\text{p}K_{\text{Mg}}^0$, the 'intrinsic' Mg^{2+} binding constant extrapolated to $\theta_{\text{Mg}} = 0$. The experimental values in the table are not necessarily the numerical values given for the quantity called 'K' in the cited source; rather, the experimental values in the table conform to the definition of K given in (30), extrapolated to $\theta_{\text{Mg}} = 0$. The agreement is quite good, especially if it is remembered that half a pK unit corresponds to a free energy discrepancy of only 0·7 kcal at 25 °C.

In Fig. 1 the Mg^{2+} binding data of Clement *et al.* (1973) at 10^{-3} M ionic strength clearly show the predicted upward curvature of a Scatchard plot. In Fig. 2 data from a variety of sources have all been 'normalized' to 0·1 M ionic strength by applying the theoretical curve

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

¶ From Clement, Sturm & Daune (1973); $M^+ = Na^+$.

of Fig. 3 to the original data (ranging in ionic strengths from 10^{-3} to 0·2 M). The resulting comparison shows that the ionic strength dependence of K_2 is about right (otherwise, many of the points would lie off the graph) and that the dependence on θ_2 is also given reasonably well. In Fig. 3 Krakauer's curve-fitting expression (1974) for poly A·poly U was used to obtain the points, which accounts for their regularity. The overall variation of slope is about the same for both theory and data points; the detailed curvature as a function of θ_2 cannot be tested on the basis of currently available data. Equation (47) predicts that the primary driving force for non-specific binding of divalent metal ions is the local counterion diffusion potential. If $c_1 \approx c_1^{loc}$, the potential disappears, and binding becomes very weak. Since $c_1^{loc} \approx 1$ M for DNA, the precise prediction is that the association constant for Mg or Ca ion binding should still be appreciable at 0·1 M but should fall to very low values at ionic strengths in the neighbourhood of 1 M. Fig. 2 indicates that K_2 is about 10^2 at 0·1 M. Data are not available for ionic strengths higher than 0·2 M, for which K_{Mg} was measured to be 59 (Zubay & Doty, 1958), but the theoretical prediction

$$\mathrm{d} \log K_2 / \mathrm{d} \log c_1 = -2,$$

which is more or less in line with observation, suggests strongly that measured values of K_2 at 1 M will be found to be of order unity, if indeed such small values can be measured at all.

3. *Conclusion.* From the reasonably successful comparison of theory and experiment for Mg^{2+} binding I conclude that the molecular model on which the theory is based may be quite realistic; in particular, Mg^{2+}

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

(and probably many other divalent metal cations) binds to polynucleotides in the delocalized mode. The immediate environment of a bound Mg^{2+} ion is very nearly the same as in free solution; the bound state is characterized by essentially complete hydration and free translational and rotational mobility. In view of the independent evidence outlined in Section II consistent with the same conclusion, the case for delocalized binding of Mg^{2+} is a strong one.

E. *Binding of small cations with complex structure*

1. *Introduction.* It is reasonable to wonder how well equation (29) may work for cationic substances with relatively small values of N, but with 'structure', typically due to discretely protonated nitrogen atoms on the same molecule. One would certainly worry about the naïve use of (29) for any but the lowest values of θ_N, since excluded volume effects among bound cations have not been considered. However, the few binding data that do exist are fortunately concerned with the 'intrinsic' binding at $\theta_N = 0$. For DNA substitution of the values $\xi = 4{\cdot}2$, $V_P = 646$ cm^3 from Table 1 and $\theta_N = 0$ into (29) yields

$$\log K_N = -0{\cdot}62 + 0{\cdot}51N - N \log c_1, \tag{58}$$

and the equation may be easily compared with available data, provided the latter are used in a form consistent with the definition, (30), of K_N.

2. *Oligolysine.* Record, Lohman & de Haseth (1976) have reanalysed the data of Latt & Sober (1967) for the binding of a series of oligolysines with charge state $+N$, $N = 3$ to 8. The experimental results in NaCl could be adequately represented by

$$\log K_N = (-0{\cdot}62 + 1{\cdot}46) + (0{\cdot}51 - 0{\cdot}68)\, N - 0{\cdot}9N \log c_1, \tag{59}$$

where the first two terms have been written as sums to facilitate comparison with equation (58). The polynucleotide used was poly A · poly U, the structure of which is close enough to DNA (see Table 1) to allow direct comparison of (59) with (58). (The reader, if worried by this statement, may change the numerical values $-0{\cdot}62$ and $0{\cdot}51$ in (58) and (59) to $-0{\cdot}66$ and $0{\cdot}55$, respectively, to correspond exactly to the specification for poly A · poly U in Table 1.) The form of (59) is correctly predicted by (58). Log K_N is linear in both N and log c_1. As a function of N it has a non-zero intercept that is independent of c_1 and a slope that varies linearly with log c_1. As a function of log c_1 both the intercept and slope vary linearly with N.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

Interpretation of the numerical value of the intercept at $N = 0$ is made difficult by the presence of an extra lysine bearing an ϵ-DNP group on each member of the series used in the binding experiments. Equation (58) reflects only ionic and ideal mixing effects; the non-zero intercept is due to the translational entropy of the oligolysine molecule, as a unit, within the free volume that defines the bound state. As suggested by Latt & Sober (1967), the DNP group may contribute significantly to the binding, and its contribution would then show up in the intercept, providing thereby a satisfactory explanation for the discrepancy of 1·46 pK units between measured and predicted intercepts. It should be stressed, however, that observation of a non-zero intercept does not imply by itself a specific interaction independent of the ionic contribution, since (58) possesses a non-zero intercept but is derived exclusively from nonspecific ionic theory.

The linear dependence on N originates theoretically from the difference in ideal entropies of mixing of N M^+ ions in the condensed state relative to bulk solution (that is, from the counterion diffusion potential), since N condensed univalent cations diffuse into bulk solution as one N-valent cation binds. There is reasonable agreement between the theoretical slope $-N$ as a function of log c_1 and the measured result $-0{\cdot}9N$.

The concentration-independent second term of (59) is 0·68 pK units lower, on an electrostatically equivalent basis (i.e. divide by N), than the corresponding theoretical term in (58). That is, per equivalent bound, this contribution to the binding free energy is observed to be 0·93 kcal *less* than predicted (at 25 °C). I shall discuss below the possible significance of this fact.

Unpublished data of Lohman and Record for the binding of pentalysine (charge state $N = 5$) to DNA at pH 6 can be represented by (Record, personal communication)

$$\log K_5 = -0{\cdot}62 + (0{\cdot}51 - 0{\cdot}57)(5) - 5{\cdot}3 \log c_1, \qquad (60)$$

where, again, the form facilitates comparison with (58). The observed slope $-5{\cdot}3$ of the log c_1 dependence compares favourably with the predicted value -5 from (58). Having, in writing (60), simply *assumed* that the form of (58) applies with the value $-0{\cdot}62$ as the correct result of extrapolation of log K_N to $N = 0$ (the pentalysine used by Lohman and Record does not have the extra ϵ-DNP lys group of the Latt–Sober compounds), I now note that the apparent discrepancy in the

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

second term is 0·57 pK units per equivalent; at room temperature, the observed binding free energy corresponding to this term is 0·78 kcal/(bound equiv.) less than predicted, a value quite similar to that obtained above for the Latt–Sober series. See Record *et al.* (1978) for a discussion of these data from another point of view.

3. *Spermine.* Spermine is a polyamine with charge state $N = 4$. For the ionic strength $c_1 = 0{\cdot}15$ M-NaCl, an observed value of K_4 for binding to DNA may easily be extracted from the data of Shapiro *et al.* (1969*b*). The value is $\log K_4 = 2{\cdot}89$, or

$$\log K_4 = -0{\cdot}62 + (0{\cdot}51 - 0{\cdot}46)(4) - (4)\log(0{\cdot}15). \tag{61}$$

Comparison with (58) yields an apparent discrepancy in the second term of 0·46 pK units; the observed binding free energy is 0·63 kcal/(bound equiv.) less than predicted at 25 °C.

4. *Lys-trp-lys.* Data for the binding of this tripeptide (charge state $N = 2$) to poly A are available (Brun, Toulmé & Hélène, 1975) and may be represented by (Record, Lohman & de Haseth, 1976)†

$$\log K_2 = -1{\cdot}8 - 2{\cdot}4 \log c_1. \tag{62}$$

Parameters for poly A are listed in Table 1; the corresponding numerical form of the theoretical equation (29) at $\theta_2 = 0$ is

$$\log K_N = -0{\cdot}23 - 0{\cdot}02N - N \log c_1. \tag{63}$$

Accordingly, the empirical equation (62) can be recast into the form

$$\log K_2 = -0{\cdot}23 - (0{\cdot}02 + 0{\cdot}77)(2) - 2{\cdot}4 \log c_1. \tag{64}$$

The observed coefficient $-2{\cdot}4$ of the $\log c_1$ dependence is in reasonable agreement with the value -2 predicted from (63). The discrepancy of 0·77 pK units in the second term corresponds to an observed binding free energy lower than predicted by the amount 1·0 kcal/(bound equiv.) at 25 °C. Record *et al.* (1978) have also analysed these data within the context of their binding theory.

5. *Discussion and conclusion.* It is striking that substances with charge states as diverse as lys-trp-lys and octalysine and with structures as distinct as spermine and oligolysine should all have observed binding free energies lower than predicted by 0·6–1·0 kcal/bound equiv. It

† Equation (62) represents the stability constant of the complex denoted as 'A' by Brun *et al.* and conceived by them as not involving interaction of the trp residue with the adenine bases. The analysis given here makes no contact with the question of whether or not A is in dynamic equilibrium with a stacked complex B.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

should first be realized that, whatever the biological importance of small binding energies, the molecular theoretician cannot help but be pleased by such small discrepancies, of the order of random thermal energy, between observation and *a priori* calculation. It is fair to conclude that the model of delocalized binding on which the theory rests may be realistic for these cationic substances. The observation that predicted binding constants *overestimate* measured values strengthens this conclusion, since localization of the cation in potential energy wells on the polynucleotide could be expected to require sources of binding free energy *in addition to* those considered in the model. The difference between observation and an *underestimated* prediction could have been consistently attributed to localization; the overestimate actually found does not encourage this line of reasoning. At the present time, therefore, I believe that interpretations of the binding of these substances in terms of ion-pair formation, stabilized by hydrogen bonds, are not warranted. Binding to the bases has been ruled out for spermine and tetralysine by the differential dialysis measurements of Shapiro, Stannard & Felsenfeld (1969).

The molecular origin of the discrepancy between theory and experiment could be a conformational change induced in the cation while in the bound state. Schematically, one may speculate as follows. When free in solution octalysine tends to project its charged lysine residues on alternate sides of the molecule. In this conformation, not all eight residues can fit simultaneously into the bound region V_P, which is only 7 Å thick, and octalysine would bind like a cation of valence lower than eight. However, if all lysine residues are brought to the same side of the molecule, octalysine can bind like an octavalent cation. Since octavalent cations preferentially displace cations of lower valence (for the same reason that Mg^{2+} displaces Na^+ ions), the latter conformer will be the bound form. The process of binding can be thermodynamically described as the sequential transformation from a '*trans*' to a '*cis*' form in solution followed by binding of the *cis* form. The first step involves bringing like charges closer together (and possibly other strains) and hence costs free energy. The observed binding constant is therefore smaller than what would be expected of a structureless octavalent cation. The structure of spermine suggests less conformational energy expenditure per equivalent than for oligolysine, and the corresponding discrepancy between theory and experiment is in fact the least of all the substances considered. The bulky tryptophan residue may impose

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

more severe restrictions on the spatial arrangement of the lysine residues in lys-trp-lys; the corresponding discrepancy is indeed the greatest of those considered.

F. *Binding of high-molecular-weight cationic substances*

1. *Introduction.* Complexes of DNA with a surprisingly large variety of cationic substances are observed to dissociate when the ionic strength is raised to about 1 M. The simplest example, the Mg/DNA complex, has already been discussed in Section IV D. Additionally, the empirical formulas in the preceding section for the binding of oligolysine show association constants that drop off to values of the order unity at 1 M ionic strength. The phenomenon is not restricted to small cations; polylysine/DNA complexes (Leng & Felsenfeld, 1966; Shapiro, Leng & Felsenfeld, 1969) and nucleohistones in chromatin (Weintraub, Palter & van Lente, 1975) dissociate at about 1 M as well. An ionic strength of 0·6 M is sufficient to elute DNA from DEAE columns (Hirsh & Schleif, 1976). Extrapolation of binding data for the complex formed from *lac* repressor and non-operator DNA (de Haseth, Lohman & Record, 1977; Record *et al.* 1978) suggests that the binding constant is of order unity at about 0·5 M ionic strength even though it is of order 10^6 at 0·1 M.

It is likely that such close phenomenological similarity has its molecular origin in structural features possessed in common by all these systems. In fact the above behaviour would be *predicted* under the assumption that all these binding processes are predominately driven by the counterion diffusion potential, the local tendency of counterions to diffuse into free solution from a region of high concentration, which for DNA has the value 1·2 M.

In the absence of clear evidence to the contrary, therefore, it does not seem necessary to invoke a specific, geometrically complementary, structure for each of the complexes, nor is it necessary to conceive of cationic groups as having entered into hydrogen-bonded ion pairs with the phosphate oxygen atoms. The dominant driving force for complexation is brought into play simultaneously with penetration of cationic groups into the free volume V_P containing a locally high concentration of univalent counterions. The resulting complex is 'loose'; the cationic substance (or positively charged region of a protein) is free to slide along the DNA surface with a layer or two of water molecules intervening. Of course, the sliding motion of a protein (a histone, for

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

example) can be prevented by purely mechanical means if the DNA helix is wrapped around it.

In the following paragraphs I shall discuss what appear to be implications of this description for three cases of interest: polylysine-DNA, repressor-DNA, and repressor-operator.

2. *The polylysine/DNA complex.* The possibility that polylysine forms a loose *non-specific* complex with DNA in the sense of the preceding paragraph is supported by at least three lines of evidence. As discussed above, the complex dissociates at about 1 M ionic strength, implying stabilization by realization of the non-specific counterion diffusion potential (tendency of counterions to diffuse into free solution from a *loosely* bound state). By direct calorimetry, Ross & Shapiro (1974) showed that the binding of polylysine to DNA is accompanied by only very small enthalpy changes; it is primarily entropy-driven, as would be true for a process driven by local counterion diffusion. (Ross & Shapiro also determined that the same is true for the binding of Mg^{2+}, spermine, and tetralysine.) Finally, Mirzabekov & Melnikova (1974) measured the effect of polylysine binding on methylation of the $N_{(7)}$ atom of guanine in the major groove of DNA and $N_{(3)}$ of adenine in the minor groove. Polylysine had no effect on the methylation reaction in either groove, in contrast to significant interference effects found for a variety of other binding substances. The conclusion suggested by the authors was that polylysine does not make contacts in either groove when bound to DNA. Indeed, it should be asked whether their data do not definitively rule out models which have the entire polylysine backbone buried in a groove with the cationic residues 'sticking out' and attached to the phosphates.

The indisputable fact remains that polylysine can quantitatively precipitate A·T-rich DNA from a mixture of A·T-rich and G·C-rich DNA (Shapiro, Leng & Felsenfeld, 1969). It may be, however, that this phenomenon has its molecular basis entirely in the base-specific properties of DNA itself, and not in any specific properties of the complex. If A·T-rich DNA were inherently more flexible than G·C-rich DNA, then even the loose, nonspecific binding of polylysine to the former could more easily induce folding of the double helix in the vicinity of the bound polylysine molecule. In effect, then, polylysine may bind to a more completely 'doubled over' region of DNA if the latter is rich in A·T base pairs, hence to a region of somewhat higher charge density than would be available in G·C-rich DNA. Even a 5°′

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

differential increase in charge density would be enormously magnified, first because, according to (16), the local concentration c_1^{loc} of univalent counterions would be relatively increased by the factor $(1{\cdot}05)^2 = 1{\cdot}10$, and then because (47) implies that the ratio of affinities for a 50-residue polylysine bound to A·T-rich relative to G·C-rich DNA would be $(1{\cdot}10)^{50}$, or two orders of magnitude. Even a 1% effect in the charge densities translates into an affinity ratio of 3 for a 50-residue polylysine and 7 for 100 residues. Concerning the hypothesis that A·T-rich DNA may be less stiff than its G·C-rich counterpart, there is no evidence one way or the other as far as I know; nevertheless, in view of the detailed analysis in Section VI of electrostatic effects on DNA flexibility, it may be a reasonable conjecture.

3. *The complex of lac repressor with non-operator DNA.* As mentioned in paragraph 1 of this section, the affinity of *lac* repressor for non-operator DNA extrapolates to very low values at ionic strengths of the order of 1 M, a behaviour consistent with a loose and mobile complex. In addition, no volume change on binding could be detected by Revzin & von Hippel (1977), the likely implication being that the cationic groups on repressor (the binding region of repressor, for both operator and non-operator DNA, is known to be cationic), do not approach DNA sufficiently closely to release water of hydration from either repressor or DNA.

Methylation protection experiments (Kolchinsky *et al.* 1976) indicate, in agreement with other evidence (Lin & Riggs, 1972; Richmond & Steitz, 1976), that repressor makes no contacts in the major groove of non-operator DNA. Repressor does protect the minor groove against methylation, but the measure of protection is small, about 15%, a figure that can be contrasted to the 78% effect obtained with ethidium bromide.

These considerations are all consistent with a counterion-potentiated complex (de Haseth *et al.* 1977) perturbed by interactions in the minor groove that are too weak to prevent either substantial repressor mobility when bound or complete dissociation when the ionic strength is raised. It is reasonable to speculate that the weak interactions may involve contacts between cationic residues in the binding region of repressor with thymine $O_{(2)}$ atoms located in the minor groove (see Section III F).

4. *Repressor/operator complex.* The repressor/operator complex *is* specific. Under physiological conditions its binding affinity is some eight orders of magnitude higher than the affinity of repressor for non-operator DNA (Record, de Haseth & Lohman, 1977; Revzin &

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

von Hippel, 1977). Its binding constant does not extrapolate to a small value at 1 M salt (Record *et al.* 1977). However, the same region of repressor that is responsible for its DNA binding capability is also necessary for binding to the operator segment (Bourgeois & Pfahl, 1976). Moreover, the ionic strength dependencies of the binding to operator and to non-specific DNA, although significantly different, are similar both in form and magnitude (Record *et al.* 1977). It can therefore be concluded (Record *et al.* 1977) that the stability conferred on the repressor/DNA complex by the counterion diffusion potential is largely transferred to the repressor/operator complex, and that the enhanced stability of the latter is due to superposition on the counterion potential of a rather strong interaction in the grooves.

Methylation experiments (Gilbert, Maxam & Mirzabekov, 1975) show that both major and minor grooves on the operator are protected when repressor is bound. Taking into account their result that repressor interacts weakly with only the minor groove in non-operator DNA, Kolchinsky *et al.* (1976) have proposed that when repressor initially binds to a non-operator region of operator-containing DNA, it proceeds to wander around, poking into the minor groove until it roughly recognizes the operator, whereupon it clamps down firmly on the operator, surrounding it and interacting strongly in both grooves. To supplement this attractive picture I offer a conjecture which may be extreme but that is nonetheless consistent with available data. If, as suggested in paragraph 3, the occasional probing by repressor of the non-operator minor groove is accomplished by means of weak contacts of one or two cationic residues with thymine $O_{(2)}$ atoms, it is then possible that, upon encountering a sterically specific sequence of thymine $O_{(2)}$ atoms in the minor groove of the operator, the repressor falls into a deep potential well created by entropic release of one or two water molecules from each of several 'partially ionic pairs' formed from cationic residues and thymine $O_{(2)}$'s. The repressor could be pictured as swinging around to cover the major groove, without actually forming stabilizing contacts there, although that could happen also. This conjecture is consistent with the known facts that the 'extra' stability of the repressor/operator complex, over and above that of the non-operator DNA/repressor complex, is also entropic (Riggs, Bourgeois & Cohn, 1970), and that under conditions conducive to dehydration thymine and uracil $O_{(2)}$ atoms are substantially anionic in character (Section III F).

V. Ionic effects on the DNA helix–coil transition

A. *Electrostatic free energy and entropy of transition*

The coil form of DNA (separated strands) has a lower charge density than the native duplex helical form. It is expected, therefore, that the electrostatic free energy in the coil phase is lower than that in the helix phase. To proceed quantitatively, define $\Delta\bar{g}$ as the difference 'coil minus helix' of the free energies per mole phosphate in units of RT, and let $\Delta\bar{g}^0$ refer to the non-electrostatic contribution. The prescription given in Section II C for calculating the free energy of a polyelectrolyte solution characterized by any value of b (axial charge spacing) is now applied to both coil and helix forms of DNA, and the difference is taken. The result for DNA in an aqueous solution of excess 1 : 1 salt is

$$\Delta(\bar{g}-\bar{g}^0) = \Delta[(1-\xi^{-1})\ln(c_1^{\infty}/c_1)-\xi^{-1}\ln(\kappa b)], \tag{65}$$

where all quantities have been defined in Section II. The numerical result may be obtained by reference to Table 1 and equation (5),

$$\Delta\bar{g} = \Delta\bar{g}^0 - 1{\cdot}11 + 0{\cdot}36\log c_1, \tag{66}$$

where the coefficient of $\log c_1$ is the numerical value of $\frac{1}{2}(\Delta\xi^{-1})\ln 10$. The ionic contribution to the enthalpy change, which is contained in the slight temperature dependence of the product of absolute temperature and bulk dielectric constant of water, is less than 0·1 kcal per mole phosphate and may be neglected for practical purposes. Equation (66) implies therefore that the ionic contribution to the entropy change is about 3 entropy units per mole phosphate for ionic strengths in the neighbourhood of 0·1 M. For comparison, the total entropy change from all sources is about 11 or 12 entropy units per mole base.

B. *Dependence of T_m on ionic strength*

The dependence of T_m on ionic strength is implicit in the defining relation

$$\Delta\bar{g}(T_m, c_1) = 0. \tag{67}$$

Application of the Gibbs–Helmholtz identity to both sides of this equation, together with equation (65), gives (Manning, 1972*b*)

$$\mathrm{d}T_m/\mathrm{d}\log c_1 = \tfrac{1}{2}(\Delta\xi^{-1})\,(2{\cdot}30RT_m^2/\Delta h^0), \tag{68}$$

where Δh^0 is the enthalpy change *per mole phosphate* at the melting temperature. The value of $\Delta\xi^{-1}$ from Table 1 is 0·32. It is an empirical fact that the quantity $2{\cdot}30RT_m^2/\Delta h^0$ is nearly independent of T_m. Values

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

determined from three separate calorimetric studies are 115°, 129° and 156° (Record, Woodbury & Lohman, 1976). The corresponding theoretical values of $dT_m/d \log c_1$ from equation (68) are 18°, 21° and 25° respectively. A recent experimental value of $dT_m/d \log c_1$ is 19·5° (Record, 1975). Agreement between theory and experiment is close; the 'discrepancy' noted in a previous publication (Manning, 1972*b*) was due to use of an incorrect value for b for the coil form.

A few words should be devoted at this point to the appropriate values of b. For the duplex helix the value 1·7 Å given in Table 1 is merely the familiar 3·4 Å step height of the B form divided by the two phosphate groups per step. For the separated strand the value $b = 4{\cdot}0$ Å in Table 1 was chosen as that which provides the best average agreement of (68) with measurement (Record, Woodbury & Lohman, 1976; Manning, 1976*a*). However, closely similar values of b for the coil have also been obtained by independent means (Manning, 1976*a*). The value 3·8 Å was determined by low-angle X-ray scattering on poly C in solution at elevated temperature (Gulik, Inoue & Luzzati, 1970). An identical value was deduced from an *a priori* conformational energy analysis, assuming equal proportions of C(3′)-*endo* and C(2′)-*endo* residues and the absence of all-*trans* arrangements of the phosphodiester link (Olson & Manning, 1976). Therefore equation (68) can either be viewed as a means of converting calorimetric and melting temperature measurements into a numerical value of the axial charge spacing for a single strand, or as an independent theoretical equation which accurately predicts the ionic strength dependence of T_m from calorimetric data and known values of the charge spacings of helix and coil.

C. *Role of the counterion diffusion potential*

The coil form of DNA (separated strands) has a lower charge density than the native duplex helical form. Therefore the structural transition native → coil is a mechanism for relief of phosphate–phosphate repulsive stress. At temperatures greater than T_m this mechanism for compensation of phosphate repulsion becomes available to the system as an alternative to counterion binding. Therefore, in accordance with the discussion at the end of Section II C, the potential for local counterion diffusion is realized and accompanies the spontaneous transition as the ionic contribution to the overall driving force, identifiable quantitatively as the first term on the r.h.s. of equation (65).

The second term in (65) is also electrostatic but acts in the opposite

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

direction to stabilize the helix. Its physical origin is in the fact that the net charge per phosphate, $-\xi^{-1}q$, is lower for the helix than for the coil, so that screened electrostatic repulsion among pairs of phosphates is *greater* for the coil form. The relation $(\kappa b)^2 = e^{-1}(c_1/c_1^{1oo})$ mentioned in IIC may be used to show numerically that this 'counter-driving force' is considerably smaller than the counterion diffusion term. Interestingly, however, the magnitude of the ionic-strength dependence (the log c_1 term) contributed by this effect is fully 50% as large as that from counterion diffusion.

A qualitative prediction following from this discussion is that the ionic-strength dependence of T_m should level off as c_1 approaches c_1^{1oo}, or about 1 M. Precisely this behaviour is in fact commonly observed (Schildkraut & Lifson, 1965). The related consequences of ionic strengths of about 1 M for multivalent cation binding should be recalled (see Section IVF, 1).

D. *Effect of strong electric fields on T_m*

The dissociation-field theory described in Section IIIE may be used to calculate the effect of an electric field on the stability of the DNA double helix (Manning, 1977*c*). Let $\bar{g}(0)$ be the free energy, minimized as in Section IIC, of a polyelectrolyte solution in the absence of an electric field (in units of RT per polyelectrolyte equivalent); the corresponding quantity in the presence of a field $\boldsymbol{E}$ is designated by $\bar{g}(\boldsymbol{E})$. The explicit free energy calculation gives, to first order in $\boldsymbol{E}$,

$$\bar{g}(\boldsymbol{E}) - \bar{g}(0) = (1 - \xi^{-1})\,\bar{\bar{E}}, \tag{69}$$

where $\bar{\bar{E}}$ has been defined by equation (23) and all counterions are assumed univalent. The physical meaning of this equation is transparent; the number of condensed counterions is $1 - \xi^{-1}$ per polyion charge, and each of these ions has the additional energy $\bar{\bar{E}}$ (in units of kT) when the field is applied. The actual dissociation of some of the condensed counterions enters only as a negligible second-order effect. It is understood that the field is 'pulsed' for a time sufficiently short to eliminate orientational effects.

If this relation is applied both to double helical DNA and to its separated strands,

$$\Delta\bar{g}(\boldsymbol{E}) - \Delta\bar{g}(0) = \Delta[(1 - \xi^{-1})\,\bar{\bar{E}}]. \tag{70}$$

The quantity $\bar{\bar{E}}$ is slightly different for single strands and double helix

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

(since the parameter a in equation (23) depends on ξ), but the dominant effect is simply that $1-\xi^{-1}$ is larger for the double helix relative to separated strands (the right-hand side of equation (70) is negative). Intact DNA binds the greater number of cations and hence suffers the greater increase of energy when the field is turned on ($\Delta\bar{g}(E) < \Delta\bar{g}(0)$). The free energy of the double helix becomes relatively higher, and the tendency for strand separation is enhanced. The T_m is lowered by the field. Upon insertion of the appropriate numerical values equation (70) becomes

$$\Delta\bar{g}(E)-\Delta\bar{g}(0) = -0{\cdot}94\times 10^{-3}\,E, \tag{71}$$

if E is in kV/cm.

Now if strand separation is actually to occur, $\Delta\bar{g}(E)$ must be reduced by the field to the value zero. Field-induced strand separation is a *threshold* phenomenon that does not occur for fields below a critical, or threshold, value. Let E_{th} denote the threshold field. Then, from (71)

$$E_{\text{th}} = 1060\Delta\bar{g}(0). \tag{72}$$

It follows immediately from equation (66) that E_{th} is linear in $\log c_1$ with

$$\mathrm{d}E_{\text{th}}/\mathrm{d}\,\log c_1 = 350\ \text{kV/cm}. \tag{73}$$

Field-induced melting has not been unambiguously observed. The predicted effect is small; experiments would have to be done at an ionic strength such that the T_m in the absence of the field is only a few degrees higher than the temperature of the apparatus. Melting might then be observed at a field of order 50 kV/cm (Manning, 1977*c*). At significantly higher ionic strengths (higher T_m) equation (73) suggests that the highest attainable fields might not be sufficient to induce melting (i.e. to lower the T_m to the ambient temperature). Detailed measurements on the non-cooperative unstacking of poly C, however, have revealed a threshold field that varies linearly with the logarithm of the ionic strength (Pörschke, 1976*b*). It is not clear at the moment whether it is easier to extend the theory to non-cooperative melting or to do the experiment for DNA.

E. *Effect of pH on T_m; average axial phosphate spacing of single strand DNA as a function of pH*

Titration of the bases with acid or alkali affects the polyelectrolyte behaviour only by changing the value of ξ (Record, Woodbury & Lohman, 1976). Heretofore, ξ was considered as being built up by the

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

negative phosphate charges only; the bases were tacitly assumed to be untitrated, and (68), for example, applies only to the pH band about pH 7 for which the bases are in fact uncharged, at least if Table 1 is to be used for the numerical values of ξ. Protonation of bases decreases the value of ξ; deprotonation augments the negative phosphate charge, and consequently ξ is increased.

For a given pH, let the extent of titration per nucleotide be k_h and k_c for duplex DNA and a coiled single strand, respectively. Then (Record, Woodbury & Lohman, 1976)

$$\xi_h' = \xi_h(1 \mp k_h), \tag{74}$$

where ξ_h' is the value of ξ to be used in polyelectrolyte calculations, ξ_h is its value based only on the phosphate charges (equal to 4·2), and the upper and lower sign refer, respectively, to acid and alkaline titration. An analogous expression holds for the separated strands. The number of condensed M^+ cations per nucleotide is $1-\xi_h'^{-1}$, while the screening free energy per mole nucleotide given by equation (8) for the neutral pH case with $N = 1$ turns out to be unmodified because of the distinction that must now be made between moles of nucleotides and polyion equivalents (Record, Woodbury & Lohman, 1976). The result for the ionic strength dependence of T_m, analogous to equation (68), is

$$\mathrm{d}T_m/\mathrm{d}\log c_1 = (2{\cdot}30RT_m^2/\Delta h^0)\,(\tfrac{1}{2}\Delta\xi^{-1} \pm \Delta k). \tag{75}$$

Note that if the bases are untitrated ($k_h = k_c = 0$), or if there is no *differential* titration ($\Delta k = 0$), then equation (75) reduces to equation (68). The situation is somewhat more complicated than indicated by equation (75) since acid titration can in practice lower ξ' to the extent that it becomes less than unity, so that no M^+ cations condense (recall that the charge fraction is ξ'^{-1}) and other expressions apply for the free energy (Manning, 1969). The details are presented in full by Record, Woodbury & Lohman (1976).

The extents of titration k_c and k_h are experimentally accessible at each pH, as is $\mathrm{d}T_m/\mathrm{d}\log c_1$ and Δh^0. It may be assumed that $\xi_h = 4{\cdot}2$ regardless of pH because of the double helical rigidity. However, it is possible that the average axial nucleotide spacing on the single strand may increase with the total charge placed on the chain. Hence, ξ_c is regarded as the sole adjustable parameter in equation (75) and the values of b_c in Table 6 are those required to bring (75) into agreement with data (Record, Woodbury & Lohman, 1976). It is seen from the table that the

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

TABLE 6. *Variation of single-strand nucleotide spacing (b_c) with pH*†

pH	ξ_c	b_c (Å)
11·3	1·14	6·3
11·0	1·19	6·0
10·8	1·27	5·7
9·0	1·49	4·8
7·0	1·72	4·1
4·8	2·50	2·9
4·5	2·78	2·6
3·7	4·00	1·8
3·2	4·17	1·7

† Reproduced with permission from Record, Woodbury & Lohman (1976).

axial nucleotide spacing (contour length divided by number of bases) does indeed increase with pH, reaching the value characteristic of a fully extended chain at the highest pH. Apparently the all-*trans* conformation, which may be excluded at neutral pH (Olson & Manning, 1976) becomes dominant upon sufficient deprotonation of the bases with consequent strong close-range electrostatic repulsion. Finally, the value at the lowest pH suggests that the single strand has 'folded over' on itself and adopted a spacing similar to that of the double helix (recall that $b_h = 1{\cdot}7$ Å and $\xi_h = 4{\cdot}2$).

F. *Ionic effects of strandedness on T_m*

The four transitions of the (poly A, poly U) system provide a nice test of the theory (Record, Woodbury & Lohman, 1976). Only two of the four transitions are thermodynamically independent and may be chosen as

(1) poly A·poly U → poly A + poly U,
(2) poly A·2 poly U → poly A + 2 poly U.

It is easy to show (Record, Woodbury & Lohman, 1976; de Marky, unpublished) that the corresponding theoretical equations for

$$\mathrm{d}T_m/\mathrm{d}\log c_1$$

have the same form as (68),

$$\mathrm{d}T_m/\mathrm{d}\log c_1 = \tfrac{1}{2}(\Delta_i \xi^{-1})\,(2{\cdot}30RT_m^2/\Delta h^0), \tag{76}$$

but with $\Delta_i \xi^{-1}$ given by the number-averaged differences,

$$\Delta_1 \xi^{-1} = \tfrac{1}{2}\xi_{\mathrm{A}}^{-1} + \tfrac{1}{2}\xi_{\mathrm{U}}^{-1} - \xi_{\mathrm{A{\cdot}U}}^{-1} \tag{77}$$

$$\Delta_2 \xi^{-1} = \tfrac{1}{3}\xi_{\mathrm{A}}^{-1} + \tfrac{2}{3}\xi_{\mathrm{U}}^{-1} + \xi_{\mathrm{A{\cdot}2\,U}}^{-1}, \tag{78}$$

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

where the subscripts '1' and '2' refer to the transition number. If it is assumed that $\xi_A = \xi_U$, then $\Delta_i \xi^{-1}$ collapses to the quantity $\Delta\xi^{-1}$ of equation (68). The values of $\xi_{A\cdot U}$ and $\xi_{A\cdot 2U}$ are known from X-ray data: $\xi_{A\cdot U} = 4{\cdot}6$, $\xi_{A\cdot 2U} = 6{\cdot}8$ (Record, Woodbury & Lohman, 1976). The required calorimetric and T_m data are available (Krakauer & Sturtevant, 1968) and have been tabulated in convenient form by Record, Woodbury & Lohman (1976).

Let us assume first that $\xi_A = \xi_U = 1{\cdot}9$, the numerical value for unstacked (high-temperature) poly C (see Section VB). The values of $dT_m/d \log [Na^+]$ predicted from (76) are then 20° for transition (1) and 24° for transition (2); the observed values are 19·6° and 26° respectively. For the K^+ salt the $\Delta h^0/T_m^2$ data are slightly different. Predicted values of $dT_m/d \log [K^+]$ are 21° and 28° for transitions (1) and (2), respectively, while the corresponding measured values are 17·4° and 27°.

Equation (76) may be used in another way (Record, Woodbury & Lohman, 1976). Written for both transitions (1) and (2), two equations in the two unknowns ξ_A and ξ_U are obtained, all other quantities being given from the available data. The values $\xi_A = 2{\cdot}3$ and $\xi_U = 1{\cdot}6$ are obtained from the Na^+ data; the K^+ data yield $\xi_A = 3{\cdot}1$ and $\xi_U = 1{\cdot}6$. It is not unreasonable that the axial phosphate spacing should be greater for unstacked poly U than for poly A, which is partially stacked even at typical melting temperatures. The axial spacing b for poly U corresponding to $\xi = 1{\cdot}6$ (obtained in both Na^+ and K^+ salts) is 4·5 Å, which could be slightly high (Manning, 1976*a*). The axial spacings for poly A corresponding to the ξ values 2·3 (Na^+) and 3·1 (K^+) are 3·1 Å and 2·3 Å. The former value is essentially the same as that which characterizes the fully stacked low-temperature form of poly A (Stannard & Felsenfeld, 1975), but the latter value is much too small to be rationalized. Using a similar method, Pless & Ts'O (1977) have determined the axial charge spacings for poly dA and dT_8 as 3·3 and 4·9 Å, respectively.

G. *Effect of Mg^{2+} on T_m*

Section IVB outlined a method for obtaining the free energy of a polynucleotide solution in which Mg^{2+} ions are present along with excess 1 : 1 salt. Therefore it is possible to calculate $\Delta\bar{g}$ and T_m for the DNA melting transition under these conditions (deMarky & Manning, in preparation). Theory and measurements are compared in Fig. 6. The

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

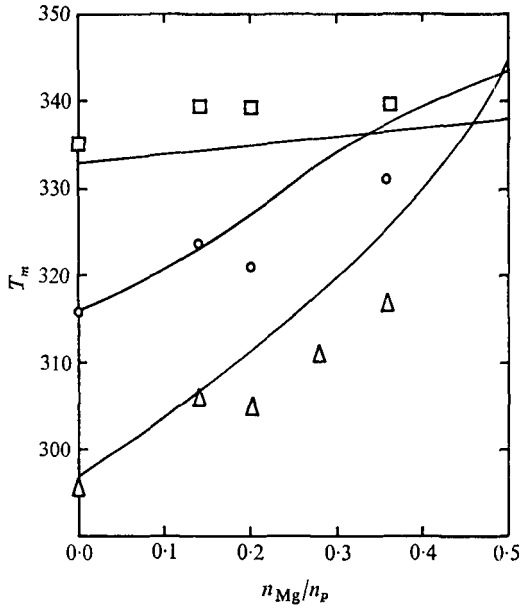

Fig. 6. Melting temperature of DNA as a function of added Mg^{2+} at three different ionic strengths, 10^{-2}, 10^{-3} and 10^{-4} M, from top to bottom at left. The theory (solid curves) has been adjusted to match the data at the single point of zero Mg^{2+} and 10^{-3} M (middle curve at origin). Data from Record (1975).

abscissa in the figure is equivalents of total added Mg^{2+} per mole phosphate, so that the points and curves refer to low binding levels of Mg^{2+}. The data points are taken from Record (1975). The single theoretical point at 10^{-3} M-NaCl and $n_{Mg} = 0$ is forced to coincide with the measured value (since T_m reflects a non-ionic contribution in addition to ionic effects), but all other points on the curves are determined from *a priori* theory with the sole parameters b_h and b_c, both of which are known independently. It is especially to be noted that the near-independence of T_m on added Mg at 10^{-2} M-NaCl, both as observed and predicted by theory, does not mean that Mg^{2+} ions are not bound at this ionic strength. The theoretical and measured binding constants in Table 5 show that Mg remains strongly bound at 10^{-2} M, at least to the double helix, and theoretical values of K_{Mg} for the single strand are also appreciable (an order of magnitude lower). Therefore the invariance of T_m at this ionic strength reflects a delicate differential balance between Mg^{2+} binding to the two DNA forms, and the success-

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

ful prediction correspondingly suggests a high degree of theoretical accuracy.

One of the more interesting phenomena associated with Mg^{2+} binding is the cross-over of the curves seen at the high end of the added Mg^{2+} range in Fig. 6. The data do exhibit such a cross-over (Record, 1975; Dove & Davidson, 1962), but at somewhat higher values of added Mg^{2+}. Beyond the region of cross-over addition of 1 : 1 salt (increased ionic strength) results in destabilization of the double helix for a fixed value of total added Mg^{2+}. The explanation of this phenomenon (Manning, 1972*c*; deMarky & Manning, 1975) is particularly simple for levels of added Mg^{2+} sufficiently high that its binding is essentially saturated (polynucleotide charge fraction equal to $\frac{1}{2}\xi^{-1}$) for both double helix and single strand over a range of ionic strengths. In Section C it was pointed out that melting in the absence of Mg^{2+} is accompanied by release of condensed M^+ ions (increased entropy) and an increase of repulsive electrostatic free energy. The former effect dominates, and, since it destabilizes the double helix but decreases in magnitude as the ionic strength increases, the double helix becomes more stable at higher ionic strengths. At saturating levels of Mg^{2+}, however, no M^+ cations are condensed, having been entirely replaced by Mg^{2+}. The melting transition is consequently unaccompanied by release of condensed M^+, since there are none to be released. The only remaining effect dependent on ionic strength is the increase of electrostatic free energy, which stabilizes the double helix but decreases in magnitude with increasing ionic strength. Therefore an increased ionic strength destabilizes the double helix.

The effect of Mg^{2+} on T_m has also been discussed by Krakauer (1974) and by Record *et al.* (1978).

H. *Ionic effects on the renaturation rate*

The rate of association of separated but complementary polynucleotide strands to form double helixes is strongly dependent on ionic strength (Wetmur, 1976). Measured values of the apparent second-order rate constant k_2 (Ross & Sturtevant, 1960; Studier, 1969) can be fitted by the empirical relation (Manning, 1976*b*)

$$\mathrm{d}\log k_2/\mathrm{d}\log c_1 \approx 3{\cdot}6. \tag{79}$$

The theory (Manning, 1976*b*) is based on the assumption that the rate-determining step is a pre-equilibrium between separated strands

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

and a non-bonded precursor to the nucleated species (Wetmur & Davidson, 1968). The problem then reduces to the calculation of $\Delta\bar{g}$ for the process of bringing together two separated strands, each characterized by the charge-density parameter ξ_c, to form an aligned but non-bonded double-stranded configuration of charge density $2\xi_c$ and of length Q base pairs. The theoretical prediction is then easily demonstrated (Manning, 1976*b*) to be

$$\mathrm{d}\log k_2/\mathrm{d}\log c_1 = Q/2\xi_c. \tag{80}$$

Comparison of (79) and (80) with the value $\xi_c = 1{\cdot}9$ from Table 1 yields the value $Q = 14$, which is comparable to the persistence length of an unstacked single strand.

The effect of added Mg^{2+} has also been treated, and the observed second-order dependence of the association rate on Mg^{2+} concentration (Felsenfeld & Rich, 1957) has been demonstrated to be consistent with the value of Q given above (Manning, 1976*b*).

I. *The mistake of adopting the Debye–Hückel approximation*

A frequently used procedure to calculate the ionic contributions to the free energy of a closely interacting array of charge centres is pair-wise summation of Debye–Hückel potentials. Although everyone is aware that some sort of approximation is thereby being made, just how bad this approximation really is may not be sufficiently appreciated. The helix–coil transition provides a good example.

Suppose pair-wise summation of Debye–Hückel potentials is performed for an infinitely long, linear array of charges with spacing b, and that the difference is then taken for two values of b. The result, which should immediately be compared with (65), is

$$\Delta(\bar{g}-\bar{g}^0) = -\Delta(\xi \ln \kappa b). \tag{81}$$

The comparison shows clearly that, by ignoring the physical reality of bound counterions and their degrees of freedom, the Debye–Hückel procedure has completely missed the molecular phenomena underlying the transition! Another qualitative error is the direct variation with ξ in equation (81); the correct variation is inverse.

Substitution of numerical values from Table 1 into equation (81) yields

$$\Delta\bar{g} = \Delta\bar{g}^0 - 2{\cdot}93 + 2{\cdot}76 \log c_1, \tag{82}$$

which may be compared with (66). Although (82) does give the correct

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

form of the ionic-strength dependence, the slope is an order of magnitude too high. At 0·1 M and 25 °C the electrostatic free energy (sum of the last two terms) predicted by equation (82) is $-3{\cdot}37$ kcal/mole P, about four times the value $-0{\cdot}87$ kcal/mole P from the more accurate (66). Similarly, the slope of T_m *v.* log c_1 is about an order of magnitude too high in the Debye–Hückel approximation.

Within the context of such gross inaccuracy, use of exact coordinates for the charge centres can provide only the illusion of computational sophistication.

VI. Electrostatic contribution to DNA stiffness

A. *Harrington's measurements of persistence length*

Recent measurements (Harrington, 1978) of high-molecular-weight DNA persistence lengths in aqueous NaCl over a range of nearly three magnitudes of ionic strength provide the possibility of new insight into local DNA structure. Harrington's data are portrayed in Fig. 7 in the form of a graph of persistence length a (in ångström units) against log c_1, the logarithm of ionic strength. The measurements cover the range 0·005 M $\leqslant c_1 \leqslant$ 2·0 M. The solid line with greater numerical slope is the least-squares linear best fit based on the four points of lowest ionic strength. The equation of this line is

$$a = 221 - 559 \log c_1 \quad \text{(based on } c_1 \leqslant 0{\cdot}2 \text{ M)}. \tag{83}$$

The other straight line in Fig. 7 is the corresponding fit based on the five most dilute concentrations; its equation is

$$a = 317 - 504 \log c_1 \quad \text{(based on } c_1 \leqslant 0{\cdot}6 \text{ M)}. \tag{84}$$

Although there are not enough points to determine unambiguously whether a is an inherently linear function of log c_1 at the low end of the ionic strength range, the fit is reasonable. Moreover, Fig. 7 is strongly reminiscent of observed plots of T_m *v.* log c_1, which also begin to level off from steep linearity at ionic strengths between 0·2 and 0·6 M (Schildkraut & Lifson, 1965). As discussed in Section V, this type of dependence is related to the counterion diffusion potential. I have accordingly sought for a conformational change, closely linked to the persistence length, which may be driven by the counterion diffusion potential.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

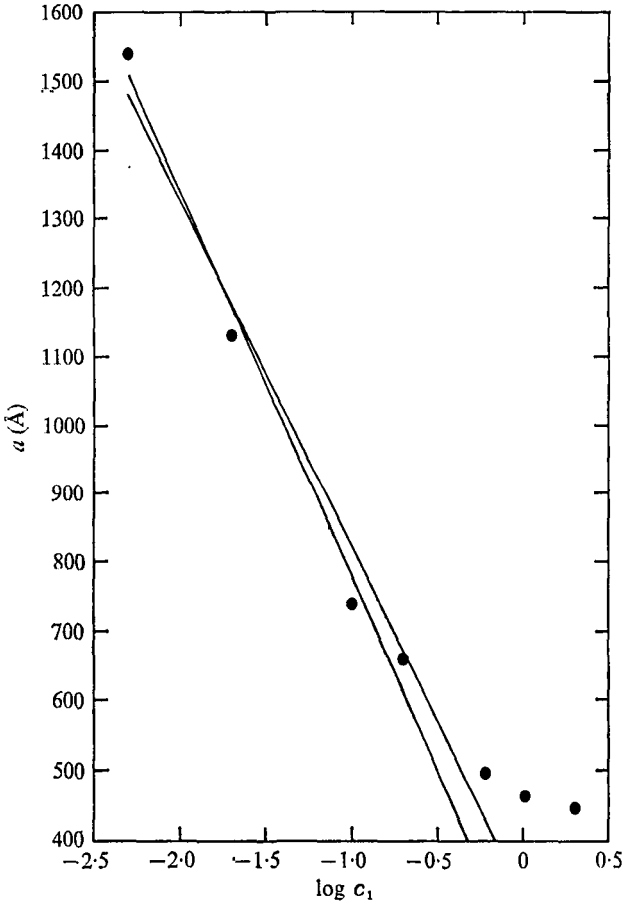

Fig. 7. Harrington's persistence length data (1978) in logarithmic representation. Solid lines are linear regressions as described in text.

B. *Polyelectrolyte theory of the persistence length*

Suppose that on a scale of length l high-molecular-weight DNA behaves like a rigid rod with elastic bending capability. Then a positive free energy ΔG must accompany the bending of a mole of segments of length l through a small angle θ (see Fig. 8). The persistence length is related to ΔG by the formula (Bloomfield *et al.* 1974)

$$\Delta G = (RTa/2l)\,\theta^2. \tag{85}$$

It is the spontaneous process bent → straight, with negative free energy

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

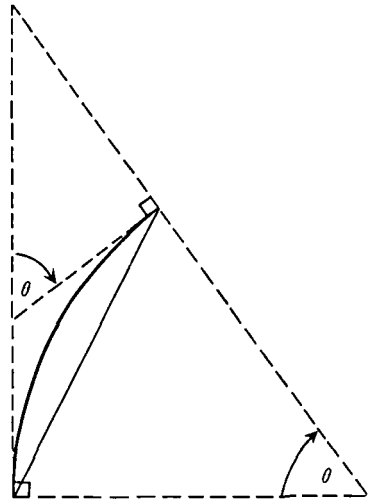

Fig. 8. Geometrical construction used to derive equation (93).

$-\Delta G$, that I presently believe, on the basis of the analysis to follow, to be primarily driven by local counterion diffusion.

With reference to the geometrical construction in Fig. 8, where the heavy circular arc is a segment of DNA of length l bent through an angle θ, let us first note the relation between l, θ, and the end-to-end distance of the arc, denoted by $l(\theta)$ and represented in the figure by the thin solid line:

$$l(\theta) = \sqrt{2}\, l\theta^{-1}\sqrt{(1-\cos\theta)}. \tag{86}$$

Expansion of $\cos\theta$ for small angles θ yields

$$\Delta l = -\tfrac{1}{24} l\theta^2, \tag{87}$$

where

$$\Delta l \equiv l(\theta) - l. \tag{88}$$

When $\theta = 0$, the segment is straight, its end-to-end distance $l(0)$ is the same as its contour length l, and $\Delta l = 0$.

Now denote by n_l the number of phosphates in the segment. This quantity is independent of θ. Define an effective charge spacing $b(\theta)$ of the bent segment by

$$b(\theta) = l(\theta)/n_l. \tag{89}$$

Then, corresponding to equations (87) and (88),

$$\Delta b = b(\theta) - b = -\tfrac{1}{24} b\theta^2, \tag{90}$$

where $b = l/n_l$, the usual axial charge spacing (1·7 Å from Table 1).

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

The effective charge spacing $b(\theta)$ in the bent conformation is less than that of the straight conformer. The corresponding formula for $\xi(\theta)$, the charge density parameter generalized from equation (1) as proportional to the reciprocal of $b(\theta)$, is

$$\Delta\xi = \xi(\theta) - \xi = \tfrac{1}{24}\xi\theta^2. \tag{91}$$

The charge density increases when the segment is bent. The electrostatic contribution to ΔG will therefore be positive.

Turn now to equation (65), which gives a formula for $\Delta\bar{g}$, the free energy difference per mole phosphate, in units of RT, between two forms of DNA with charge densities ξ_{final} and ξ_{initial}. Identify the former with $\xi(\theta)$ and the latter with ξ. Expand $\Delta\bar{g}$ in powers of θ, noting that c_1^{loc} is a function of ξ through V_P as well as directly, and retain the lowest-order term only. The result is

$$\Delta\bar{g} = \Delta\bar{g}^0 + (\theta^2/24)\,\xi^{-1}\,[2\xi - 1 + \ln\,(c_1^{\text{loc}}/c_1) + \ln\,\kappa b], \tag{92}$$

where $\Delta\bar{g}^0$, the non-electrostatic contribution, is also assumed proportional to θ^2. In this form it appears that the large positive contribution 2ξ is independent of the counterion diffusion potential. However, it should be remembered that equation (92) is simply a differential form of equation (65); the term 2ξ originates in the expansion of

$$(1 - \xi^{-1})\,\ln\,(c_1^{\text{loc}}/c_1).$$

Substitution of (92) into (85) yields

$$a = a_0 + (l^2/12b)\,\xi^{-1}[2\xi - 1 + \ln\,(c_1^{\text{loc}}/c_1) + \ln\,\kappa b), \tag{93}$$

where a_0 is the contribution to the persistence length originating from the nonelectrostatic free energy $\Delta\bar{g}^0$ of bending. With the numerical values for duplex DNA in Table 1,

$$a = a_0 + 0{\cdot}0815l^2 - 0{\cdot}0134l^2 \log c_1, \tag{94}$$

where a and l are in ångströms.

Comparison of (94) with either of the empirical equations (83) or (84) shows identical forms if l is independent of ionic strength. If the slope of the $\log c_1$ dependence in (83) is compared with that of (94), the numerical value of l emerges as

$$l = 204\ \text{Å}. \tag{95}$$

If (84) is used instead, a similar value 194 Å is found for l. If (95) is now substituted back into (94), the latter becomes

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

$$a = a_0 + 3392 - 559 \log c_1. \tag{96}$$

The discussion to follow is based on (95) and (96), which in turn follow from comparison of (94) with (83); if (84) had been used instead, nothing substantive would require change.

C. *Discussion of the numerical results*

To assess the theory properly it is necessary to have some feeling for the numbers involved. The increment in b corresponding to a small bending angle θ, given by (90), is quite plausible. With $b = 1{\cdot}7$ Å and θ taken as one radian, Δb is about a tenth of an ångström, a value that could easily be the consequence of a slight structural distortion of the charge distribution. The value of about 200 Å (about 60 base pairs) for l is equally consistent. Recall that l is the length of a DNA segment which must retain rigid mechanical properties over the range of ionic strengths, $c_1 \lesssim 1$ M, represented by the empirical (83) or (84). Reference to Fig. 7 shows that the persistence length is maintained at a value of about 450 Å even at very high ionic strengths. Therefore a segment l somewhat less than half this length does behave nearly like a rigid rod (Bloomfield *et al.* 1974).

At 0·1 M ionic strength (96) predicts that the polyelectrolyte contribution to the persistence length (sum of last two terms) is 3950 Å, whereas the observed persistence length at 0·1 M from Fig. 7 is only 750 Å. *The net effect of other contributions is to render DNA more flexible.* In more general quantitative terms, the value of a_0 calculated by comparison of (96) and (83) is negative,

$$a_0 = -3171 \text{ Å}. \tag{97}$$

To see if this number is physically sensible, let us translate it into an equivalent free energy by applying (85) with ΔG and a replaced by ΔG_0 and a_0, respectively. At 25 °C, and with a_0 and l given by (97) and (95), respectively, ΔG^0 has the value $-4{\cdot}6$ kcal for an angle θ of 1 radian. Bending of a segment of length l would be a spontaneous process if polyelectrolyte effects are ignored, driven by the free energy $-4{\cdot}6$ kcal/(radian)^2. Since the segment l contains $(204/3{\cdot}4) = 60$ base pairs, this free energy is a mere -77 cal/mole base pair, and it is easy to imagine an increased entropy of base motion (increased breathing) when DNA is locally bent as a possible source of this free energy.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

D. *Implications for DNA condensation and nucleosome formation*

According to the above analysis, removal of the polyelectrolyte effect, or counterion diffusion potential, at ionic strengths for which (83) and (96) are valid (a range that includes physiological conditions) would have as a consequence the spontaneous bending, or folding, of the DNA molecule. Mathematically, removal of the counterion diffusion potential is accomplished by setting the valence of a phosphate group equal to zero; the last two terms in (96) are then replaced by zero, and a reduces to the negative quantity a_0. Physically, 'removal' of the polyelectrolyte effect at 0·1 M salt, for example, occurs at sufficiently high levels of multivalent cation binding. For example, even bound loosely, a polylysine molecule, or possibly two acting simultaneously, can completely neutralize the phosphate charge in its vicinity, neutralization being understood in the long-range sense of zero net charge. Or saturated binding of trivalent spermidine, which produces

$$1-(3\xi)^{-1} = 92\%$$

phosphate charge neutralization, might be enough. The prediction is that DNA should then spontaneously fold, or 'condense', and that is exactly what happens (Gosule & Schellman, 1976). If the histone core of a nucleosome possesses a sufficiently high positive surface charge density, the possibility is also raised that a nucleosome is formed by the spontaneous wrapping of DNA around the protein core, driven solely by the non-specific counterion diffusion potential.

It is interesting that quite different considerations have led Riemer & Bloomfield (1978) to identify electrostatic repulsion as the primary resistance to DNA packaging in phage heads.

E. *Further discussion*

The procedural simplicity and appealing results obtained here should not be allowed to obscure a number of questions that can be raised. The extent to which the theoretical conclusions may depend on the accuracy of the data is not clear. Persistence length measurements are not straightforward. The dependence of Harrington's values on ionic strength is considerably steeper than that indicated by previous estimates (Harrington, 1978). His methods, however, do appear to be considerably more direct than those used previously. At any rate the experimental data require careful assessment, confirmation, and extension to include more data points at low ionic strength.

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

An apparent difficulty with the theoretical interpretation is illustrated by the behaviour of poly A, which is rigid when its bases are stacked at low temperatures (Stannard & Felsenfeld, 1975), but becomes flexible as the bases unstack in response to a temperature increase at a fixed ionic strength. The charge densities of unstacked and stacked single strands are similar (Olson & Manning, 1976). Stiffness, therefore, appears to be correlated with base stacking rather than with electrostatic repulsion. However, these two aspects of polynucleotide structure are not necessarily independent. A stacked conformation may provide the steric constraints that render obligatory the accompaniment of bending by the quasi-linear charge compression assumed in the theory; bending of an unstacked single strand may not require so severe an increase in electrostatic stress.

The behaviour of the persistence length at high ionic strengths, outside the range of validity of (96), is interesting and may also be a source of concern. An important distinction must be drawn here between the polyelectrolyte effect, or counterion diffusion potential, and electrostatic effects in general. By definition, mathematical reduction of the phosphate valence to zero abolishes all electrostatic effects along with the counterion diffusion potential. Sufficient cationic binding accomplishes the same thing. However, augmentation of the ionic strength to high levels may not. Although the counterion diffusion potential disappears at high ionic strength, nearest-neighbour electrostatic repulsion may survive because of the finite size of the screening ions. Indeed, the nearest-neighbour phosphate–phosphate distance of about 6–7 Å is not much larger, if at all, than current estimates of the effective hydrated diameter of the Na^+ ion. Under these conditions (96) would be replaced by

$$a = a_0 + a_{nn,\mathrm{el}}, \tag{98}$$

where a_0 would have about the same value as given by (97) and the nearest-neighbour electrostatic phosphate–phosphate repulsive contribution $a_{nn,\mathrm{el}}$ is the only survival of the last two terms of (96). Both terms on the r.h.s. of (98) would be expected to depend slightly on ionic strength indirectly through solvent effects, but I shall assume ionic-strength independence as a first approximation. Fig. 7 shows that $a \approx 450$ Å at high ionic strength. Hence, with (97), an estimate for $_{nn,\mathrm{el}}$ is 3600 Å; translated into a free energy of bending by means of (85), this value is equivalent to a bending free energy of 5·2 kcal/(radian)^2 for the segment of length l, or only 87 cal/mole base pair/

Downloaded from https://www.cambridge.org/core. University of Alberta Libraries, on 04 Sep 2019 at 07:19:36, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0033583500002031

(radian)^2. As a consistency check, I note that unscreened coulomb repulsions between each of the two phosphates in a base pair and their respective nearest neighbours at distance about 7 Å (which happens also to be about equal to the Bjerrum length) gives a free energy of bending of about $(2RT/24) = 50$ cal. This rough estimate assumes applicability of the bulk dielectric constant and totally unscreened phosphate charges; the factor $(24)^{-1}$ appears in (90).

Let us recapitulate. Even at high ionic strength segments of length $l \approx 200$ Å maintain their rigidity, since a is still observed to be more than twice as great. The rigidity under these conditions cannot be attributed to the counterion diffusion potential, which emerges only at lower ionic strength as the cause of increased segmental rigidity; a 200 Å segment becomes *harder* to bend as the ionic strength decreases, but it is still stiff even at high ionic strength, at least up to 2 M. The residual stiffness at high ionic strength can be attributed to surviving nearest-neighbour repulsions among the phosphates. If the latter could also be eliminated at high ionic strength, then DNA would become locally flexible in accord with what would then be the negative value a_0 of the persistence length. Recall again that at lower ionic strength, including physiological, *all* electrostatic effects can be eliminated by binding of multivalent cationic substances, leaving a_0 as the only contribution and thus rendering DNA locally flexible.

During the course of fifteen years of experience in polyelectrolyte theory I have accumulated many debts to many people. Special thanks are due to Bruno Zimm for initial motivation and guidance; to U. P. Strauss for sustained interest and encouragement; to Wilma Olson for whatever rudimentary knowledge of structure I may possess; to Alfred Holtzer, Tom Record and the late Lars Onsager for particular insights that led to new advances; and to Will McClure and Gary Felsenfeld for recent valuable discussions.

The Role of Solitons in the Energy and Electron Transfer in One-Dimensional Molecular Systems

A.S.Davydov

Institute for Theoretical Physics, Academy of Sciences of the Ukrainian SSR, Kiev, USSR

Abstract

Theory of motion of quasi-particles, electrons and a vibrational excitation along molecular chains is developed without using the adiabatic approximation and the perturbation theory. It is shown that the motion of quasi-particles is accompanied by a local chain deformation. The deceleration of a soliton by external dissipative forces is studied. The effect of thermal vibrations on the soliton motion is analysed.

1. Introduction

When studing biological phenomena on a molecular level it was established that many processes are associated with an electron transfer along protein molecules from donor to acceptor molecules or with a transfer of energy released under hydrolysis of adenosine triphosphate (ATP) molecules.

The energy of ATP molecule hydrolysis equal to 0.54 eV is only 20 times greater than the average energy to thermal vibrations. Many researchs suggested that the energy of the ATP hydrolysis moves along protein molecules as vibrational oscillations of atoms C = O contained in peptide groups of protein molecules. However, at standard conditions the life time of such vibrations is only 10^{-13}s. Therefore many doubts have been expressed concerning the possibility of an effective transfer of vibrational energy along protein molecules.

Great difficulties are also experienced in the explanation of the effective transfer from donor to acceptor molecules. The experimental data show that such a transfer is possible the distance of the order of 70 A^{o}. The electron transfer to such great distances cannot be explained by the usual theory of quantum mechanical tunneling.

One of possible explanations of the electron transfer at large distances is connected with the assumption that the transfer process is facilitated by protein molecules to which a donor and acceptor of electrons are attached. The donor-acceptor model of the electron transfer through protein molecules was developed in [1-2]. In these papers a protein molecule was modelling by a quasi-one-dimensional molecular system which containes one extra electron passed into a molecule from a donor. In these and in most other papers in which the motion of quasi-particles (electrons, excitons etc.) was studied in periodic structures an adiabatic approximation was used. When using such an approximation one assumes that molecules slightly displace with respect to stable equilibrium positions. The interaction of a quasi-particle with such displacements is considered as a perturbation decelerating its motion.

Recently in our institute the study has been made of the motion of quasi-particles - electrons and vibrational excitation - along molecular chains without using the adiabatic approximation and the perturbation theory. Giving the perturbation theory up leads to a description of quasi-particle motion by means of nonlinear equations. Their solution shows [3-9] that the motion of a quasi-particle is accompanied by a local deformation of a chain, i.e. a displacement of equilibrium positions. The simultaneous motion of a quasi-particle and a local deformation is described by a wave function in the form of a solitary wave-soliton - which is a solution of a nonlinear Schrodinger equation.

Solitons transport a dipole vibrational excitation or an electron with a local decrease of mutual distances between peptide groups. These solitons always travel with a velocity less than that of a sound, therefore, they do not expend energy to generate phonons. The energy expenditure is required to break the electron coupling or vibrational excitations of peptide groups with a local deformation of a molecule. Thus, the motion of an electron or a vibrational excitation of peptide groups along a protein molecule holds without energy loss and resembles superconductivity and superfluidity phenomena.

Below we consider the basic results of theoretical investigations [3-9].

2. Solitons in a One-Dimensional Molecular System at Very Low Temperatures

We consider a one-dimensional molecular chain with repetitive peptide groups as a simplest protein molecule. As a result of a resonant interaction of vibrational excitations of peptide groups, in such a chain the collective states appear which may be described by the Hamiltonian

$$H = H_e + H_{ph} + H_{int} \tag{2.1}$$

where

$$H_e = \sum_n \left(\mathcal{E}_o - \frac{\hbar^2}{ma^2}\right) B_n^+ B_n + \\ + \frac{\hbar^2}{2ma^2} B_n^+ \left(B_{n-1} + B_{n+1}\right) \tag{2.2}$$

is the Hamiltonian of collective excitations - excitons in the chain with peptide groups fixed rigidly in the equilibrium positions (at the points na); excitons are described by plane waves. a is the distance between the nearest points, m is the effective exciton mass; $\mathcal{E}_o$ is the energy of the exciton band bottom; B_n^+ and B_n are the creation and annihilation operators of the vibrational excitation on the group of the number n.

$$H_{ph} = \frac{1}{2} \sum_n \left(\frac{1}{M} \hat{p}_n^2 + \varkappa u_n^2\right) \tag{2.3}$$

is the operator of longitudinal displacements u_n in peptide groups of the mass M from equilibrium positions, $\varkappa$ is the viscosity coefficient, $\hat{p}_n$ is the momentum operator.

$$H_{int} = \chi \sum_n \left(u_{n+1} - u_{n-1}\right) B_n^+ B_n \tag{2.4}$$

is the operator of interaction of vibrational excitations with displacements of peptide groups. χ is the parameter of this interaction.

The operator (2.1) may also describe the motion of an extra electron in a molecular chain. In this case the operator (2.2) will characterize the extra electron motion in repetitive potential

wells caused by constant electric dipole moments of peptide groups. Then m is the effective electron mass, $\mathcal{E}_0$ is the energy of the conductivity band bottom *).

Let us determine the Hamiltonian function in our system by the equality

$$\mathcal{H} = \langle \psi(t) | H | \psi(t) \rangle$$

where the function

$$\psi(t) = \sum_n \varphi_n(t) U(t) B_n^+ |0\rangle , \quad \sum_n |\varphi_n|^2 = 1 \tag{2.5}$$

contains the unitary operator of displacements

$$U(t) = \exp\left\{ -\frac{i}{\hbar} \sum_n \left[\beta_n(t) \hat{p}_n - \pi_n(t) u_n \right] \right\} . \tag{2.6}$$

The Hamiltonian function $\mathcal{H}$ depends on $\varphi_n(t)$, $\beta_n(t)$ and on their canonically conjugate $i\hbar\varphi_n^*(t)$ and $\pi_n(t)$. In this case $|\varphi_n(t)|^2$ determines the possibility of vibrational excitation of the group n; $\beta_n(t)$ characterizes the displacement of equilibrium positions of peptide groups.

Using the Hamiltonian function $\mathcal{H}$ we may find the Hamiltonian equation

$$i\hbar \frac{\partial \varphi_n}{\partial t} = \frac{\partial \mathcal{H}}{\partial \varphi_n^*} , \quad \frac{\partial \beta_n}{\partial t} = \frac{\partial \mathcal{H}}{\partial \pi_n} , \quad \frac{\partial \pi_n}{\partial t} = -\frac{\partial \mathcal{H}}{\partial \beta_n} .$$

In the continuum approximation these equations are reduced to two equations

$$\left[i\hbar \frac{\partial}{\partial t} - \mathcal{E}_0 + \frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + 2\varkappa \rho(x,t) \right] \varphi(x,t) = 0, \tag{2.7}$$

---

*) Below we shall speak only about the motion of vibrational excitation. However all the results equally refer to the electron motion. It is sufficient to replace the word exciton by the word electron.

$$\left(\frac{\partial^2}{\partial t^2} - V_{aq}^2 \frac{\partial^2}{\partial x^2}\right)\rho(x,t) + \frac{2\varkappa a^2}{M}\frac{\partial^2}{\partial x^2}|\varphi(x,t)|^2 = 0 \qquad (2.8)$$

where $V_{aq} = a\sqrt{\frac{\varkappa}{M}}$ is the velocity of the longitudinal sound in the chain

$$\rho(x,t) = -a\,\frac{\partial\beta(x,t)}{\partial x} \qquad (2.9)$$

is the relative decrease in distances between neighbouring peptide groups.

Owing to translational invariance of the chain we may seek solution of the set of equations (2.7) and (2.8) in the form of excitations spreading with a constant velocity V. Assuming

$$\rho(x,t) = \rho(\xi) \quad , \quad |\varphi(x,t)|^2 = f(\xi)$$

where

$$\xi \equiv x - x_0 - Vt \qquad (2.10)$$

we find the equation

$$\rho(\xi) = \frac{2\varkappa}{\varkappa a(1-S^2)}|\varphi(x,t)|^2 \quad , \quad S \equiv V/V_{aq} \qquad (2.11)$$

from Eq.(2.8) integrating twice over the variable ξ. Substituting (2.11) into the equation (2.8) we obtain the nonlinear Schrodinger equation

$$\left(i\hbar\frac{\partial}{\partial t} - \mathcal{E}_0 + \frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + G(S)|\varphi(x,t)|^2\right)\varphi(x,t) = 0 \qquad (2.12)$$

with the nonlinearity parameter

$$G(S) = \frac{G(0)}{1-S^2} \qquad G(0) \equiv 4\varkappa^2/\varkappa a \,. \qquad (2.13)$$

At $S > 1$ the value $G(S) < 0$, therefore the solution normalized by the condition

$$\frac{1}{a}\int |\varphi(x,t)|^2 dx = 1 \tag{2.14}$$

is absent in an infinite chain. In a chain of a finite length L $(L \gg a)$ the solution of Eq.(2.12) is expressed by a plane wave

$$\varphi(x,t) = L^{-1/2} \exp\{i[kx - \omega(k)t]\} \tag{2.15}$$

and corresponds to the energy

$$\hbar\omega(k) = \mathcal{E}_0 + \frac{a}{L}|G(s)| + \frac{\hbar^2 k^2}{2m}, \quad G(s) < 0, \tag{2.15a}$$

where $k = mV/\hbar$. Thus, at $s > 1$ the collective excitations in the chain are excitons.

With velocities V less than that of longitudinal sound V_{aq} the value $G(s) > 0$. In this case the equation (2.12) has the following solution normalized by the condition (2.14)

$$\varphi(x,t) = \frac{\sqrt{a\mu}\, \exp\{i[k\xi - (\omega - kV)t]\}}{\sqrt{2}\, \cosh(\mu\xi)}, \tag{2.16}$$

$$\mu = \frac{amG(s)}{2\hbar^2} = \frac{2amJ^2}{\mathcal{J}\hbar^2(1-s^2)}, \tag{2.17}$$

$$\hbar\omega = \mathcal{E}_0 + \frac{\hbar^2(k^2 - \mu^2)}{2m}, \quad k = mV/\hbar. \tag{2.18}$$

The excitations described by the function (2.16) are called solitons. The value $\Delta x = \pi/\mu$ characterizes the region of the excitation localization (the soliton size). The continuum approximation used is justified when the inequality $\Delta x \gg a$ is satisfied. With fixed parameters of the chain ($\mathcal{J}$, J, m) this inequality imposes a restriction on the soliton motion velocity.

According to (2.11) the decrease in the distances between peptide groups is determined by the expression

$$\rho(\xi) = \frac{a\mu\chi}{(1-s^2)\,2e\cosh^2(\mu\xi)}. \tag{2.19}$$

The displacement of equilibrium positions of molecules is expressed by the function

$$\beta(\xi) = \frac{\chi}{2e(1-s^2)}\left[1-\tanh(\mu\xi)\right]. \tag{2.19a}$$

The soliton energy travelling with velocity V involves also the energy of local deformation. It is determined by the expression

$$E(V) = \mathcal{E}_0 + \frac{1}{2}mV^2 - \frac{4ma^2\chi^4(1-3s^2)}{3e^2\hbar^2(1-s^2)^2}$$

At $s \ll 1$ this expression is transformed to the form

$$E(V) = \mathcal{E}_0 + \frac{1}{2}m_{sol}V^2 - \frac{4ma^2\chi^4}{3e^2\hbar^2}, \tag{2.20}$$

where

$$m_{sol} = m\left(1 + \frac{8M\chi^4}{3e^3}\right). \tag{2.21}$$

In the chain of the finite length L the equation (2.12) permits also solutions of the exciton type described by plane waves (2.15) with the energy

$$\hbar\omega(k) = \mathcal{E}_0 - \frac{aG(s)}{L} + \frac{\hbar^2k^2}{2m}, \quad k = mV/\hbar. \tag{2.22}$$

At $a \ll L$ the inequality

$$\frac{aG(s)}{L} \ll \frac{4ma^2\chi^4}{3e^2\hbar^2} \tag{2.23}$$

is usually satisfied, therefore, the internal soliton energy (at $V = 0$) is less than the sum of the internal exciton and deformation energy. Thus, the exciton excitations are unstable.

The exciton motion is not practically accompanied by the chain deformation. The exciton transport only the vibrational excitation energy. The soliton motion corresponds to the vibrational excitation motion in conjunction with a local deformation. Therefore, the effective soliton mass (m_{sol}) is greater than the effective exciton mass (m). This difference is especially great in soft chains (small $\mathcal{J}$) and at a strong coupling of a vibrational excitation with deformation (large χ). Travelling with a velocity less than that of a sound the solitons expend no energy to generate phonons.

The excitons are excited by light in protein molecules. The soliton excitation is forbidden by the Frank-Condon principle according to which an optical transfer should not be accompanied by displacement of heavy particles. The solitons may be excited only under local external influences for example, under chemical reactions occuring with molecules attached to the end of protein molecule.

The simple model of a quasi-one-dimensional periodic structure under consideration is referred to each of three chains formed in an α-helical protein molecule by hydrogen bonds between peptide groups. In studying the electron motion each chain acts independently. When vibrational excitations of the dipole type are investigated an additional resonance interaction appears between the peptide groups contained in different chains. Therefore, all three chains should be considered as a whole. This problem was solved in [4].

In the paper of Hymen, Mc Layhlin and Scott [14] the collective excitations in alpha-helical protein molecules of the finite length ($L = 200a$) were computed without making use of the continuum approximation. The conditions of soliton excitation and spreading in such molecules were elucidated. Authors of [14] say that numerical studies of dynamic model for α-helix protein confirm the prediction in [4] of soliton formation.

3. Deceleration of Solitons by external dissipative forces

The possibility of making use of the motion of soliton to explain some phenomena in physics and biology is inevitably connected with studying the physical conditions leading to nonlinearity and dispersion. The properties of solitons are manifested under their interaction with external fields and other degrees of freedom of the system. Mathematical study of these interactions is usually carried out by the perturbation theory methods. Different variants of the perturbation theory for solitons in one-dimensional systems were developed by Karpman and Maslov [10], Bishop and Krumhanse et al [11], Kinner and Mc Laughlin [12] and by other investigators.

In this section we give the results of investigations [8] concerning the influence of external effects on solitons described by the set of equations (2.7), (2.8). The nonlinearity of the collective excitations described by these equations is determined by the interaction of an exciton (electron) with a local chain deformation generated by this exciton. Below we shall consider only the solitons moving with velocity V significantly less then that of sound waves V_{aq}.

If a molecular chain is in a certain medium, then a moving soliton will be acted upon by a friction force and it will be decelerated. The friction forces decelerate the displacements of peptide groups. We consider a case when the friction forces are proportional to the velocity of displacements $\sim \gamma \frac{\partial \beta}{\partial t}$. In this case the equations (2.8) determining the relative displacement $\rho(x,t)$ are transformed to the form (see [8]):

$$\left(\frac{\partial^2}{\partial t^2} - V_{aq}^2 \frac{\partial^2}{\partial x^2}\right) \rho(x,t) + \frac{2\chi a V_{aq}^2}{\varepsilon} \frac{\partial^2}{\partial x^2} |\varphi(x,t)|^2 = -\varepsilon\gamma \frac{\partial \rho(x,t)}{\partial t} . \qquad (3.1)$$

For convenience, a small positive parameter $\varepsilon \ll 1$ is introduced into the deceleration coefficient $\varepsilon\gamma$. We introduce the transformation

$$\varphi(x,t) = \Phi(x,t) \exp\left(-\varepsilon_0 t/\hbar\right)$$

then according to (2.7) the function $\Phi(x,t)$ will satisfy the equation

$$\left[i\hbar \frac{\partial}{\partial t} + \frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + 2\varkappa \rho(x,t) \right] \Phi(x,t) = 0 . \qquad (3.2)$$

In order to solve the set of equations (3.1), (3.2) we use the method of slowly varying coefficients introduced by Van der-Pole and developed in detail by Bogoliubov and Mitropolskii [13] .

Assume

$$\Phi(x,t) = \Phi_0(x,t) + \varepsilon \Phi_1(x,t) , \qquad (3.3)$$

$$\rho(x,t) = \rho_0(x,t) + \varepsilon \rho_1(x,t) , \qquad (3.4)$$

where

$$\Phi_0(x,t) = \frac{\sqrt{a\mu}\, \exp\{ i [k(x-\xi) + \Theta] \}}{\sqrt{2}\, \cosh [\mu(x-\xi)]} \qquad (3.5)$$

$$\xi = x_0 + \frac{\hbar k}{m} t , \qquad \mu = \frac{2am\varkappa^2}{\partial e \hbar^2} , \qquad (3.5a)$$

$$\rho_0(x,t) = \frac{2\varkappa}{\partial e} |\Phi(x,t)|^2 . \qquad (3.6)$$

The function (3.5) describes the soliton travelling with velocity $V = \hbar k/m$. The value

$$x = \xi \equiv x_0 + \frac{\hbar k}{m} t \qquad (3.7)$$

determines the position of the soliton centre at the time moment t :

$$\Theta = \hbar (k^2 + \mu^2) t / 2m \qquad (3.8)$$

is the phase of the wave function (3.5).

The presence of friction results in gradual changing the parameters k and ω of the function (3.5) and in a small changing the form of the function (3.5) which is taken into account by the term $\varepsilon\Phi_1$ in (3.3). We express these changes by the unknown functions $f(k)$ and $\varphi(k)$ using the equations

$$\frac{dk}{dt} = \varepsilon f(k), \tag{3.9}$$

$$\frac{d\omega}{dt} = \frac{\hbar^2}{2m}(k^2+\mu^2) + \varepsilon\varphi(k), \tag{3.9a}$$

$$\frac{d^2\xi}{dt^2} = \varepsilon\hbar f(k)/m\,. \tag{3.9b}$$

Substituting (3.4) into Eq.(3.1) and taking into account (3.5) and (3.6) and a smooth dependence $\rho_1(x,t)$ on time we obtain

$$\rho_1(x,t) = -\frac{a\chi\hbar}{2emV_{aq}^2}\{\gamma k^2 + f(k)\}\tanh[\mu(x-\xi)]\,. \tag{3.10}$$

Using (3.3) and (3.4) and the equalities

$$\frac{\partial\Phi_0}{\partial k} = i(x-\xi)\Phi_0\,, \qquad \frac{\partial\Phi_0}{\partial\omega} = i\Phi_0$$

we may transform the equation (3.2) to the form

$$\left[i\hbar\frac{\partial}{\partial t} + \frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + \frac{8\chi^2}{2e}|\Phi_0|^2\right]\Phi_1 + \frac{4\chi^2}{2e}\Phi_0^2\Phi_1^* = S(\Phi_0)\,, \tag{3.11}$$

where

$$S(\Phi_0) \equiv \left[(x-\xi)f(k) + \varphi(k) - 2\chi\rho_1(x,t)\right]\Phi_0\,. \tag{3.12}$$

The unknown functions $f(k)$ and $\varphi(k)$ introduced into (3.9) are determined provided that the function Φ_1 in (3.11) has no secular terms increasing quadratically with time. One may show [8] that

such secular terms contain multipliers $\frac{\partial \Phi_0}{\partial \xi}$ and $\frac{\partial \Phi_0}{\partial \omega}$. Therefore, the condition that Φ_1 involves no secular terms is reduced to the requirement of orthogonality of the functions $\frac{\partial \Phi_0}{\partial \xi}$ and $\frac{\partial \Phi_0}{\partial \omega}$ in the right-hand side of (3.11) i.e. to the fulfillment of the equalities

$$\int S^*(\Phi_0) \frac{\partial \Phi_0}{\partial \xi} dx = \int S^*(\Phi_0) \frac{\partial \Phi_0}{\partial \omega} dx = 0. \tag{3.13}$$

When these equalities are satisfied only virtual exciton states contribute into $\Phi_1(x,t)$. They cause the soliton from distortion and the so called "tail outgrowing" [10].

Since the energy of exciton states exceeds that of a soliton by the value $ma^2\varkappa^4/\varkappa^2\hbar^2$, then at large $\varkappa$ and small $\varkappa$ the value $B_1(x,t)$ will be very small for all times t less than $k_0/\varepsilon f(k_0)$. Therefore, the explicit form of the function $B_1(x,t)$ is not calculated.

The inequalities (3.13) yield the explicit expressions of the unknown functions

$$f(k) = \frac{4m\varkappa}{\hbar} \int \rho_1(x,t) |\Phi_0(x,t)|^2 \tanh[m(x-\xi)] dx,$$
$$\varphi(k) = \frac{2\varkappa}{a\hbar} \int \rho_1(x,t) |\Phi_0(x,t)|^2 dx. \tag{3.14}$$

Substituting ρ_1 and Φ_0 into (3.14) we obtain

$$\varphi(k) = 0, \qquad f(k) = -\frac{\gamma D k}{1+D} \tag{3.15}$$

where

$$D = \frac{8a^2\varkappa^4}{3\varkappa^2\hbar^2 V_{aq}^2} = \frac{m_{sol} - m}{m} > 0. \tag{3.16}$$

Substituting (3.15) into (3.9) and integrating over time we obtain the exponential law of decreasing $k(t)$ and hence of decreasing

soliton velocity

$$V(t) = V_0 \exp(-\alpha t) \tag{3.17}$$

where the damping coefficient due to overcoming the friction forces

$$\alpha = \varepsilon\gamma \frac{m_{sol} - m}{m_{sol}}. \tag{3.17a}$$

If the friction force is proportional to the square of velocity and has an opposite direction, i.e. is proportional to $\varepsilon\lambda\left(\frac{\partial\beta}{\partial t}\right)^2$, then when the soliton moves along the positive direction of the axis x the equation (2.8) is replaced by the equation

$$\left(\frac{\partial^2}{\partial t^2} - V_{aq}^2 \frac{\partial^2}{\partial x^2}\right)\rho(x,t) + \frac{2\chi V_{aq}^2}{ae}\frac{\partial^2}{\partial x^2}|\varphi(x,t)|^2 = -\varepsilon\lambda\frac{V}{a}\frac{\partial}{\partial t}[\rho(x,t)]^2.$$

Assuming

$$\Phi(x,t) = \Phi_0(x,t) + \varepsilon\Phi_1^1(x,t),$$

$$\rho(x,t) = \rho_0(x,t) + \varepsilon\rho_1(x,t),$$

where $\Phi_0(x,t)$ and $\rho_0(x,t)$ are determined by the expressions (3.5) and (3.6), respectively, we obtain

$$\rho_1^1(x,t) = -\frac{a\chi\hbar f(k)}{m a e V_{aq}^2}\tanh[\mu(x-\xi)] - \frac{\lambda V^2 a \chi^2 \mu}{a e^2 V_{aq}^2}\left\{\tanh[\mu(x-\xi)] - \frac{1}{3}\tanh^2[\mu(x-\xi)]\right\}. \tag{3.18}$$

The unkown functions of Eqs (3.9) are now determined by the expressions

$$\varphi(k) = 0, \quad f(k) = \frac{4\mu\chi}{\hbar}\int\rho_1^1(x,t)\tanh[\mu(x-\xi)]\,|\Phi_0|^2\,dx. \tag{3.19}$$

Substituting (3.18) into (3.19) we obtain the final expression

$$f(k) = -\frac{\lambda A}{1+D} V^2 \tag{3.20}$$

where D is determined by the formula (3.16) and

$$A = \frac{16 a \mu^2 \chi^3}{15 e^2 \hbar V_{aq}^2} .$$

Using (3.20) we transform the equation (3.9b) to the form

$$\frac{dV}{dt} = -\delta V^2 , \qquad \delta = \frac{\varepsilon \lambda 16 a \mu^2 \chi^3}{15 m_{sol} e^2 V_{aq}^2} . \tag{3.21}$$

Integrating (3.21) we obtain the final expression of the law of the soliton velocity change in the presence of friction proportional to the square of velocity

$$V(t) = \frac{V_0}{1+V_0 \delta t} \approx V_0 (1 - V_0 \delta t) . \tag{3.22}$$

Thus, with friction proportional to the square of velocity, the soliton velocity decreases with time by the law close to that of linear with the proportionality coefficient δV_0^2 .

4. Motion of a soliton (electron) in the presence of external nonhomogeneous fields

The presence of external and small local nonmonogeneities in the arrangement of molecules may be taken into account by introducing in (3.2) the small potential energy $\varepsilon U(x)$ depending on the coordinate x . In this case the set of equations determining the soliton motion with velocity $V \ll V_{aq}$ takes the form

$$\left[i\hbar \frac{\partial}{\partial t} + \frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + 2\chi \rho(x,t) \right] \Phi(x) = \varepsilon U(x) \Phi(x) , \tag{4.1}$$

$$\left[\frac{\partial^2}{\partial t^2} - V_{aq}^2 \frac{\partial^2}{\partial x^2} \right] \rho(x,t) + \frac{2\chi}{e} V_{aq}^2 \frac{\partial^2}{\partial x^2} |\Phi(x,t)|^2 = 0 . \tag{4.2}$$

We may seek the solution of this set of equation in the first approximation in the form

$$\Phi(x,t) = \Phi_0(x,t) + \varepsilon \Phi_1(x,t), \tag{4.3}$$

$$\rho(x,t) = \rho_0(x,t) + \varepsilon \rho_1(x,t), \tag{4.4}$$

where

$$\rho_0(x,t) = \frac{2\alpha}{\partial e} |\Phi_0(x,t)|^2. \tag{4.5}$$

The function Φ_0 has the form (3.5) with parameters k, ξ, ω which vary with time according to Eqs (3.9).

Substituting (4.4) into Eqs (4.1) and (4.2) we obtain

$$\left[i\hbar\frac{\partial}{\partial t} + \frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + \frac{4\alpha^2}{\partial e}|\Phi(x,t)|^2\right]\Phi(x,t) = \varepsilon\left[U(x) + \rho_1(x,t)\right]\Phi(x,t), \tag{4.6}$$

$$\left(\frac{\partial^2}{\partial t^2} - V_{aq}^2\frac{\partial^2}{\partial x^2}\right)\rho_1(x,t) = -\frac{1}{\varepsilon}\frac{\partial \rho_0(x,t)}{\partial \xi}\frac{d^2\xi}{dt^2}. \tag{4.7}$$

Using the value (3.9b) and a weak dependence $\rho_1(x,t)$ on time we obtain (at $S \ll 1$) the equation

$$\frac{\partial^2 \rho_1}{\partial x^2} = \frac{2a\hbar\alpha\mu^2}{m\partial e V_{aq}^2} f(k)\frac{\sinh[\mu(x-\xi)]}{\cosh^3[\mu(x-\xi)]}.$$

After integration over x we have

$$\rho_1(x,t) = -\frac{a\alpha\hbar}{m\partial e V_{aq}^2} f(k)\tanh[\mu(x-\xi)]. \tag{4.8}$$

To obtain the equation determining the correction $\Phi_1(x,t)$ to the function $\Phi_0(x,t)$, we substitute (4.3) into (4.6). Then we obtain

$$\left(i\hbar\frac{\partial}{\partial t}+\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}+\frac{8\chi^2}{\varepsilon}|\Phi_0(x,t)|^2\right)\Phi_1(x,t)+$$
$$+\frac{4\chi^2}{\varepsilon}\Phi_0^2(x,t)\,\Phi_1^*(x,t)=S(\Phi_0), \tag{4.9}$$

where
$$S(\Phi_0)\equiv[U(x)-2\chi\rho_1]\Phi_0-$$
$$-i\hbar\left[f(k)\frac{\partial\Phi_0}{\partial k}+\varphi(k)\frac{\partial\Phi_0}{\partial\xi}\right]. \tag{4.10}$$

The condition that Φ_1 involves no secular terms is now reduced to the equality

$$\int S^*(\Phi_0)\frac{\partial\Phi_0}{\partial\xi}\,dx=0,$$

from which taking into account (4.8) we obtain two equations

$$\varphi(k)=-\frac{1}{a\hbar}\int U(x)\,|\Phi_0|^2\,dx, \tag{4.11}$$

$$f(k)=-\frac{2\mu}{(1+D)\hbar}\int|\Phi_0(x,t)|^2\,U(x)\tanh[\mu(x-\xi)]\,dx, \tag{4.12}$$

where D is determined by the expression (3.16).

Substituting the value $f(k)$ obtained into Eq.(3.9b) and taking account the equality $m_{sol}=m(1+D)$ we find the equation

$$m_{sol}\frac{d^2\xi}{dt^2}=F \tag{4.13}$$

determining the motion of the soliton centre.

The equation (4.13) resembles the Newton equation for a particle with a soliton mass moving under the influence of the force

$$F \equiv -2\mu\varepsilon \int U(x) |\Phi_0(x,t)|^2 \tanh[\mu(x-\xi)]\, dx. \quad (4.14)$$

Hence, the soliton motion is effected upon by the potential field $U(x)$ over the whole region where $|\Phi_0|^2 \neq 0$.

It is essential that the equation (4.13) involves an effective soliton mass rather than an exciton (electron) mass which enters directly in the nonlinear equation (3.2). This effect is due to the fact that in the molecular chains under consideration the nonlinearity is caused by the interaction of an exciton (electron) with the chain deformation (a phonon subsystem). The perturbation acts not only on an exciton (electrons) but also on a phonon subsystem which leads to the appearance of an additional term $\varepsilon \rho_1(x,t)$ in the right-hand side of Eq. (4.6).

In a number of papers when studying the role of the perturbation $\varepsilon U(x)$ a nonlinear equation of the form

$$\left(i\hbar\frac{\partial}{\partial t} + \frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + G|\Phi(x,t)|^2\right)\Phi(x,t) = \varepsilon U(x)\Phi(x) \quad (4.15)$$

was considered without studying the nature of nonlinearity. In this case we obtain for the function $f(k)$ the value

$$f(k) = -\frac{2m}{\hbar}\int U(x)|\Phi_0(x,t)|^2 \tanh[\mu(x-\xi)]\, dx$$

which leads to the equation

$$m\frac{d^2\xi}{dt^2} = F$$

for a quasi-particle with a mass m oppearing in the equation (4.15).

Thus, in studying the dynamical behaviour of solitons described by a Schrodinger equation it is very important to know physical factors causing the equation nonlinearity.

5. The motion of a soliton in a one-dimensional molecular chain with allowance for thermal vibrations

In the above sections the assumption was made that the chain was

at a absolute zero temperature. It is interesting to investigate the influence of thermal vibrations of molecules on the soliton properties. This problem was considered in Ref. [9] . Below the basic results obtained in that paper are given.

To analize the role of thermal motion it is necessary to express the displacements u_n in the peptide groups through the operators of creation b_q^+ and annihilation b_q of the phonons with wave numbers q

$$u_n = \sum_q \left(\frac{\hbar}{2MN\Omega_q}\right)^{1/2} (b_q + b_{-q}^+) \exp(iqna) \tag{5.1}$$

where $N(\gg 1)$ is the number of molecules in the chain

$$\Omega_q = |q| V_{aq} , \qquad V_{aq} = a\sqrt{2e/M} . \tag{5.2}$$

With temperature distinct from zero we should pass to the statistical description of quantum states of the system. The Hamiltonian function averaged by means of the density matrix of phonon states

$$\rho_{\nu\nu} = \frac{\langle\nu|\exp(-H_{ph}/\Theta)|\nu\rangle}{\sum_\nu \langle\nu|\exp(-H_{ph}/\Theta)|\nu\rangle} , \qquad \Theta = kT, \tag{5.3}$$

takes the form

$$\mathcal{H} = \sum_n \Big\{ (\varepsilon_0 - \frac{\hbar^2}{ma^2}) \varphi_n^* \varphi_n - \frac{\hbar^2 e^{-\bar{W}_n}}{2ma^2} \varphi_n^* (\varphi_{n-1} + \varphi_{n+1}) -$$

$$- \frac{1}{\sqrt{N}} \sum_q F(q) |\varphi_n|^2 (\beta_{qn} + \beta_{-q,n}) + \sum_q \hbar\Omega_q [\bar{\nu}_q + |\beta_{qn}|^2] \Big\} , \tag{5.4}$$

where

$$\bar{W}_n \approx \frac{a^2}{2} \sum_q (2\bar{\nu}_q + 1) q^2 |\beta_{qn}|^2 ,$$

$$F(q) \approx i 2a\varkappa \frac{q}{|q|} \left(\frac{\hbar|q|}{2MV_{aq}}\right)^{1/2} , \tag{5.5}$$

$$\bar{\nu}_q = \left[\exp\left(\frac{\hbar\Omega_q}{\Theta}\right) - 1\right]^{-1}.$$

$\bar{\nu}_q$ is the average number of phonons in the state q ; $\beta_{qn}(t)$ determine the average values of displacements so that

$$\langle u_n(t)\rangle = -\sum_q \left(\frac{\hbar}{2MN\Omega_q}\right)^{1/2} \left[\beta_{qn}(t) + \beta^*_{-q,n}(t)\right].$$

The function (5.4) depends on φ_n , β_{qn} on canonically conjugate generalized momenta $i\hbar\varphi^*_n$ and $i\hbar\beta^*_{qn}$. Using this function we find the Hamiltonian equations which in the continuum approximation (for excitations moving with a velocity $V < V_{aq}$) are reduced to the following approximate equations

$$\left[i\hbar\frac{\partial}{\partial t} - \mathcal{E}_0 + \frac{\hbar^2}{2m(\Theta)}\frac{\partial^2}{\partial x^2} + G(\Theta)\,|\varphi(x,t)|^2\right]\varphi(x,t) = 0, \tag{5.6}$$

$$\rho(x,t) = -\frac{2a\chi\,|\varphi(x,t)|^2}{M(1-s^2)V_{aq}^2}, \qquad s = V/V_{aq}. \tag{5.7}$$

The Schrodinger equation (5.6) involves the parameters depending on temperature Θ .

The nonlinearity parameter is determined by the expression

$$G(\Theta) = \left[1 - \tfrac{1}{4}B\,F(\Theta)\right]G \tag{5.8}$$

where

$$G = 4a^2\chi^2 / M(1-s^2)V_{aq}^2, \tag{5.9}$$

$$B = \pi a^4\chi^2 / M(1-s^2)\hbar V_{aq}^3. \tag{5.10}$$

$$F(\Theta)=\frac{a^2}{\pi^2}\int_0^{\pi/a}\left(1+2\frac{\bar{J}}{q}\right)q\,dq=\begin{cases}\frac{1}{2}+\frac{2\Theta}{\hbar\Omega_0} & \text{if } \frac{\hbar\Omega_0}{\Theta}\ll 1;\ \Omega_0=\pi V_{aq}/a;\\ \frac{1}{2}+\frac{\pi^2\Theta^2}{6\hbar\Omega_0^2} & \text{if } \frac{\hbar\Omega_0}{\Theta}\gg 1.\end{cases} \tag{5.11}$$

The effective exciton (electron) mass increases with increasing temperature by the exponential law

$$m(\Theta)=m\exp\left(\frac{1}{4}\mu_0^2 a^2 B F(\Theta)\right) \tag{5.12}$$

where

$$\mu_0=4ma^3\chi^2/(2MV_{aq}^2\hbar^2(1-s^2)) \tag{5.13}$$

The increase in the effective exciton mass is due to the decrease in the resonance interaction between peptide groups caused by the phase coherence distortion of vibrational excitations in the neighbouring groups.

The nonlinearity parameter (5.8) decreases with increasing temperature. The nonlinearity parameter decrease is associated with the effective decrease in the connection of an exciton with the chain deformation. With sufficiently high temperature the parameter $G(\Theta)$ may become negative. Then the equation (5.6) will have no localized (soliton) solutions. Unfortunately,this conclusion is only qualitatively meaningful since the theory is valid only when the inequality

$$BF(\Theta)<1 \tag{5.14}$$

is satisfied.

With the inequality $S<1$ satisfied, the increase in the velocity of the excitation propagation according to (5.12), (5.10) and (5.13) leads to the increase in the values B and μ_0 causing the exciton mass increase since it acts as increasing temperature. The change of the nonlinearity parameter (5.8) is more complex. At $V\to V_{aq}$, according to (5.9), the value $G(\Theta)$ increases whill the multiplier $\left[1-\frac{1}{4}BF(\Theta)\right]$ decreases.

Solving the equation (5.6) we find that the probability of excita-

tion distribution along the chain is determined by the function

$$|\varphi(x,t)|^2 = \frac{a\mu(\Theta)}{2\cosh^2\{\mu(\Theta)[x-x_0-Vt]\}} \tag{5.15}$$

where

$$\mu(\Theta) = a\, m(\Theta) G(\Theta)/2\hbar^2. \tag{5.16}$$

In accordance with (5.7) the decrease in equilibrium distances between neighbouring molecules is determined by the function

$$\rho(x,t) = -\frac{2a^3\varkappa\mu(\Theta)}{MV_{aq}^2\cosh^2\{\mu(\Theta)[x-x_0-Vt]\}} \tag{5.17}$$

The energy of a soliton travveling with velocity $V \ll V_{aq}$ is proportional to the square of velocity

$$E_{sol}(V) = E_{sol}(0) + \frac{1}{2} m_{sol} V^2, \tag{5.18}$$

with the soliton mass

$$m_{sol} = m(\Theta)\left[1 + \frac{a^2 G^2(\Theta)}{6\hbar^2 V_{aq}^2}\right] \tag{5.19}$$

and the energy at rest

$$E_{sol}(0) = \mathcal{E}_0 - m(\Theta) a^2 G^2(\Theta)/12\hbar^2. \tag{5.20}$$

The soliton size is determined by the value

$$l \cong \frac{\pi}{\mu(\Theta)} = 2\pi\hbar^2/a\, m(\Theta) G(\Theta). \tag{5.21}$$

We substitute the values (5.8) and (5.12) into this expression. Then when the continuum approximation $a\mu_0 \ll 1$ and inequality (5.14) are satisfied

$$l \approx 2\pi\hbar^2/(ma[1-\tfrac{1}{4}BF(\Theta)]G). \tag{5.22}$$

Thus, with increasing temperature the soliton size increases and its properties more and more approximate the exciton properties. The fact whether a soliton transforms into an axciton continuously or discontinuously can be clarified only on the basis of a new theory valid in the region $V \approx V_{aq}$.

The Theory of Contraction of Proteins under their Excitation

A. S. DAVYDOV

The Institute of Theoretical Physics,
Academy of Sciences of the Ukrainian S.S.R.,
Kiev, U.S.S.R.

(*Received* 23 *April* 1972)

This paper develops the quantum theory of contraction of α-helical proteins under the excitation of their peptide groups, which form three parallel chains of hydrogen bonds along the molecule. In the region embraced by an excitation, the pitch of the helix decreases, and the "contracted" region of the helix moves along the molecule at a rate proportional to the energy of resonance interaction between peptide groups. The movement of the excitation region from the head of the myosin molecule to its tail results in movement of the myosin filaments along the actin ones in the myofibril of the muscle, and thus leads to a decrease in length of the muscle fibre.

1. Introduction

As yet, there is no complete understanding of the mechanism for muscle contraction in vertebrates or invertebrates. Apparently it is an established fact that the energy required for the contraction of muscle fibres is released when adenosine triphosphate (ATP) transforms into adenosine diphosphate (ADP) and phosphate. Such a transformation occurs in the presence of Ca^{2+} ions, which trigger an enzyme action of the protein molecules of the muscles. The mechanism converting this chemical energy into a mechanical motion is still not completely understood. In the present paper we propose a new mechanism responsible for the contraction of protein molecules when they are excited by the energy released in the hydrolysis of ATP.

2. Current Concepts of the Mechanism for Muscle Contraction

As is well known, long polymer protein molecules (polypeptides) are the chief contractile elements of muscles and other biological objects that con-

vert chemical energy into mechanical motion. The striated muscles of vertebrate animals and insects have received a very detailed study (see, for example, the review of Volkenstein (1970)). These muscles are bundles of fibres each of which is made up of several thousands of densely packed filaments called myofibrils. The myofibril is the functional unit of the muscle contractile system.

Each myofibril is divided into separate strictly repeating segments, or sarcomeres, built up of an interpenetrating system of thin (actin) and thick (myosin) protein filaments. The thick filaments are situated in the centre part of the sarcomeres and consist of several hundred myosin molecules. These molecules are built up of two identical polypeptide chains coiled up in the form of a helix. In turn, each of these chains has the form of an α-helix in the long (tail) portion of the molecule. In the head portion the molecule has two projections ("heads"). Separate myosin molecules in thick filaments are oriented in opposite directions from the centre.

The thin filaments of the sarcomere start from the Z-plates (which separate the sarcomeres from each other) and run to the centre of the sarcomere, partially penetrating into the spaces between thick filaments. They are made up of double helices of globular G-actin molecules. Each filament contains about 400 molecules.

Many hypotheses have been proposed to account for the machinery of contraction. Some of these hypotheses were based on the properties of polyelectrolytes which lead to the folding and unfolding of protein chains when the charges of their radicals are changed. These hypotheses differed from each other in the assumptions concerning the character of the distribution and the change in electric charges along the protein molecules (Meyer, 1929; Kuhn, Toth & Ebner, 1962; Wohlisch, 1940; Botts, Morales & Cellular, 1951; Risemann & Kirkwood, 1948). No direct evidence is available for the rearrangement of molecules during the contraction of muscle fibres.

Hypotheses have often been advanced (Astbury, 1950; Huxley, A., 1957; Ooswa *et al.*, 1961) to account for the contraction and relaxation of muscles by postulating the structural transformation of myosin and actin molecules.

A number of authors (Pryor, 1950; Kuhn, 1960; Flory, 1956; Hill, 1968) have associated muscle contraction with phase transitions of the protein molecules. But the bulk of X-ray evidence on living contracting muscle does not support the hypothesis that there is any large scale rearrangement in the filaments of muscle (see review paper by J. Hanson (1968)).

Using electron-microscope data, Huxley H. & Hanson (1954) and Huxley & Nidergerke (1954) established that the contraction of myofibrils was connected with the fact that thin actin filaments move along the channels between the thick myosin filaments without overall changes in length. These

data served as a basis in constructing the presently widely accepted "sliding model" for the mechanism of muscle contraction and relaxation.

A phenomenological theory of the sliding model has been developed by Davies (1963). Davies' theory runs into a number of difficulties. It overestimates the role of electrostatic repulsion, regarding it as causing the myosin molecule's head to change from an α-helical to a stretched, disordered configuration.

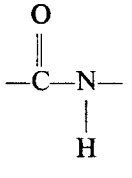
The distance between the G-actin monomers in the actin filament is about 55 Å. Consequently, every miniature contraction cycle should, according to Davies' theory, move the actin filament ~55 Å farther, so that the molecule's head should shorten and stretch by about 70 Å during each cycle.

If the negative electric charge at the base of the myosin molecule's head so strongly repels the ATP^- complex, attached to the head, that the latter stretches, then the same charge will not allow the sarcoplasmic ATP to approach the ADP (which formed at the head after the ATP broke down) to replace it or charge it to ATP.

Davies' theory does not make it clear why the myosin molecule has, besides its head, a very long (~1300 Å) α-helical tail that takes no active part in the contraction. It is unlikely that nature is so wasteful.

3. Collective Excitations of Peptide Groups in α-Helical Protein Molecules

The contractile proteins, like all other proteins, are synthesized by a linear polymerization of various amino acids. Polymerization results in a periodically repeating sequence of peptide groups



(1)

The formation of hydrogen bonds between the oxygen and hydrogen atoms of the peptide groups of the first and fourth, second and fifth, etc., amino acid residues stimulates the polypeptide chains of amino acid residues to fold up into α-helices. Thus there forms an α-helix 10·1 Å in diameter, containing three chains of hydrogen bonds whose directions almost coincide with that of the helix axis.

As the peptide groups are regularly positioned, collective (exciton) excitations forming broad bands correspond to electric dipole excitations. Moffitt (1956), using the theory of molecular crystal spectra developed by

Davydov (1951, 1971), developed the theory of collective excitations of a type which correspond in energy range (5–7 eV) to the electronic excitations of peptide groups. In calculations it was assumed that the peptide groups were fixed in the positions which they occupy in a non-excited molecule.

As this author has shown (1969), if the deformability of a crystal lattice is taken into account one is led to the fact that an exciton excitation in a one-dimensional crystal is accompanied by a local crystal deformation. We shall consider this effect for the case where α-helical molecules are subject to excitations of less than the 0·48 eV of energy released during ATP hydrolysis. This energy range corresponds to the energy of 0·23 eV of the valence vibration C=O in the peptide group. The electric dipole moment of this vibration is directed along the hydrogen bond. The dipole–dipole interaction between adjacent peptide groups placed along the chain of hydrogen bonds is an order of magnitude higher than the similar interaction between the nearest groups of adjacent chains, so that the excitations of the peptide groups of the three hydrogen-bond chains may be treated independently. For the sake of simplicity we shall consider only one of them in what follows.

Let $\mathbf{r}_n$ be a radius-vector determining the position of the nth peptide group (see Fig. 1). The number n takes the values $1, 2, \ldots, N$ ($N \sim 200$–300). Then

$$R_n = |\mathbf{r}_{n+1} - \mathbf{r}_n| \tag{2}$$

is the distance between two adjacent peptide groups. Suppose that the potential interaction energy of these groups when in the ground state is

$$U_0 = \sum_n u_0(R_n), \tag{3}$$

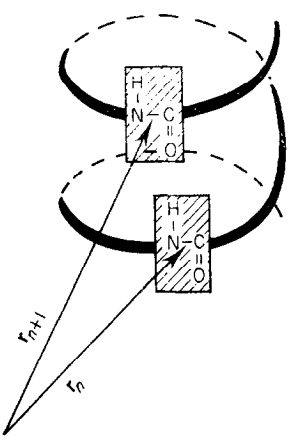


FIG. 1.

where

$$u_0(R) = C/R^s - A/R^3, \tag{4}$$

The quantities C, A and s are the parameters of the theory. They depend on the properties of peptide groups themselves and the environment in which they happen to be (cytoplasm, radicals, etc.). To the minimum of potential energy, equation (3), there correspond the equilibrium distances

$$R_0 = (sC/3A)^{\sigma}, \qquad \sigma = (s-3)^{-1}. \tag{5}$$

The value of R_0 is of the order of 5·4 Å.

Suppose that the peptide group in a protein molecule can go into an excited state with excitation energy ε, and that an electric dipole transition moment directed along the molecule corresponds to this excitation.

Let us introduce the operators of creation B_n^+ and annihilation B_n of an excitation on group n. Then for fixed values of R_n the operator for the excitation energy of the whole chain will have the form

$$H = \sum_n \{[\varepsilon + D(R_n)]B_n^+ B_n + M(R_n)[B_n B_{n+1}^+ + B_n^+ B_{n+1}]\}, \tag{6}$$

where

$$D(R) = -\alpha/R^3 \tag{7}$$

is the change in static interaction energy of two adjacent groups when one of them goes into an excited state:

$$M(R) = -\gamma/R^3 \tag{8}$$

is the energy of resonance dipole–dipole interactions between adjacent groups. $\gamma = 2\mathbf{d}$; $\mathbf{d}$ is the electric moment of the dipole excitation.

To simplify our calculation we take periodic boundary conditions. The $R_N = |\mathbf{r}_1 - \mathbf{r}_N|$ and the sums over n in all formulae are extended over the values from 1 to N.

If the ground state of the chain is $|0>$, then at fixed R_n the excited states are characterized by the functions

$$\Psi = \sum_n a_n B_n^+ |0\rangle \tag{9}$$

which are defined by the sets of complex numbers a_n satisfying the condition

$$\sum_n a_n^* a_n = 1. \tag{10}$$

To every set of numbers a_n and R_n there corresponds the excitation energy

$$E(\{a_n\}, \{R_n\}) = \sum_n \{[\varepsilon + D(R_n)]a_n^* a_n + M(R_n)[a_n a_{n+1}^* + a_n^* a_{n+1}]\}. \tag{11}$$

For a fixed set of numbers $\{a_n\}$, the expression (11) is dependent on the distance R_n and is the potential energy, additional to that in equation (3), for peptide groups.

Hence the total potential energy takes the form

$$U(\{a_n\}, \{R_n\}) = \varepsilon + \sum_n \{u_0(R_n) + D(R_n)a_n^* a_n + M(R_n)[a_n a_{n+1}^* + a_n^* a_{n+1}]\}. \quad (12)$$

Our task is to find sets a_n and R_n corresponding to an absolute minimum of the energy given in equation (12), at a fixed number of simultaneous elementary excitations—that is, when the condition (10) is satisfied.

We obtain the minimization of the energy, (formula (12)), in two stages. We first find the values $R_n = \rho_n$ that correspond to the minimum of formula for a fixed set of values of the a_n. These values of R_n determine new equilibrium distances between the peptide groups in an excited chain:

$$\rho_n = R_0\{1 + \kappa a_n^* a_n + \eta[a_n a_{n+1}^* + a_n^* a_{n+1}]\}^{-\sigma}, \quad (13)$$

where

$$\kappa = \frac{\alpha}{A}, \qquad \eta = \frac{\gamma}{A} > 0 \qquad (\eta < \kappa < 1). \quad (14)$$

To find the coefficients a_n which minimize formula (12), we insert the values (13) and keep the terms of order not higher than κ, η, κ^2. As a result we obtain the functional

$$U(\{a_n\}) = Nw_0 + \varepsilon - (3\sigma+1)\kappa v w_0 - \Lambda \sum_n (a_n a_{n+1}^* + a_n^* a_{n+1}) - G \sum_n (a_n^* a_n)^2, \quad (15)$$

where

$$w_0 = -u_0(R_0) = \frac{A}{\sigma S R_0^3}, \qquad G = \tfrac{3}{2}(\sigma+1)\sigma\kappa^2 w_0, \qquad \Lambda = \frac{(3\sigma+1)\gamma}{\sigma S R_0^3} \quad (16)$$

are parameters independent of n. With our choice of boundary conditions the potential energy (equation (12)) is therefore invariant under the substitution of $n+m$ for n, where m is an integer. Consequently, the energy states of the chain may be classified by means of the wave numbers

$$k = \frac{2\pi}{N\rho_0} j, \quad (j = 0, \pm 1, \pm \ldots N/2), \quad (17)$$

where ρ_0 is the average distance between peptide groups in the region of excitation. Considering only small values of k (long wave approximation), one can go over in equation (12) to a continuous model of the chain.

4. Collective Excitations in Long Wave Approximation

To go over to a continuous model of the chain in the case of long wave excitation we perform the substitution

$$1 = \sum_n a_n^* a_n \Rightarrow \int a^*(x)a(x)\,dx, \quad (18)$$

$$\varepsilon - \Lambda \sum_n (a_n a_{n+1}^* + a_n^* a_{n+1}) \Rightarrow (\varepsilon - 2\Lambda) + \int a^*(x) \left(- \frac{\hbar^2}{2m^* \rho_0^2} \frac{\mathrm{d}^2}{\mathrm{d}x^2} \right) a(x)\, \mathrm{d}x, \quad (19)$$

where

$$m^* = \hbar^2/(2\Lambda\rho_0^2) \quad (20)$$

is the effective mass of a free exciton. Then equation (15) reduces to the form

$$U(k, \{a(x)\}) = (\varepsilon - 2\Lambda) - (3\sigma + 1)\kappa w_0 - N w_0 + \\ + \int a^*(x) \left[- \frac{\hbar^2}{2m^* \rho_0^2} \frac{d^2}{\mathrm{d}x^2} \right] a(x)\, \mathrm{d}x - G \int [a^*(x) a(x)]^2\, \mathrm{d}x. \quad (21)$$

With $G = 0$, to the extremum of the functional (21) correspond the values $a(x)$ with the form of plane waves

$$a(x) = \sqrt{\frac{1}{N}} \exp(ikx\rho_0). \quad (22)$$

With $G \neq 0$ we represent $a(x)$ in the form of modulated plane waves

$$a(x) = \varphi(x) \exp(ikx\rho_0), \quad (23)$$

where $\varphi(x)$ is a real function to be defined from the condition that formula (21) be a minimum, subject to the condition that the equality (18) be satisfied.

Substituting equation (23) into equation (21) we find

$$U(k, \varphi(x)) = -N w_0 + (\varepsilon - 2\Lambda) - (3\sigma + 1)\kappa w_0 + \\ + \frac{\hbar^2 k}{2m^* \rho_0^2} - \frac{\hbar^2}{2m^* \rho_0^2} \int \varphi(x) \frac{\mathrm{d}^2 \varphi(x)}{\mathrm{d}x^2}\, \mathrm{d}x - G \int \varphi^4(x)\, \mathrm{d}x. \quad (24)$$

Varying the functional (24) under the additional condition (18), we derive a non-linear equation

$$\frac{\hbar^2}{2m^* \rho_0^2} \frac{\mathrm{d}^2 \varphi(x)}{\mathrm{d}x^2} + 2G\varphi^3(x) - \chi\varphi(x) = 0 \quad (25)$$

to define $\varphi(x)$. Its solution that corresponds to the minimum of equation (24) at fixed $k \approx 0$, has the form

$$\varphi(x) = \sqrt{\mu/2}\, \mathrm{ch}^{-1}(\mu\xi), \quad (26)$$

where

$$\xi = x - x_0, \qquad \mu \equiv \frac{2G}{\Delta E}, \qquad \chi \equiv \frac{G^2}{\Delta E}, \quad (27)$$

and x_0 is the point on the chain where the maximum value of $\varphi(x)$ is concentrated. $\Delta E \approx 4\Lambda$ is the energy bandwidth of free excitons.

In the long wave approximation, we can put, in expression (13),

$$a_n a_{n+1}^* + a_n^* a_{n+1} \approx 2a_n^* a_n.$$

Going to a continuous model and making use of the values (26) we then obtain

$$\rho(\xi) \approx R_0 \left[1 - \frac{\sigma(\kappa+2\eta)G}{\Delta E . \mathrm{ch}^2(\mu\xi)}\right]. \tag{28}$$

Consequently, a maximum shortening of the distance between peptide groups takes place at the point $x = x_0$. The distance decreases by the amount

$$\Delta\rho_{\max} = \sigma(\kappa+2\eta)GR_0/\Delta E. \tag{29}$$

A substantial decrease in the distances between peptide groups should be observed for the length of the chain which contains $\Delta\xi$ peptide groups, where

$$\Delta\xi = \pi\Delta E/2G. \tag{30}$$

In this region the mean distance between peptide groups becomes

$$\rho_0 = R_0[1 - 0{\cdot}6\sigma(\kappa+2\eta)G/\Delta E]. \tag{31}$$

The total length of the chain in the excited state is determined by the expression

$$L \approx \left(1 - \frac{\sigma(\kappa+2\eta)}{N}\right) \approx NR_0. \tag{32}$$

Substituting equation (26) into equation (24) we find the excitation energy (above the ground-state energy—Nw_0) for a fixed value k

$$E(k) = \left[\varepsilon - \frac{\Delta E}{2} - (3\sigma+1)\kappa w_0\right] + \frac{\hbar^2k^2}{2m^*} - \frac{G^2}{3\Delta E}. \tag{33}$$

Thus, the excitation energy of a chain of resonantly interacting peptide groups of an α-helix is much less than the excitation energy ε of groups of isolated amino acid residues contained in the same cytoplasm.

Using equation (33) it is possible to calculate a group velocity of movement of the excitation along the α-helical molecule

$$V_g = \frac{1}{\hbar}\,\mathrm{grad}_k\, E(k) = \frac{\hbar k}{m^*} = \frac{k}{\hbar}\Delta E\rho_0^2. \tag{34}$$

It follows from equation (34) that the velocity of movement of the contracted region along the molecule is proportional to the energy ΔE of the resonance interaction between peptide groups, and proportional to the quasi-momentum of the excitation. Parallel with the solution (26), equation (25) allows other solutions as well. However, at fixed k they do not correspond to the energy minimum of equation (24). For example, the solutions $\varphi = \sqrt{1/N}$ and $\chi = 2G/N$, which reduce equation (23) to plane waves, correspond to the excitation energy

$$E(k) = \left[\varepsilon - \frac{\Delta E}{2} - (3\sigma+1)\kappa W_0\right] + \frac{\hbar^2k^2}{2m^*} - \frac{G}{N}.$$

Excitations of such a type are uniformly distributed along the whole length of the molecule.

We have considered the collective longitudinal excitations of one chain of peptide groups of an α-helical protein molecule. The excitation energy of this chain is less than 0·23 eV provided that it corresponds to the excitation of the valence vibration C=O. Therefore it appears likely that the disintegration energy of one ATP molecule is sufficient to excite one, two, and even all three chains formed by hydrogen bonds in the molecule.

To simplify calculations we have considered periodic boundary conditions, taking no account of excitation relaxation (attenuation) processes. When relaxation processes are taken into account, an excitation that arises at one end of a long molecule will spread to its other end at a decreasing rate, that is, it will give up a portion of its energy as it travels. At the same time the probability grows that the remaining portion of the excitation energy will all turn into heat before reaching the end of a molecule.

5. Excitation of Myosin Molecules and the "Sliding Model"

A quantum theory of the conformational change of a certain region of α-helical protein molecules under the excitation of their peptide groups has been developed in sections 3 and 4.† In the myofibrils of muscles such excitations may be generated by the disintegration energy of ATP molecules when, in the presence of Ca^{2+}, they interact with the active ATPase centres of the heads of the myosin molecules. The resulting collective excitation leads to shortening of the distances between peptide groups in some region of every hydrogen-bonded chain in the myosin molecule. As a result, in this region the helical mysoin molecule thickens and bends, getting into a closer contact with the surrounding actin filaments.

The resulting collective excitation should travel from the head, where the ATPase centre is located, to the tail of the molecule. Since the frictional resistance (to motion) of the displaced twisted section of myosin filament relative to the surrounding actin filaments is considerably elevated, the movement of this "contracted" region from the head of the molecule to its tail will make the whole myosin filament move along actin filaments in the direction from the tail to the head (see Fig. 2). Such a "sliding" of a myosin filament over actin filaments will result in a slight shortening of the length of the I-discs of the sarcomere. The subsequent excitations that arise in the region

† This conformation corresponds in some respects to the possibilities discussed in the short paper by Volkenstein (1972). In that paper he introduced the notion "conformon" for excitation of the system of the long-wave phonons, electrons and local deformations of macromolecules.

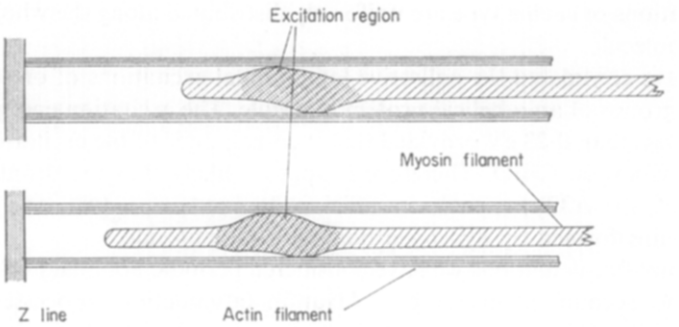

FIG. 2.

of the head (where the ATP is hydrolyzed in the presence of Ca^{2+}) and spread along myosin filaments to the sarcomere centre will lead to further movement of actin filaments with respect to myosin filaments. This movement resembles the movement of a snake ("concertina progression" (Gans, 1970)) in a straight narrow channel.

In the theory proposed here (and agreeing with the experimentally established "sliding model") the whole long helical protein molecule (and not only the head section as in Davies' theory) is the working element of the muscle. The second feature of the theory is that the "contracted" region spreads along the whole molecule, although an excitation initially arises in a separate part where the ATP energy is released.

So the main points of our theory are that: (1) the energy of hydrolysis of ATP is used in muscle to excite the carboxyl group at a peptide bond in the head of a myosin molecule; (2) this excitation is accompanied by a local distortion and contraction of the myosin molecule without gross overall changes in its length (see equation (32)); (3) the excitation with its attendant local contraction propagates down the molecule from head to tail because of resonance interaction between excited and non-excited peptide groups; and (4) this leads to a net movement of the myosin filament relative to the neighbouring actin filaments.

6. Some Numerical Estimates

The electric dipole moment of the vibration C=O in a peptide group with frequency $\sim 1660\,\mathrm{cm}^{-1}$, is equal to $\mathbf{d} \approx 0{\cdot}29$ Debye (Chirgadze & Rashevskaja, 1969). Therefore the radiation lifetime of the excited state with respect to spontaneous emission is

$$\tau = \frac{3\hbar}{4d^2}\left(\frac{c}{\omega}\right)^3 \approx 10^{-1}\ \mathrm{sec}; \qquad \Delta E \approx 2 \times 10^{-15}\ \mathrm{erg}.$$

Excitons with kinetic energy equal $0{\cdot}07\,\Delta E$ have the wave number $k = 0{\cdot}5/R_0$. They have the group velocity $Vg = \hbar km^*/$, $m^* = 2\hbar^2/\Delta E\rho^2$, (Davydov, 1971, Ch. II, sec. 2), which is equal about 30 m/sec. When the deformability of a chain is taken into account, motion of the excitation is accompanied by a local distortion of the chain and this group velocity will decrease, as the effective mass m^* will increase. For quantitative description of this effect one must develop the theory in the next approximation which can take into account the motion of the peptide group. The velocity of the motion of the peptide group is not connected with the velocity of an exciton. The bigger the mass of a peptide group the smaller will be the role of deformation. If the mass of a peptide group is M_0, the increase in the effective mass will be

$$m^* \Rightarrow m^*(1 - m^*B)^{-1},$$

where B is proportional $1/M_0$.

The Vibrational Structure of Davydov Solitons

Alwyn C. Scott

Center for Nonlinear Studies, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, U.S.A.

Received December 29, 1981; accepted February 4, 1982

Abstract

Internal oscillations of an alpha-helix soliton are studied numerically on a modified version of Davydov's equations and analytically on an approximating system of coupled nonlinear Schrödinger equations. The numerical results are used to interpret lines in recently measured laser-Raman spectra of metabolically active *E. coli*. Agreement between measured and calculated lines appears to be within the uncertainties of computation and measurement.

1. Introduction

The idea that bond energy could be transported along one-dimensional molecular chains (such as alpha-helix protein molecules) by solitary waves (or "solitons") was first proposed by Davydov and Kislukha in 1973 [1]. Since that time Davydov and his co-workers have published a number of papers that discuss various soliton parameters including lifetime, damping, energy, and wave structure [1]. The physical notion of Davydov's alpha-helix soliton can be understood rather easily with reference to Fig. 1. The energy to be transported is stored as "stretching" quanta of the amide-I bond (i.e., $C=O$) which has an absorption peak at 1653 cm^{-1} corresponding to a quantum unit of 0.205 eV. Naïvely one would expect such energy to disperse rapidly ($\sim 10^{-12}$ s) via dipole–dipole interactions throughout all the amide-I bonds. But if certain nonlinearities of the system are taken into consideration, it is seen that localized bond energy generates longitudinal sound which in turn acts as a potential well to trap the bond energy and prevent its dispersion. Thus the Davydov soliton can be viewed as a local region of conformational change which is mobile.

The most important nonlinearity in the problem is a parameter (χ_1) that gives the change in energy of an amide-I bond (newton-meters) per unit extension of its associated hydrogen bond (meters). In 1979 a theoretical study of an analytically tractable approximation to Davydov's equations (the nonlinear Schrödinger equation) showed that there is a threshold level for χ_1 below which solitons could not be expected to form, and this conclusion was supported by numerical integration of Davydov's equations [3]. Estimates by both Davydov and myself indicated for a real alpha-helix protein that χ_1 was about the right order of magnitude to support soliton formation.

Recently Kuprievich and Kudritskaja [4] have obtained χ_1 from SCF calculations on formamide dimer as 0.34×10^{-10} newtons. Using a form of Davydov's equations that have been extended to improve accuracy, I have recently found exactly the same value of χ_1 as the threshold for soliton formation [5]. Thus there is now substantial numerical evidence that Davydov solitons can form on real alpha-helix protein.

During the course of this study [5] some cursory observations were made of an "interspine oscillation" in bond energy between the three spines (etc., $\cdots$H–N–C=O $\cdots$ H–N–C=O $\cdots$, etc.) that run longitudinally along the helix. (One of these three spines is cross-hatched in Fig. 1). After the manuscript for [5] was completed, I became aware of Webb's recent review of laser-Raman spectra measured on metabolically active cells [6]. Of particular interest was a spectrum (see Fig. 2) taken from *E. coli* and consisting of nine definite lines which could be assigned rather closely to simple sums and differences of two predetermined frequencies: (i) The frequency of interaction of the soliton with unit cells of the alpha-helix, and (ii) The frequency of the above mentioned interspine oscillation [7]. Thus laser-Raman spectroscopy (LRS) may provide direct experimental confirmation that Davydov solitons play a functional role in metabolic processes. If so, LRS could become even more valuable as a probe into the secret details of life processes.

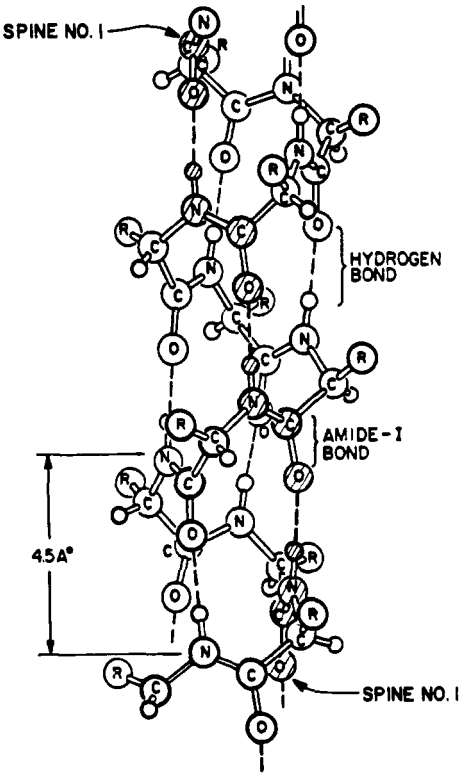

Fig. 1. Alpha-helix (redrawn from [2] with permission of the author). The atoms of a single "spine" are cross-hatched.

The aim of this paper is to provide the basis for a critical evaluation of the above hypothesis (that Fig. 2 displays the vibrational structure of an alpha-helix soliton). The following section lists the numerical and analytical models to be studied beginning with that developed in [5] and proceeding toward simpler and more tractable approximations. Section 3 discusses the linear problem of interspine interaction below the level for soliton formation. This is important not only because the linear

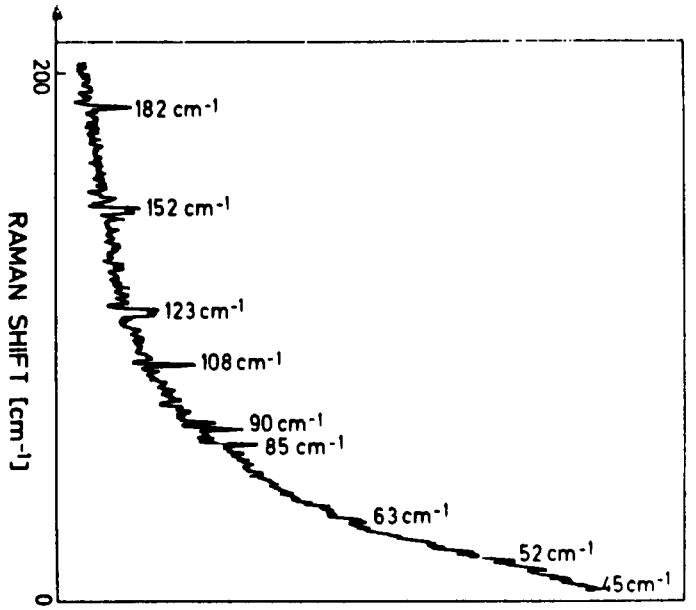

Fig. 2. Laser-Raman spectrum from metabolically active *E. coli* (from [6] with permission of the author).

problem suggests ways to analyze the nonlinear problem above threshold, but also because it is necessary to understand the dynamic differences above and below threshold in order to consider whether Fig. 2 represents the spectrum of a soliton or mere linear vibrations of the protein. In Section 4 the simplest representation of the nonlinear problem is considered: Three coupled nonlinear Schrödinger (NLS) equations. At this level of approximation, a family of exact soliton solutions is obtained which display the salient features of the solitary wave observed on the original numerical model. A detailed description of this numerical solitary wave is presented in Section V and discussed in the context of the analytical solution developed in the previous section. The differences between nonlinear system dynamics above threshold and linear dynamics below threshold are also developed. A critical discussion of the differences between the spectrum of Fig. 2 and my numerical prediction of it is presented in Section VI. In particular, it is shown that the best possible numerical results differ only slightly from those obtained from the numerical model without any adjustment of the physical parameters. The residual differences between predicted and measured spectra must be attributed to errors in measurement. Section 7 provides a concluding discussion. The analytical results of Section 4 are readily extended from three to an arbitrary number of interacting NLS equations; this extension is noted in an appendix.

2. Alpha-helix models

In this section the several numerical and analytical models to be considered are listed in order of decreasing complexity.

2.1. *Modified Davydov (MD) equations*

The following equations were developed in [5] to describe the coupled propagation of bond energy probability density, $A_{n\alpha}$, and longitudinal displacement of an amide-I bond, $B_{n\alpha}$.

$$\mathrm{i}\frac{\mathrm{d}A_{n\alpha}}{\mathrm{d}\tau} + J(A_{n+1,\alpha} - 2A_{n\alpha} + A_{n-1,\alpha}) - k_1(B_{n+1,\alpha} - B_{n-1,\alpha})A_{n\alpha} = LF_L + \{k_2[B_{n-1,\alpha}A_{n-1,\alpha} - B_{n+1,\alpha}A_{n+1,\alpha} + B_{n\alpha}(A_{n+1,\alpha} - A_{n-1,\alpha})] - 2JA_{n\alpha} + NF_N + PF_P + QF_Q + RF_R + SF_S + TF_T + UF_U + VF_V + XF_X + ZF_Z\} \quad \text{(MD1)}$$

$$\frac{\mathrm{d}^2B_{n\alpha}}{\mathrm{d}\tau^2} - (B_{n+1,\alpha} - 2B_{n\alpha} + B_{n-1,\alpha}) = k_3(|A_{n+1,\alpha}|^2 - |A_{n-1,\alpha}|^2) + \{k_4[A^*_{n\alpha}(A_{n+1,\alpha} - A_{n-1,\alpha}) + A_{n\alpha}(A^*_{n+1,\alpha} - A^*_{n-1,\alpha})]\} \quad \text{(MD2)}$$

In these equations the $\{J, L, \ldots, Z\}$ are dipole–dipole interaction energies between pairs of amide-I bonds. They have the normalized values given in Table I. The subscript n counts unit cells along the helix while α specifies one of the three spines (see Fig. 1). The symbol F_L is shorthand for the dipole–dipole interactions between laterally adjacent amide-I bonds; thus:

$$\mathrm{i}\dot{A}_{n1} = L(A_{n2} + A_{n-1,3}) + \text{etc.}$$
$$\mathrm{i}\dot{A}_{n2} = L(A_{n3} + A_{n1}) + \text{etc.}$$
$$\mathrm{i}\dot{A}_{n3} = L(A_{n2} + A_{n+1,1}) + \text{etc.} \quad \text{(1a, b, c)}$$

Similar definitions of the symbols $F_N, \ldots, F_Z$ are given in [5].

The constants $k_1, \ldots, k_4$ represent nonlinear coupling between bond energy dispersion and longitudinal sound. They are

$$k_1 = \frac{10^{-11}}{\hbar}\sqrt{\frac{M}{w}}\chi_1$$
$$k_2 = \frac{10^{-11}}{\hbar}\sqrt{\frac{M}{w}}\chi_2$$
$$k_3 = \frac{10^{11}}{w}\chi_1$$
$$k_4 = \frac{10^{11}}{w}\chi_2 \quad \text{(2a, b, c, d)}$$

where M is one third of the mass of a unit cell, w is the linear force constant of a hydrogen bond, χ_1 (as previously noted) is the change in amide-I bond energy per unit extension of an adjacent hydrogen bond, and χ_2 is the change in the longitudinal (nearest neighbor) dipole–dipole coupling term, J, per unit of differential displacement.

The time scale, τ, measures laboratory time in units of

Table I

Term	Energy (computer units)
J	0.145
L	0.231
N	0.073
P	0.034
Q	0.019
R	0.012
S	0.0089
T	0.0073
U	0.0037
V	0.0030
X	0.0022
Z	0.0017

$$\sqrt{\frac{M}{w}} = 0.99 \times 10^{-13}\,\mathrm{s} \tag{3}$$

and $B_{n\alpha}$ measures longitudinal displacement in units of 10^{-11} m.

It is important to emphasize (see [5] for details) that there are no adjustable parameters in the MD system.

2.2. *Coupled Zakharov (CZ) equations*

The MD system can be simplified by noting [5] that $k_2 \ll k_1$ and $k_4 \ll k_3$ and also from Table I that J and L are substantially larger than the other dipole–dipole interaction terms. Furthermore the term "$-2JA_{n\alpha}$" in MD1 can be removed by scaling. Thus the $\{\ \}$ terms can be neglected in both MD1 and MD2. Also the discrete variable, n, can be approximated as a continuous variable, ξ, by writing

$$B_{n+1,\alpha} - B_{n-1,\alpha} \doteq 2\frac{\partial \tilde{B}_\alpha}{\partial \xi}$$

$$|A_{n+1,\alpha}|^2 - |A_{n-1,\alpha}|^2 \doteq 2\frac{\partial |\tilde{A}_\alpha|^2}{\partial \xi}$$

Finally it is convenient to define

$$\tilde{\rho}_\alpha \equiv \frac{\partial \tilde{B}_\alpha}{\partial \xi} \tag{4}$$

whereupon the MD system reduces to

$$\mathrm{i}\frac{\partial \tilde{A}_\alpha}{\partial \tau} + J\frac{\partial^2 \tilde{A}_\alpha}{\partial \xi^2} - 2k_1\tilde{\rho}_\alpha\tilde{A}_\alpha \doteq L(\tilde{A}_{\alpha+1} + \tilde{A}_{\alpha-1}) \tag{CZ1}$$

$$\frac{\partial^2 \tilde{\rho}_\alpha}{\partial \tau^2} - \frac{\partial^2 \tilde{\rho}_\alpha}{\partial \xi^2} \doteq 2k_3\frac{\partial^2 |\tilde{A}_\alpha|^2}{\partial \xi^2} \tag{CZ2}$$

where $\alpha = 1, 2, 3$. Writing

$$\tilde{A}_\alpha = A_\alpha/4k_1k_3J$$

$$\tilde{\rho}_\alpha = \rho_\alpha/2k_1J$$

$$\xi = Jx$$

$$\tau = Jt$$

puts CZ into the normalized form*

$$\mathrm{i}A_{\alpha,t} + A_{\alpha,xx} - \rho_\alpha A_\alpha \doteq \epsilon(A_{\alpha+1} + A_{\alpha-1}) \tag{CZ1'}$$

$$\rho_{\alpha,tt} - \rho_{\alpha,xx} \doteq (|A_\alpha|^2)_{xx} \tag{CZ2'}$$

where

$$\epsilon = JL \tag{5}$$

2.3. *Coupled nonlinear Schrödinger (CNLS) equations*

For the solitary wave solutions that arise in this study, the velocities observed are small compared with unity (longitudinal sound speed). Thus the first term in (CZ2') can be neglected, leading to the coupled system of nonlinear Schrödinger equations.

$$\mathrm{i}A_{1,t} + A_{1,xx} + |A_1|^2A_1 \doteq \epsilon(A_2 + A_3)$$

$$\mathrm{i}A_{2,t} + A_{2,xx} + |A_2|^2A_2 \doteq \epsilon(A_1 + A_3)$$

$$\mathrm{i}A_{3,t} + A_{3,xx} + |A_3|^2A_3 \doteq \epsilon(A_1 + A_2) \tag{CNLS}$$

* From here on a subscript notation is used to indicate partial differentiation.

2.4. *Coupled nonlinear Schrödinger equations with no bending (CNLSNB)*

A slightly different form of coupled nonlinear Schrödinger equations can be obtained from CZ' under the assumption that the dynamics introduces no bending of the alpha-helix. This assumption is equivalent to requiring

$$\rho_1 = \rho_2 = \rho_3 = \tfrac{1}{3}(|A_1|^2 + |A_2|^2 + |A_3|^2) \tag{6}$$

whereupon the three coupled nonlinear Schrödinger equations can be written in vector form as

$$\mathrm{i}\bar{A}_t + \bar{A}_{xx} + \tfrac{1}{3}(\bar{A}^*\cdot\bar{A})\bar{A} = Z\bar{A} \tag{CNLSNB}$$

where $\bar{A} = \mathrm{col}\,(A_1, A_2, A_3)$ and

$$Z = \begin{bmatrix} 0 & \epsilon & \epsilon \\ \epsilon & 0 & \epsilon \\ \epsilon & \epsilon & 0 \end{bmatrix}. \tag{7}$$

This "no bending" assumption is not unreasonable physically since the valence structure of the helix might be expected to inhibit differences in the ρ_α's, but CNLSNB is primarily interesting because, as we shall see in Section 4, it is completely integrable.

2.5. *Coupled linear Schrödinger (CLS) equations*

As the amplitudes of $\bar{A}$ approach zero, both CNLS and CNLSNB become the coupled linear Schrödinger equations which can be written in vector form as

$$\mathrm{i}\bar{A}_t + \bar{A}_{xx} = Z\bar{A} \tag{CLS}$$

3. Linear analysis below threshold for soliton formation

A general solution of CLS can be written as a generalized sum of elementary solutions of the form $\bar{A}\exp(\mathrm{i}\omega t + \mathrm{i}kx)$ whereupon CLS requires

$$[Z + (\omega + k^2)I]\bar{A} = 0 \tag{8}$$

From the work of Ferrers and of Garbieri [8]

$$\det[Z + (\omega + k^2)I] = (\omega + k^2 - \epsilon)^2(\omega + k^2 + 2\epsilon) \tag{9}$$

Thus eq. (8) has a *symmetric* eigenvector

$$\bar{A}_s = \begin{bmatrix} A_s \\ A_s \\ A_s \end{bmatrix}$$

at $\omega + k^2 = -2\epsilon$, and two linearly independent *unsymmetric* eigenvectors at $\omega + k^2 = \epsilon$ which can be written as

$$\bar{A}_{u1} = \begin{bmatrix} A_{u1} \\ A_{u1}\mathrm{e}^{2\pi\mathrm{i}/3} \\ A_{u1}\mathrm{e}^{-2\pi\mathrm{i}/3} \end{bmatrix} \quad \text{and} \quad \bar{A}_{u2} = \begin{bmatrix} A_{u2} \\ A_{u2}\mathrm{e}^{-2\pi\mathrm{i}/3} \\ A_{u2}\mathrm{e}^{2\pi\mathrm{i}/3} \end{bmatrix}$$

A general solution of CLS is then

$$\bar{A} = \begin{bmatrix} A_s \\ A_s \\ A_s \end{bmatrix} \int_{-\infty}^{\infty} F(k)\exp\mathrm{i}[kx - (k^2 + 2\epsilon)t]\,\mathrm{d}k$$

$$+\begin{bmatrix} A_{u1} \\ A_{u1}e^{2\pi i/3} \\ A_{u1}e^{-2\pi i/3} \end{bmatrix} \int_{-\infty}^{\infty} G(k) \exp i[kx-(k^2-\epsilon)t]\,dk$$

$$+\begin{bmatrix} A_{u2} \\ A_{u2}e^{-2\pi i/3} \\ A_{u2}e^{2\pi i/3} \end{bmatrix} \int_{-\infty}^{\infty} H(k) \exp i[kx-(k^2-\epsilon)t]\,dk \quad (10)$$

In the long wavelength limit ($k \to 0$) interaction of the symmetric mode with either of the unsymmetric modes will generate sinusoidal terms of the form $\exp(3\epsilon i t)$. In general, however, initial conditions will require the solution to be distributed over a band of k values which in turn implies nonperiodic behavior in time.

4. Coupled mode solitons on CNLS and CNLSNB

In this section we seek solitary wave (or "soliton") solutions of coupled nonlinear Schrödinger equations. Beginning with CNLS and introducing the transformation

$$\bar{A} = \bar{\phi} e^{i\omega t} \quad (11)$$

where $\bar{\phi} = \text{col}(\phi_1, \phi_2, \phi_3)$ one finds the condition

$$\det[Z + \omega I] = 0 \quad (12)$$

Equation (12) has a single root at $\omega = -2\epsilon$ corresponding to a *symmetric* solitary wave

$$\bar{A}_s = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \phi e^{-2i\epsilon t} \quad (13)$$

where

$$i\phi_t + \phi_{xx} + |\phi|^2\phi = 0 \quad (14)$$

Equation (12) also has a double root at $\omega = \epsilon$ which correspond to two unsymmetric solitary waves

$$\bar{A}_{u1} = \begin{bmatrix} 1 \\ e^{2\pi i/3} \\ e^{-2\pi i/3} \end{bmatrix} \phi e^{i\epsilon t} \quad \text{and} \quad \bar{A}_{u2} = \begin{bmatrix} 1 \\ e^{-2\pi i/3} \\ e^{2\pi i/3} \end{bmatrix} \phi e^{i\epsilon t} \quad (15a, b)$$

where, again, ϕ is a soliton solution of eq. (14).

It is of particular interest to consider mixed solitary waves with symmetric and unsymmetric components for these display pulsations in the magnitudes of the spine amplitudes. For example taking

$$\bar{A} = a\bar{A}_{u1} + \bar{A}_s = \begin{bmatrix} a e^{i\epsilon t} + e^{-2i\epsilon t} \\ a e^{i\epsilon t + 2\pi i/3} + e^{-2i\epsilon t} \\ a e^{i\epsilon t - 2\pi i/3} + e^{-2i\epsilon t} \end{bmatrix} \phi_m \quad (16)$$

leads to the requirements that ϕ_m must satisfy the three pde's:

$$i\phi_{m,t} + \phi_{m,xx} + |\phi_m|^2\phi_m[1 + a^2 + 2a\cos 3\epsilon t] = 0$$

$$i\phi_{m,t} + \phi_{m,xx} + |\phi_m|^2\phi_m[1 + a^2 + 2a\cos(3\epsilon t + 2\pi/3)] = 0$$

$$i\phi_{m,t} + \phi_{m,xx} + |\phi_m|^2\phi_m[1 + a^2 + 2a\cos(3\epsilon t - 2\pi/3)] = 0 \quad (17a, b, c)$$

Thus this mixed mode satisfies CNLS only approximately for $|a| \ll 1$ or $|a| \gg 1$.

If, however, the mixed mode (16) is substituted into CNLSNB, eqs. (17) become

$$i\phi_{m,t} + \phi_{m,xx} + (1 + a^2)|\phi_m|^2\phi_m = 0 \quad (18)$$

so

$$\phi_m = \frac{A_0}{\sqrt{1+a^2}} \text{sech}\left(\frac{A_0(x-st)}{\sqrt{2}}\right) \exp i\left(\frac{s}{2}x + \frac{A_0^2}{2}t\right) \quad (19)$$

A somewhat more compact analysis of CNLSNB proceeds by introducing the transformation

$$\bar{A} = M(t)\bar{\phi} \quad (20)$$

with additional constraints

$$M^T M^* = 3I \quad (21)$$

and

$$iM_t = ZM \quad (22)$$

Under eq. (20) CNLSNB reduces to

$$i\bar{\phi}_t + \bar{\phi}_{xx} + (\bar{\phi}^* \cdot \bar{\phi})\bar{\phi} = 0 \quad (23)$$

Assuming the columns of M to have time dependence as $\exp(i\omega t)$, eq. (22) implies

$$[Z + \omega I]M = 0 \quad (24)$$

which, with eq. (12), leads to

$$M = \begin{bmatrix} 1 & 1 & e^{-3i\epsilon t} \\ e^{2\pi i/3} & e^{-2\pi i/3} & e^{-3i\epsilon t} \\ e^{-2\pi i/3} & e^{2\pi i/3} & e^{-3i\epsilon t} \end{bmatrix} e^{i\epsilon t} \quad (25)$$

Manakov [9] has shown that eq. (23) is completely integrable. Thus the "mixed solitary wave" given by eqs. (16) and (19) [or from eq. (23) by taking $\bar{\phi} = \text{col}(a\phi_m, 0, \phi_m)$] is a true soliton of CNLSNB. The squared amplitudes (i.e., bond energies) of its three components are:

$$|A_1|^2 = \left[\frac{A_0^2}{1+a^2}\text{sech}^2\ \frac{A_0(x-st)}{\sqrt{2}}\right][1 + a^2 + 2a\cos 3\epsilon t]$$

$$|A_2|^2 = \left[\frac{A_0^2}{1+a^2}\text{sech}^2\ \frac{A_0(x-st)}{\sqrt{2}}\right] \times [1 + a^2 + 2a\cos(3\epsilon t + 2\pi/3)]$$

$$|A_3|^2 = \left[\frac{A_0^2}{1+a^2}\text{sech}^2\ \frac{A_0(x-st)}{\sqrt{2}}\right] \times [1 + a^2 + 2a\cos(3\epsilon t - 2\pi/3)] \quad (26a, b, c)$$

Following Gibbons et al. [10] it is straightforward to show that the Hamiltonian associated with CNLSNB is

$$H = \int_{-\infty}^{\infty} \left\{ \sum_{j=1}^{3} |A_{j,x}|^2 - \tfrac{1}{6}\left[\sum_j |A_j|^2\right]^2 + \epsilon(A_1^*A_2 + A_1A_2^* + A_1^*A_3 + A_1A_3^* + A_2^*A_3 + A_2A_3^*) \right\} dx \quad (27)$$

while the "mass"

$$m = \tfrac{1}{2}\int_{-\infty}^{\infty} [|A_1|^2 + |A_2|^2 + |A_3|^2]\,dx \quad (28)$$

Thus the energy of the soliton is

$$H = \tfrac{1}{2}ms^2 - \frac{m^3}{54} + 2m\epsilon\left(\frac{2-a^2}{1+a^2}\right) \tag{29}$$

Physical significance is readily assigned to the terms in eq. (29): the first term is kinetic energy, the second is binding energy, and the third is interspine interaction energy. It is energetically favorable for the mixed mode to add more of the unsymmetric mode by increasing a.

5. Numerical results on the modified Davydov equations

In this section we turn to numerical results obtained from integration of the MD equations. As in [5] the boundary conditions are

$$A_{n\alpha} \text{ and } B_{n\alpha} = 0 \text{ for: } n = 0, -1, -2, -3,$$

$$n = n_{\max+1}, n_{\max+2}, n_{\max+3}, \text{ and all } \tau$$

The initial condition (at $\tau = 0$) is

$$A_{11} = 1 \quad \text{and} \quad A_{12} = 1$$

$$\text{other } A_{n\alpha} = 0$$

$$\text{all } B_{n\alpha} = 0$$

With $n_{\max} = 200$ and $\chi_1 = 0.3 \times 10^{-10}$ newtons (i.e., just below threshold), Figure 3 shows the peak amplitudes on each of the three spines as a function of τ. Figure 4 shows a corresponding results for $\chi_1 = 0.4 \times 10^{-10}$ newtons (just above threshold). A well developed interspine oscillation is seen in Fig. 4 with a period (in computer units) of

$$T_1 = 21.93 \pm 0.806 \tag{30}$$

where the "±" refers to r.m.s. deviations in a series of measurements. The time dependence in Fig. 4 is qualitatively similar to that derived in eq. (26), but from eq. (5) and Table I, $\epsilon = 0.033$ which implies a period $(3\epsilon)^{-1} = 10$. This disagreement is not unexpected considering the approximations made in going from MD through Z and CNLS to CNLSNB.

The speed of the solitary wave under the conditions of Fig. 4 is

$$s = 0.3733 \pm 0.0189. \tag{31}$$

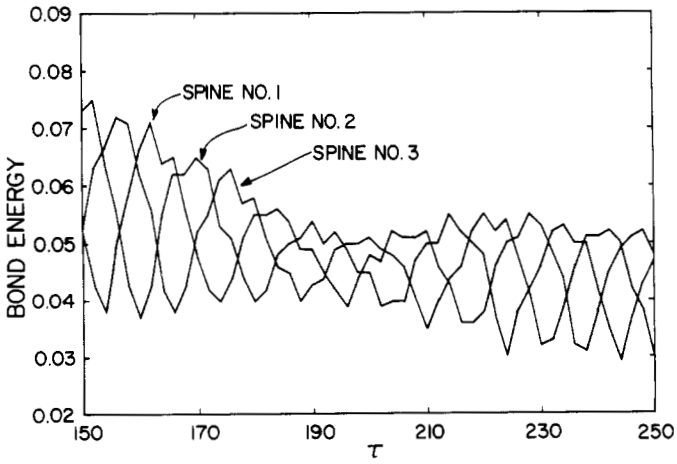

Fig. 3. Peak bond energy on each spine as a function of computer time with the nonlinear parameter $\chi_1 = 0.3 \times 10^{-10}$ newtons which is *below threshold* for soliton formation.

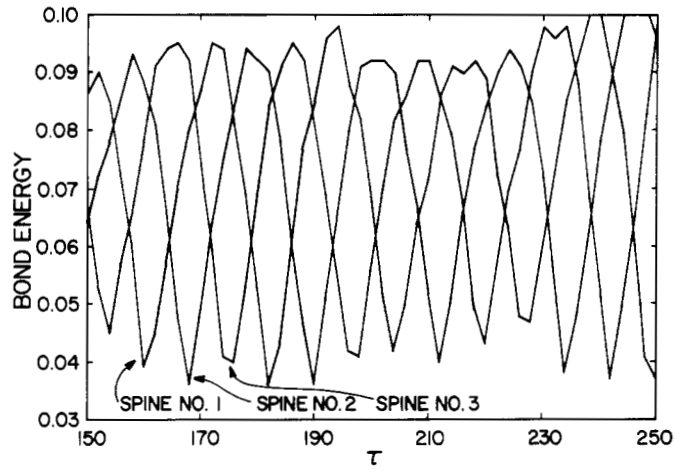

Fig. 4. Same as Fig. 3 but $\chi_1 = 0.4 \times 10^{-10}$ newtons which is *above threshold* for soliton formation.

Assuming the bond energies on each spine to be described by eq. (26), the mixing parameter, a, is

$$a = 0.22 \quad \text{at } \tau = 170$$

$$a = 0.26 \quad \text{at } \tau = 412$$

Thus there is a rather small tendency for the unsymmetric mode component to increase with τ.

As Fig. 3 shows, the situation below threshold is quite different. Although there is some tendency toward an oscillation of period T_1, the bond amplitude variations are much smaller and the frequency is less uniform. Further appreciation of the dynamic differences below and above threshold can be had by comparing the spatial shapes of the waves in Figs. 5 and 6. Not only is the oscillation frequency more variable below threshold, but a smaller fraction of the total bond energy participates in it.

6. Interpretation of laser-Raman spectral measurements as internal vibrations of alpha-helix solitons

The interspine oscillation shown in Fig. 4 has a spectral energy

$$E_1 = \frac{\sqrt{\omega/M}}{cT_1} \text{ cm}^{-1} \tag{32}$$

where numerical values for $\sqrt{\omega/M}$ and T_1 are given in eqs. (3) and (30) respectively, and c is the speed of light. Thus

$$E_1 = 15.35(1 \pm 0.0368)\,\text{cm}^{-1} \tag{33}$$

A second oscillation is generated with a period equal to the time the soliton takes to pass by a unit cell. This is s^{-1} in com-

Table II

Measured (cm^{-1})	Assignments

85	$5E_1$
90	$E_2 - 2E_1$
108	$E_2 - E_1$
123	E_2
152	$E_2 + 2E_1$
182	$E_2 + 3E_1$

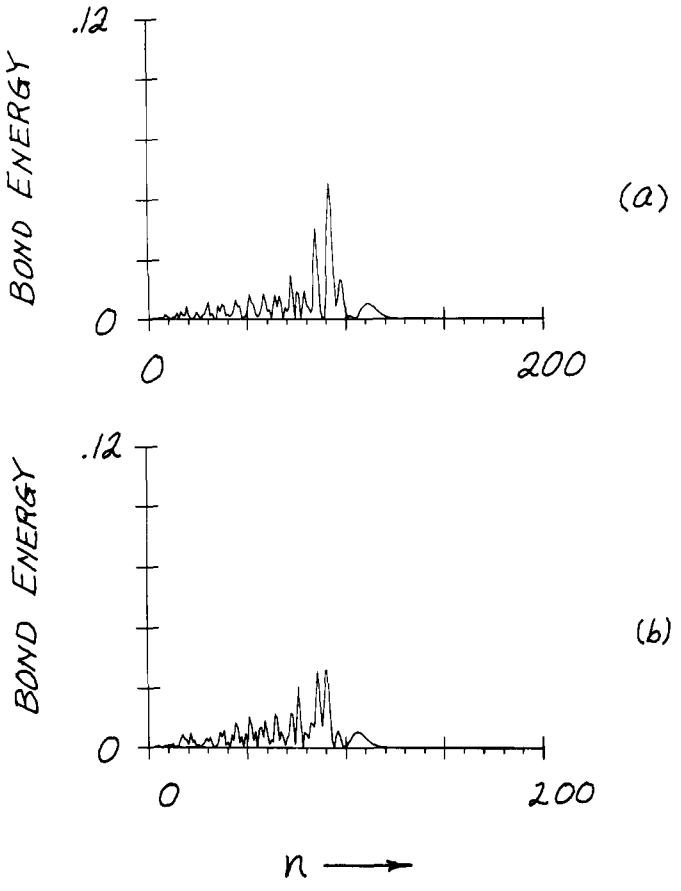

Fig. 5. Spatial wave form on spin No. 2 *below threshold* ($\chi_1 = 0.3 \times 10^{-10}$ newtons). (a) Maximum amplitude at $\tau = 234$. (b) Minimum amplitude at $\tau = 224$.

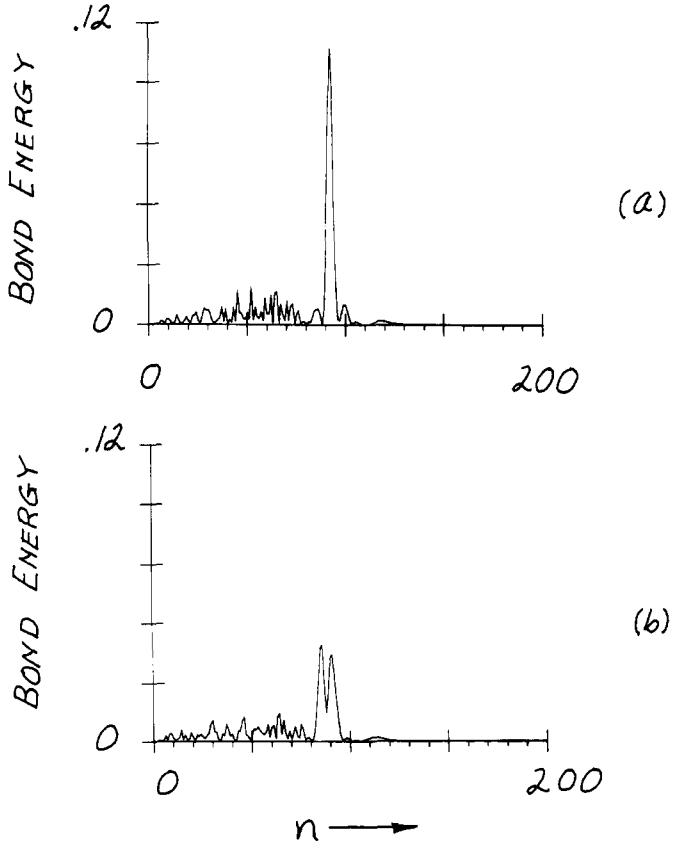

Fig. 6. Spatial waveform on spine No. 2 *above threshold* ($\chi_1 = 0.4 \times 10^{-10}$ newtons). (a) Maximum amplitude at $\tau = 246$. (b) Minimum amplitude at $\tau = 234$.

puter units, where s is given in eq. (31), so the corresponding spectral energy is

$$E_2 = 125.7(1 \pm 0.0506)\,\mathrm{cm}^{-1} \tag{34}$$

In [7] the spectral lines obtained by Webb from metabolically active *E. coli* [6] (see Fig. 2) were tentatively assigned as simple sums and differences of E_1 and E_2 as shown in Table II. With these assignments and the numerical values for E_1 and E_2 given in eqs. (33) and (34), the relation between calculated and measured line energies is plotted in Fig. 7. Broadly speaking, the differences between measurements and calculations can be attributed to errors in the numerical model (MD) and the measurement errors. With the line assignments as in Table II, the best that the numerical model can do is a least squares fit which (on integer values) is at

$$E_1 = 17\,\mathrm{cm}^{-1} \quad \text{and} \quad E_2 = 124\,\mathrm{cm}^{-1} \tag{35}$$

Assuming the three parameters in MD to be such that the fundamental energies are given by eq. (35) rather than eqs. (33) and (34) (a 10% and a 1.3% change respectively), the relation between measured and calculated lines is plotted again in Fig. 8. There are three possible explanations for the differences between measurements and calculations in Fig. 8: (i) The theory presented here is wrong, (ii) The line assignments are incorrect, and (iii) Measurement errors. Only the first line (measured at $45\,\mathrm{cm}^{-1}$) lies significantly more than a spectral bandwidth from agreement. From Fig. 2 it is seen that this line rests high on the background shoulder (of Rayleigh scattering) which may introduce additional errors into the measurement.

Further support for the hypothesis presented here is provided by the data in Fig. 9. This is a histogram of 125 lines obtained from ten experiments done by S. J. Webb and M. E. Stoneham between 1975 and 1979 [11]. With the assignments as indicated, a least squares fit to these data requires

$$E_1 = 16.8\,\mathrm{cm}^{-1} \quad \text{and} \quad E_2 = 126.0\,\mathrm{cm}^{-1} \tag{36}$$

Spectral lines calculated from these frequencies are also indicated on Fig. 9.

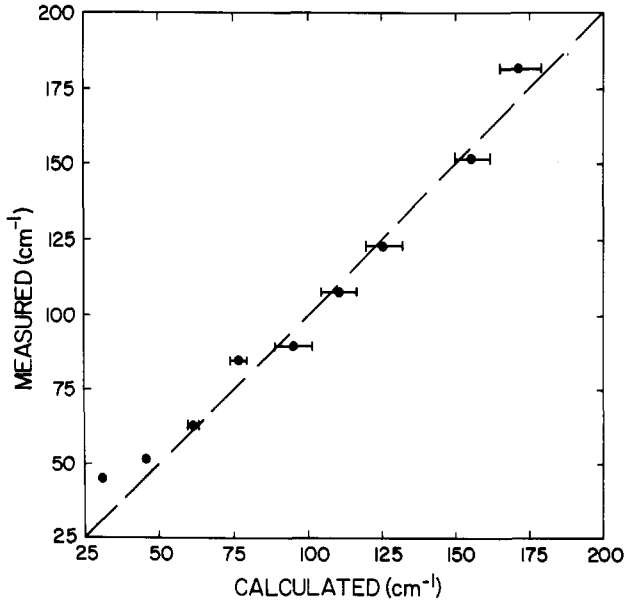

Fig. 7. Comparison laser-Raman lines measured in Fig. 2 with calculations according to the assignments in Table II from E_1 in eq. (33) and E_2 in eq. (34).

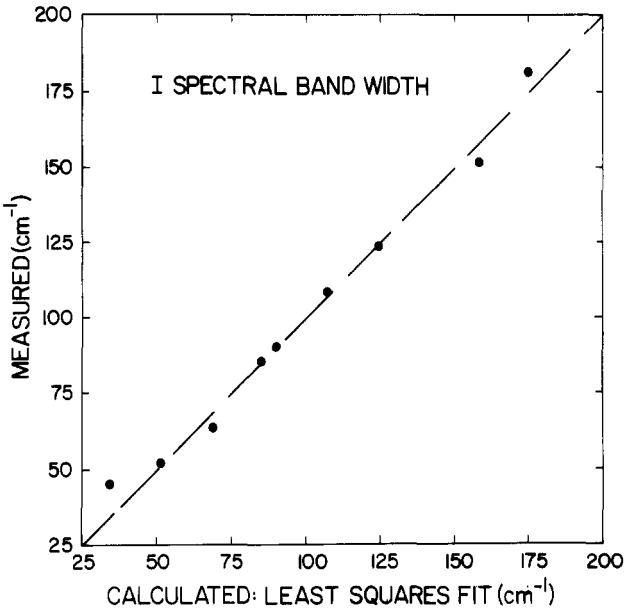

Fig. 8. Same as Fig. 7 but E_1 and E_2 are the "least-squares-fit" given in eq. (35).

7. Concluding discussion

The central question in this paper is to decide whether the laser-Raman spectrum displayed in Fig. 2 can be assigned to internal oscillations of alpha-helix solitons. According to Webb [6] these spectra are characterized by the following facts: (i) At 300 K a Raman spectrum is observed only when the cells are metabolically active, (ii) The intensity ratios of Stokes to anti-Stokes lines indicate that the Raman active states are produced *in vivo* by non-thermal means, and (iii) Spectral lines below 300 cm^{-1} shift to lower wave numbers as the cells progress through their life cycles. Although broad laser-Raman spectra have been observed on the alpha-helix proteins in aqueous solution and in crystalline form [12–14], such an explanation is unlikely for the lines in Fig. 2.

A convenient summary of the foregoing results is provided by Table III.

Since there was no adjustment of parameters in MD prior to the calculations of row (1), the agreement displayed in this table is quite remarkable. There is little difficulty in supposing the MD parameters to be slightly changed to obtain the fundamental energies listed in row (2) or row (3). Since E_2 is related to the frequency at which a soliton interferes with the alpha-helix periodicity, it could be expected to change with the soliton speed under varying metabolic conditions.

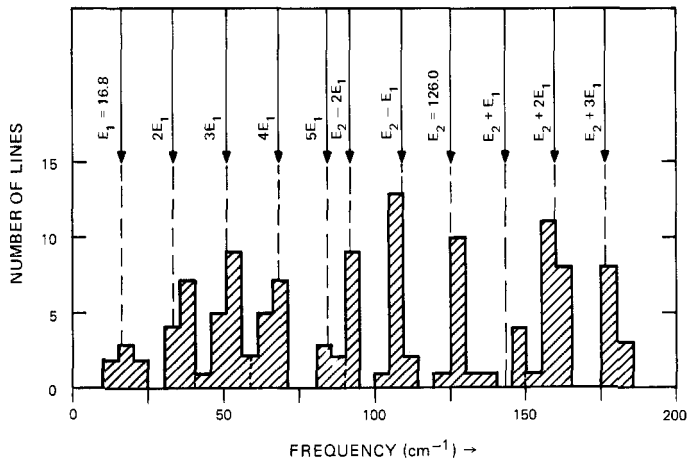

Fig. 9. Histogram of lines from ten laser-Raman experiments on metabolically active *E. coli*. Calculated lines are from the least squares fit values of E_1 and E_2 given in eq. (36). Data from Webb, S. J. (private communication).

Table III

Item	$E_1(cm^{-1})$	$E_2(cm^{-1})$
(1) Calculation of component frequencies from MD.	15.4 ± 3.7%	125.7 ± 5.1%
(2) Least squares fit (over integer values) to lines in Fig. 2.	17	124
(3) Least squares fit to data in Fig. 9.	16.8	126.0

Figure 8 shows the agreement between the lines measured from the spectrum of Fig. 2 and those calculated from the energies listed in the second row of Table III. Figure 9 shows the agreement between data from 125 lines measured during ten separate experiments and those calculated from the energies listed in the third row of Table III. The differences between measured and calculated lines shown in Figs. 8 and 9 must be attributed either to measurement errors or theoretical misconceptions [15]. Noting that [11, 16]: (i) The spectral band width of the measurements is 5 cm^{-1}; (ii) The lines often move several cm^{-1} during the time of measurement (~ 100 minutes); and (iii) Low frequency lines are difficult to resolve because of Rayleigh scattering (see Fig. 2), I conclude that Figs. 8 and 9 show reasonable agreement between measurements and calculations.

The reader may not agree, but certainly the evidence is strong enough to encourage a vigorous search for corroborative experiments.

Appendix

Here we consider a generalization of CNLSNB from three to n interacting channels. Thus

$$i\bar{A}_t + \bar{A}_{xx} + \frac{1}{n}(\bar{A}^* \cdot \bar{A})\bar{A} = Z\bar{A} \tag{A-1}$$

where $\bar{A} = \mathrm{col}\,(A_1, \ldots, A_n)$. If the channels are spaced close together compared with the decay constant for lateral interaction, it is reasonable to assume

$$Z = \begin{bmatrix} 0 & \epsilon & \epsilon & \ldots & \epsilon \\ \epsilon & 0 & \epsilon & \ldots & \epsilon \\ . & . & . & . & . \\ \epsilon & . & . & \epsilon & 0 \end{bmatrix}_{n \times n} \tag{A-2}$$

The transformation (20) with constraints

$$M^T M^* = nI \tag{A-3}$$

and

$$iM_t = ZM \tag{A-4}$$

reduces (A-1) to

$$i\bar{\phi}_t + \bar{\phi}_{xx} + (\bar{\phi}^* \cdot \bar{\phi})\bar{\phi} = 0 \tag{A-5}$$

where $\bar{\phi} = \mathrm{col}\,(\phi_1, \ldots, \phi_n)$.

From (A-4) the time dependence of columns of M is as $\exp(i\omega t)$ where ω satisfies $\det[Z + \omega I] = 0$. The general Ferrers–Garbieri formula for this determinant gives [8]

$$(\omega - \epsilon)^{n-1}[\omega + (n-1)\epsilon] = 0 \tag{A-6}$$

Thus one column of M has time dependence $\exp[i(n-1)\epsilon t]$ and has equal coefficients. The remaining columns have time dependence $\exp(i\epsilon t)$ and are on an orthogonal set in the null space of $Z + \epsilon I$.

Manakov [9] has given Lax operators [17] for eq. (A-5). Thus it is completely integrable using the inverse scattering transform method [18] and it has soliton solutions which, upon transformation by eq. (20), can be interpreted as solutions of eq. (A-1).

If the n channels are not spaced closely with respect to the decay constant for lateral interaction, the non-diagonal elements in Z will not be equal and the Ferrers–Garbieri formula cannot be used to factor $\det[Z + \omega I]$. For four channels arranged at the corners of a square, however,

$$Z = \begin{bmatrix} 0 & \epsilon_1 & \epsilon_1 & \epsilon_2 \\ \epsilon_1 & 0 & \epsilon_2 & \epsilon_1 \\ \epsilon_1 & \epsilon_2 & 0 & \epsilon_1 \\ \epsilon_2 & \epsilon_1 & \epsilon_1 & 0 \end{bmatrix} \tag{A-11}$$

and

$$\det[Z + \omega I] = (\omega - \epsilon_2)^2(\omega + \epsilon_2 - 2\epsilon_1)(\omega + \epsilon_2 + 2\epsilon_1) \tag{A-12}$$

Acknowledgements

It is a pleasure to thank Professor S. J. Webb for correspondence about the accuracy of laser-Raman measurements and for providing the data that is summarized in Fig. 9.

Theory of Long-range Coherence in Biological Systems. I. The Anomalous Behaviour of Human Erythrocytes

R. PAUL

Department of Chemistry, The University of Calgary, Calgary, Alberta, Canada

R. CHATTERJEE, J. A. TUSZYŃSKI AND O. G. FRITZ

Department of Physics, The University of Calgary, Calgary, Alberta, Canada

(*Received* 21 *October* 1982)

In this paper, an explicit expression of the interaction potential has been obtained, based on the Fröhlich model of long-range coherence in biological cells. These theoretical expressions are used to correlate with the experimental data obtained from the light scattering and the Brownian motion for the red blood cells (human erythrocytes). The necessary conditions are derived for the formation of rouleaux in human erythrocytes in the presence of long range interactions. The kinetics of rouleaux formation in terms of the properties of the diffusion coefficient has been investigated. It is concluded that both types of experimental data can be interpreted satisfactorily by this model.

1. Introduction

One of the remarkable features of the biological systems is the existence of an extremely high degree of order. Since any form of order in nature must eventually be the result of forces acting amongst the subsystems, a great deal of speculation regarding the origin of these forces has taken place. In a series of papers Fröhlich (1968*a*,*b*, 1970, 1973, 1977) has investigated the origin of these forces from a quantum mechanical standpoint. A brief description of his model will be given later in this paper. Recently some experimental evidence supporting Fröhlich's model has begun to emerge and we shall focus our attention on two different types of experiments for which the theoretical analysis will be carried out.

These two types of experiments are as follows: (1) Rowlands, Sewchand & Enns (1982) have conducted a series of experiments related to the Brownian motion of the human red blood cells (erythrocytes) and observed an increased rate of rouleaux formation which they correlated with the long range forces of Fröhlich. These forces may be either attractive or

0022-5193/83/180169+17 $03.00/0 © 1983 Academic Press Inc. (London) Ltd.

repulsive depending upon specific experimental conditions. The erythrocytes tend to form clusters referred to as rouleaux. The important feature about this phenomenon of rouleaux formation, is that the rate of process cannot be explained on the basis of pure Brownian motion of the erythrocytes. It is necessary to postulate the existence of long range forces of Fröhlich.

(2) In an entirely different experiment, involving quasi-elastic light scattering from suspensions of erythrocytes, one of us has observed the appearance of anomalous diffusion coefficients in a similar condition to the rouleaux formation. It is not at all surprising that the process of rouleaux formation is itself diffusion controlled and may be the consequence of anomalous diffusion. The experimental details of the light scattering experiments will be published elsewhere.

For the purpose of the theoretical investigations developed hereafter, we will adopt the following conjectures: (a) there is evidence of the unusual behaviour of biological systems for two types of experiments; (b) both experimental observations can be explained on the basis of a long range force of Fröhlich operating between the erythrocytes.

The "specific conditions" required for either rouleaux formation or anomalous diffusion are the following: (a) a constant supply of energy is needed which can be provided from the metabolic energy of the cell; (b) the existence of a transmembrance potential is required to polarize the molecules of the system.

If either of these two conditions is not satisfied, then the usual behaviour of the erythrocytes vanishes. Consequently, the interparticle potential must be sensitive to the two factors mentioned above. The details of the theoretical investigations are as follows.

2. Theory

It is convenient to consider the theoretical aspects of this problem in three stages: (1) the formulation of the mathematical form of the long range potential; (2) the development of a theory that suitably incorporates the potential into the kinetics of rouleaux formation; and (3) the inclusion of a long range potential into the formula for the diffusion coefficient of the erythrocytes. This will provide important information about the anomalous diffusion properties.

We now subsequently discuss the three stages outlined above:

THE LONG RANGE POTENTIAL

Fröhlich (1972) showed that the coupled frequency $\omega_{\pm}$ of two giant dipolar molecules separated by a distance r and possessing frequencies ω_1

and ω_2 is given by

$$\omega_{\pm}^2 = \tfrac{1}{2}(\omega_1^2 + \omega_2^2) \pm \sqrt{\tfrac{1}{4}(\omega_1^2 - \omega_2^2) + \frac{\beta^4}{\varepsilon_{\pm}'^2}} \tag{1}$$

where

$$\beta^2 = \frac{\gamma^2 e^2 (Z_1 Z_2)^{1/2}}{Mr^3} \tag{2}$$

and γ is a positive quantity of the order of unity which depends upon various angles, e denotes the electronic charge, M is the mass, Z_1 and Z_2 are the numbers of elastically bound particles in the two molecules and $\varepsilon_{\pm}'$ represents the real part of the frequency dependent dielectric constant determined at $\omega = \omega_+$ and $\omega = \omega_-$, respectively, that is:

$$\varepsilon_{\pm}' = \varepsilon'(\omega_{\pm}). \tag{3}$$

If the two dipolar molecules are identical, then under conditions of frequency resonance ($\omega_1 = \omega_2$), an interaction potential $U(r)$ exists between them expressed by

$$U(r) = \frac{\hbar}{4\bar{\omega}} \frac{e^2 Z r}{M} \left[\frac{1}{\varepsilon'(\omega_+)} - \frac{1}{\varepsilon'(\omega_-)} \right] \frac{1}{r^3} \tag{4}$$

where $\hbar$ is Planck's constant, $Z = Z_1 = Z_2$, $\bar{\omega} = \omega_1 = \omega_2$ reflecting the identical nature of the two molecules. If $\varepsilon'(\omega_+)$ turns out to equal $\varepsilon'(\omega_-)$, then the interaction potential $U(r)$ of (4) vanishes and equation (1) is reduced to a London–Van der Waals type with a much shorter range since the potential is now proportional to r^{-6}. It, therefore, follows that the long range Fröhlich potential is dependent upon the frequency of the coupled oscillators through the real part of the dielectric constant. Since the phenomena of rouleaux formation and anomalous diffusion are manifestations of the potential $U(r)$, it is clear that the quantity $\varepsilon'(\omega)$ plays a cardinal role here. In the second paper of this series (Paul, Chatterjee & Tuszyński, 1983) we have presented a detailed derivation of $\varepsilon'(\omega)$. Here we will simply apply the final equation for it which is:

$$\varepsilon'(\omega) = 1 + \frac{4\pi^2}{VkT} \sum_{5,6} \mu_{5,6}^2 (n_6 - n_5) \frac{(a_{5,6}^2 + b_{5,6}^2 - a_{5,6}\omega)}{(\omega - a_{5,6})^2 + b_{5,6}^2}. \tag{5}$$

The summation indices are expressed numerically, thus 5 and 6 should be regarded as indices not numbers., V is the volume of the suspension of erythrocytes and T is the absolute temperature. Also:

$$\mu_{5,6} = |\langle 5|\boldsymbol{\mu}|6\rangle| \tag{6}$$

where $\boldsymbol{\mu}$ is a dipole moment operator and

$$b_{5,6}^2 = \frac{|\chi|^4}{\pi^2 \hbar^4 (n_6 - n_5)^2} \Gamma_{5,6}^2(\hbar^{-1}\omega_{5,6}) \tag{7}$$

here χ is a phonon-heat bath coupling constant, $\Gamma_{5,6}$ the line width determined under the resonance conditions and n is the occupation number of the phonon state i. Finally,

$$a_{5,6} = \hbar^{-1}\omega_{5,6} \tag{8}$$

where $\omega_{5,6}$ is the difference in energy between the excited (5) and ground (6) states or $\omega_{5,6} = \omega_5 - \omega_6$. The details will be given in our second paper.

With the dielectric constant given by equation (5) and the frequencies $\omega_\pm$ by equation (1), the Fröhlich potential can now be fully defined.

So far we have obtained the form of the interaction between two giant dipoles but the relationship with the etythrocytes has not been discussed yet. A typical erythrocyte is an extremely complex object. Most important, however, is the existence of a very large electrical field across the cell membrane. This field produces intense polarization of the cell membrane resulting in the generation of the giant dipoles as envisaged in Fröhlich's theory. Furthermore, the cell membranes are not stationary objects but display various modes of vibrations which provide us with the features required from a long-range potential. In our model, we assume that the giant dipoles are located at the centre of mass of each erythrocyte. This is, of course, an assumption since the dipoles are actually located on the membranes with different orientations. The exact orientations and numbers of the dipoles are not available to us at the present time forcing us to adopt the simplified model and allow experiment to decide the validity of the assumptions. It is worth pointing out, perhaps, that since our interest lies with the long-range forces between the erythrocytes, the exact cellular details may not be of any significance.

Having obtained the analytical form of the potential acting between the erythrocytes, let us now turn our attention to the nature (attractive or repulsive) of the forces. The frequency ω appearing in equation (5) is a positive quantity and from the discussion given in section 6 of our subsequent paper we see that $\omega_5 > \omega_6$ or that

$$\omega_5 - \omega_6 > 0 \tag{9}$$

which ensures the positive nature of $a_{5,6}$ defined by equation (8). The quantities $b_{5,6}^2$ and $\mu_{5,6}^2$ are positive definite by virtue of their definitions.

From equation (1) the frequency ω_- is lower than ω_+, i.e. $\omega_+ > \omega_-$. Let us define a gap Δ as

$$\omega_+ = \omega_- + \Delta. \tag{10}$$

In order to compute the sign of the Fröhlich potential, it is necessary to calculate the relative magnitudes of the dielectric constants ε'_+ and ε'_-. These two quantities, when substituted into (4), determine the sign of $U(r)$. To evaluate the difference $\varepsilon'_+ - \varepsilon'_-$ we employ equation (5) and get:

$$\varepsilon'(\omega_+) - \varepsilon'(\omega_-) = -\frac{4\pi^2}{VkT} \sum_{5,6} \mu_{5,6}^2 \left[\left(d_{5,6} + \frac{a_{5,6}}{B_{5,6} + C_{5,6}} \right) \right] (n_6 - n_5) \tag{11}$$

where we have adopted the following notation

$$B_{5,6} = (\omega_- - a_{5,6})^2 + b_{5,6}^2 > 0. \tag{12}$$

The above is a positive quantity by virtue of the positive definiteness of the addands. We also used:

$$C_{5,6} = \Delta^2 + 2(\omega_- - a_{5,6})\Delta. \tag{13}$$

Unfortunately, no *a priori* statement about the sign of this term can be made. In a special case of a large enough gap Δ such that:

$$\Delta^2 > 2|(\omega_- - a_{5,6})|\Delta \tag{14}$$

the $C_{5,6}$ is positive:

$$C_{5,6} > 0. \tag{15}$$

We assume that the prevalent conditions allow the inequality (14) to hold thus assuring inequality (15).

Let us define

$$A_{5,6} \equiv a_{5,6}^2 + b_{5,6}^2 - a_{5,6}\omega_-. \tag{16}$$

From this definition and the inequality (15) it follows that

$$\frac{A_{5,6}}{B_{5,6} + C_{5,6}} < \frac{A_{5,6}}{B_{5,6}}. \tag{17}$$

A positive quantity $d_{5,6}$ has been introduced as

$$d_{5,6} = \frac{A_{5,6}}{B_{5,6}} - \frac{A_{5,6}}{B_{5,6} + C_{5,6}} > 0. \tag{18}$$

The right hand side of equation (11) now appears as a sum of terms, each of which contains two factors. One of these factors appearing in the

bracket is positive hence the overall sign is determined by the difference in population numbers $(n_6 - n_5)$. Recalling the fact that the state 5 corresponds to higher energy than that of the state 6 (equation (9)) we deduce that two situations are possible.

(a) If the population inversion occurs $(n_5 > n_6)$, then

$$\frac{1}{\varepsilon'_+} - \frac{1}{\varepsilon'} < 0 \tag{19}$$

and the overall sign of $U(r)$ becomes negative, and the erythrocytes experience an attractive force. An attractive force operating amongst the erythrocytes is, therefore, a signal of population inversion and holds under non-equilibrium conditions.

(b) Under equilibrium conditions $(n_5 < n_6)$ the reverse of inequality (19) must hold true:

$$\frac{1}{\varepsilon'_+} - \frac{1}{\varepsilon'} > 0. \tag{20}$$

This inequality leads to a repulsive force amongst the erythrocytes.

In the above discussion we have shown that the population inversion is of great importance in determining the nature of $U(r)$. We must, now, seek for the possible underlying mechanism causing such an inversion. It is not hard to see that metabolism must play an essential role in supplying the required energy and we are thereby led to an understanding of the prerequisite (a) mentioned in Section 1. Moreover, the reasons for the prerequisite (b) can also be found from the equations we have already developed. If, in fact, the transmembrane field is switched off, then the force causing polarizations and the appearance of the dipole moment μ has been abolished and the Fröhlich potential vanishes.

Having gathered all necessary information about the potential $U(r)$ we proceed to discuss the next stage, i.e. the kinetics of the rouleaux formation.

THE KINETICS OF ROULEAUX FORMATION

In the absence of an interaction potential the process of rouleaux formation is solely controlled by the random Brownian motion of the erythrocytes. From a mathematical standpoint this problem can be formulated in much the same way as the kinetics of diffusion controlled chemical reactions (Rowlands *et al.*, 1982). In this approach one solves the diffusion equation and calculates the flux to a spherical surface. The boundary conditions required here correspond to a zero density of erythrocytes within the spherical surface and a bulk concentration at large distances. Such an

approach has been applied to the phenomenon of colloidal coagulation by Smoluchowski and well-documented literature on the subject is available (see for example Chandrasekhar, 1943). In the event that long range forces are operative between the erythrocytes, however, it is essential to go beyond the diffusion equation. An adequate treatment for diffusion controlled chemical reactions involving interacting particles has been developed by Debye (1942) and is well suited to the present problem. While it is not our intention to present all the details it seems worthwhile to introduce the basic mathematical steps as they may contribute to a better understanding of the physical principles involved. The analysis is most conveniently introduced in the following steps.

(a) Consider two volume elements dV_A and dV_B located by the vectors $\mathbf{r}_A$ and $\mathbf{r}_B$, respectively, as shown in Fig. 1.

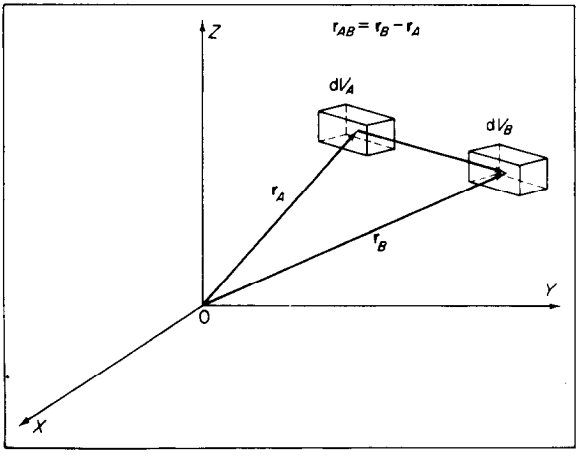

FIG. 1. Volume elements and coordinate systems.

(b) Let us introduce the following definitions. n_{AB} is the probability of finding an erythrocyte in dV_B given that dV_A already contains one erythrocyte. $N_A(\mathbf{r}_A)$ is the probability density of finding an erythrocyte in the vicinity of $\mathbf{r}_A$. N_{AB} is the joint probability of finding an erythrocyte in dV_A and dV_B.

By interchanging the labels A and B on n_{AB} and N_{AB} and by considering $N_B(\mathbf{r}_B)$ instead of $N_A(\mathbf{r}_A)$, one can interchange the physical role played by the two volume elements dV_A and dV_B.

From the above definitions it follows by straightforward physical arguments that the following equations must be true:

$$N_{AB} = N_A n_{AB} \tag{21}$$

$$N_{BA} = N_B n_{BA} \tag{22}$$

$$N_{AB} = N_{BA}. \tag{23}$$

(c) In completely general terms the functions introduced above must have the following spatial dependence:

$$N_{AB} = N_{AB}(\mathbf{r}_A, \mathbf{r}_B, \mathbf{r}_{AB}) \tag{24}$$

$$N_{BA} = N_{BA}(\mathbf{r}_B, \mathbf{r}_A, \mathbf{r}_{BA}) \tag{25}$$

and in the limit of infinite separation between the two volume elements:

$$\lim_{|\mathbf{r}_{AB}|\to\infty} N_{AB}(\mathbf{r}_A, \mathbf{r}_B, \mathbf{r}_{AB}) = N_A(\mathbf{r}_A) N_B(\mathbf{r}_B). \tag{26}$$

With no external gradients or fields present the probabilities defined above cannot depend upon the individual vectors $\mathbf{r}_A$ and $\mathbf{r}_B$ but upon the relative vector $\mathbf{r}_{AB}$ only:

$$N_{AB} = N_{AB}(\mathbf{r}_{AB}). \tag{27}$$

Consequently,

$$\lim_{|\mathbf{r}_{AB}|\to\infty} N_{AB}(\mathbf{r}_{AB}) = N_A N_B. \tag{28}$$

Clearly the erythrocytes are not stationary objects, hence in addition to the spatial dependence, each of the functions above must display time dependence as well.

(d) The joint probability function N_{AB} will, in general, satisfy a continuity equation:

$$-\frac{\partial}{\partial t} N_{AB} = \nabla_A \cdot \mathbf{J}_A + \nabla_B \cdot \mathbf{J}_B \tag{29}$$

where ∇_i, are the gradient operators with respect to $\mathbf{r}_i$ and $\mathbf{r}_i$ are fluxes defined as

$$\mathbf{J}_i \equiv \mathbf{v}_i N_{AB} \tag{30}$$

$$\mathbf{v}_i \equiv \frac{\mathrm{d}\mathbf{r}_i}{\mathrm{d}t}. \tag{31}$$

(e) The fluxes must be selected in keeping with the physical requirements of the problem. In the present case the following two constituent fluxes are employed. First, a diffusional flux governed by Fick's law and involving

a diffusion coefficient D_i, and

$$\mathbf{J}_i^{\text{diff}} = -D_i \nabla_i N_{AB}. \tag{32}$$

Second, a flux caused by a force $\mathbf{K}_{AB}$ acting upon the erythrocyte located at $\mathbf{r}_A$, given that a second erythrocyte is located at $\mathbf{r}_B$. This flux is defined by the following set of equations:

$$\mathbf{J}_A^k = \mathbf{v}_A^k N_{AB} \tag{33}$$

$$\mathbf{v}_A^k = \frac{1}{\gamma_A} \mathbf{K}_{AB}. \tag{34}$$

Here, γ_A is the frictional constant of the erythrocyte at $\mathbf{N}_A$.

Assuming that the forces $\mathbf{K}_{AB}$ and $\mathbf{K}_{BA}$ are due to a potential function U, such that

$$\mathbf{K}_{AB} = -\nabla_A U \tag{35}$$

$$\mathbf{K}_{BA} = -\nabla_B U \tag{36}$$

and inserting the total flux $(\mathbf{J}_i = \mathbf{J}_i^{\text{diff}} + \mathbf{J}_i^k)$ along with the appropriate definitions, from equations (32)–(36) into equation (29), we obtain a modified diffusion equation:

$$\frac{\partial}{\partial t} N_{AB} = D_A \nabla^2 N_{AB} + \frac{1}{\gamma_A} N_{AB} \nabla_A^2 U + \frac{1}{\gamma_A} (\nabla_A U)(\nabla_A N_{AB})$$

$$+ D_B \nabla^2 N_{AB} + \frac{1}{\gamma_B} N_{AB} \nabla_B^2 U + \frac{1}{\gamma_B} (\nabla_B U)(\nabla_B N_{AB}). \tag{37}$$

(f) In order to solve this equation with the aim of applying it to the present problem we first define a set of variables $\mathbf{R}$ and $\mathbf{r}$ as follows:

$$\mathbf{R} \equiv \frac{D_A \mathbf{r}_A + D_B \mathbf{r}_B}{D_A + D_B} \tag{38}$$

$$\mathbf{r} = \mathbf{r}_A - \mathbf{r}_B. \tag{39}$$

Then, we make the following assumptions that U and N_{AB} do not depend upon $\mathbf{R}$ and that spherical symmetry prevails.

Under these conditions a very simple equation results from equation (36).

$$-\frac{\partial N_{AB}}{\partial t} = \nabla_r \cdot \mathbf{J}_{AB}^r \tag{40}$$

with

$$J_{AB}^r = -(D_A + D_B) \frac{\partial}{\partial r} N_{AB} - \left(\frac{1}{\gamma_A} + \frac{1}{\gamma_B}\right) \frac{\partial U}{\partial r} N_{AB}. \tag{41}$$

The J'_{AB} represents the flux of erythrocytes along the vector $\mathbf{r}_{AB}$ where the origin of this vector has been placed at the origin of the coordinate system. By definition the flux is the current (I) per unit area. Thus, if the total surface area through which the erythrocytes move towards the origin is $4\pi r^2$, then

$$J'_{AB} = \frac{I}{4\pi r^2}. \tag{42}$$

By equating the right hand sides of equation (41) and (42) we obtain

$$\frac{dN_{AB}}{dr} + \left(\frac{1}{D_A + D_B}\right)\left(\frac{1}{\gamma_A} + \frac{1}{\gamma_B}\right)\frac{dU}{dr} N_{AB} = \frac{-I}{4\pi(D_A + D_B)r^2}. \tag{43}$$

If we assume that the erythrocytes "react" upon arrival at a critical spherical surface of radius r_0, then equation (43) can be integrated to yield

$$N_{AB}(r) = -\frac{I}{4\pi(D_A + D_B)} \exp\left[-\left(\frac{1}{D_A + D_B}\right)\left(\frac{1}{\gamma_A} + \frac{1}{\gamma_B}\right)U(r)\right]$$
$$\times \int_{r_0}^{r} dr' \frac{e(1/(D_A + D_B))}{r'^2}\left(\frac{1}{\gamma_A} + \frac{1}{\gamma_B}\right)U(r'). \tag{44}$$

(g) From equation (44) we require the current I. Not knowing the analytical form of $N_{AB}(r)$ we cannot do this computation in quite general terms. When $r \to \infty$ then equation (28) is true and if U vanishes asymptotically then we obtain:

$$N_A N_B = \frac{-I}{4\pi(D_A + D_B)} \cdot \frac{1}{r_0^*} \tag{45}$$

where

$$\frac{1}{r_0^*} \equiv \int_{r_0}^{\infty} dr \frac{\exp\left[(1/(D_A + D_B))(1/\gamma_A + 1/\gamma_B)U(r)\right]}{r^2}. \tag{46}$$

Solving equation (45) for I we have

$$-I = 4\pi(D_A + D_B) r_0^* N_A N_B \tag{47}$$

which is just the rate of "reaction" (rouleaux formation).

(h) Assuming that the erythrocytes A and B are identical we obtain the rate of erythrocyte depletion in the form of a simple second order kinetic equation

$$-\frac{dN}{dt} = 8\pi D r_0^* N^2 \tag{48}$$

which upon integration becomes

$$\frac{1}{N(t)} - \frac{1}{N(0)} = \frac{4kT}{3\eta}\left(\frac{r_0^*}{r}\right)t. \tag{49}$$

Here the Einstein definition of the diffusion coefficient along with the Stoke's expression for the friction coefficient have been adopted:

$$D = \frac{kT}{\gamma} \tag{50}$$

$$\gamma = 6\pi\eta r_0. \tag{51}$$

In the experimental work carried out by Rowlands *et al.* (1982), the kinetics of rouleaux formation has been studied by introducing an *ad hoc* parameter Z in the rate constant of a pure diffusion controlled process. This parameter is intended to account for the existence of an interparticle potential but the dependence of A upon the potential or even the form of the potential itself has not been explicitly stated. The expression used by these workers (Rowlands *et al.*, 1982) has the following form:

$$\frac{1}{N(t)} - \frac{1}{N(0)} = \frac{2kT}{3\eta}\Xi t \tag{52}$$

where $\Xi = Z/r_0$. Comparing equation (52) with equation (49) we notice that our parameter r_0^* plays precisely the same role as Z. The advantage, however, of using the generalized model employed by us lies in the fact that r_0^* is explicitly given in terms of Fröhlich's potential and the properties of this potential in the biological context have already been discussed.

(i) In order to link our theory with the experiments on rouleaux formation we must evaluate the integral in equation (46) which can be written as:

$$L(\alpha, r_0) = \int_{r_0}^{\infty} \mathrm{d}r \frac{e^{-\alpha/r^3}}{r^2} \tag{53}$$

where

$$\alpha = \frac{1}{(D_A + D_B)}\left(\frac{1}{\gamma_A} + \frac{1}{\gamma_B}\right)A \tag{54}$$

and

$$U(r) = -\frac{A}{r^3}. \tag{55}$$

Since this integral cannot be solved analytically, we have to resort to the numerical integration instead. We treat α (or alternatively A) as an

unknown parameter we can vary and we calculate the corresponding values of the constant Ξ according to:

$$\Xi = \frac{1}{r_0 L(\alpha, r_0)} \tag{56}$$

We have used $r_0 \cong 4$ μm as indicated by Rowlands *et al.* (1982). The results of our sample calculations for selected attractive potentials are presented in Table 1.

TABLE 1

Selected values of the parameter Ξ and the corresponding coefficients α and A.

α (10^{-9} cm^3)	A (10^{-24} ergs cm^3)	Ξ
$0{\cdot}166 \times 10^{-3}$	0·007	1·11
0·011	0·444	1·16
0·021	0·848	1·21
0·029	1·172	1·25
0·422	17·049	2·66
0·521	21·048	2·91
0·770	31·108	3·45
0·914	36·926	3·73

It is not difficult to see that the integral of equation (53) gives the values of Ξ which are always less than 1 if the Fröhlich potential is repulsive ($A < 0$) and that Ξ tends to 1 as A approaches 0. On the other hand, it is the attractive potential ($A > 0$) that provides $\Xi \geq 1$. The Ξ increases with A starting at $\Xi = 1$ for $A = 0$. In their experiments, Rowlands *et al.* (1982) used a particle concentration of 5×10^{-3} v/v and the value of Ξ they arrived at was 3·0. As seen from Table 1, $\Xi = 3.0$ corresponds to $A \cong 23 \times 10^{-24}$ erg cm^3 or $\alpha \cong 0{\cdot}57 \times 10^{-9}$ cm^3.

From our analysis employing a generalized diffusion equation and the Fröhlich potential we are able to explain the phenomenon of rouleaux formation and the dependence of the phenomenon upon the cell metabolism. Furthermore, by carrying out a numerical integration and using Rowlands' experiments data, the value of the constant in the Fröhlich potential has been obtained. Finally, the reduction of the rate of rouleaux formation to that expected under Brownian motion only by a lowering of the pH as observed by Rowlands *et al.* (1982) is explained by the destruction of the transmembrane field and the attending loss of polarization.

THE PHENOMENON OF ANOMALOUS DIFFUSION

Before we describe the experiments showing anomalous diffusion, some of the qualitative aspects of the diffusion coefficient in the presence of long range potentials must be introduced.

Pusey & Tough (1982) showed, that to a first order approximation, a non-stochastic interparticle potential $U(r)$ yields the following value of the mean square displacement (with the angular bracket denoting the average value):

$$\langle \Delta r^2(t) \rangle = 2D_0 t - \frac{D_0 t^2}{\gamma} \left\langle \frac{\partial^2 U(r)}{\partial r^2} \right\rangle \tag{56}$$

where D_0 is the diffusion coefficient of a Brownian particle in the absence of the potential. It is now possible to introduce a modified diffusion coefficient as follows

$$D = D_0 \left[1 - \frac{1}{2} \frac{t}{\gamma} \left\langle \frac{\partial^2 U(r)}{\partial r^2} \right\rangle \right]. \tag{57}$$

In applying this formula it is necessary to obtain the dependence of the potential $U(r)$ (in our case the Fröhlich potential) upon the particle density ρ. To achieve this objective let us examine equation (5). It is not hard to see that the value of summations must depend upon the total number of phonons N and therefore we write

$$\sum_{5,6} \mu_{5,6}^2 (n_6 - n_5) \frac{(a_{5,6}^2 + b_{5,6}^2 - a_{5,6}\omega)}{(\omega - a_{5,6})^2 + b_{5,6}^2} \cong NL \tag{58}$$

where L contains all the remaining quantities apart from N. With this approximation:

$$\varepsilon'(\omega) \cong 1 + \frac{4\pi^2}{kT} L\rho. \tag{59}$$

Consequently, the constant A in equation (55) to the first order approximation in the series expansion assumes the form

$$A = \frac{B}{\rho} + \ldots \tag{60}$$

where B is a parameter containing a collection of constants. Thus, the modified diffusion coefficient becomes

$$D = D_0 \left[1 + \frac{6t}{\gamma} \left\langle \frac{B}{\rho r^5} \right\rangle \right]. \tag{61}$$

It is now clear that the attractive potential increases the value of D as compared to D_0 and *vice versa*.

In order to extract the density dependence of D we apply the first order of the virial expansion, i.e.:

$$<r^n> \cong \rho^{-n/3} \tag{62}$$

and arrive at

$$\left\langle \frac{B}{\rho r^5} \right\rangle \cong B\rho^{2/3}. \tag{63}$$

We conclude that in keeping with our expectations, the coefficient D increases with the density ρ. This, in fact will account for the numerical differences between the Rowlands' results and the light scattering results.

To measure the diffusion coefficient of erythrocytes suspended in various solutions, the method of quasi-elastic light scattering has been employed. The 488 mm line of an Ar ion laser has been used and the scattered light has been detected through a pair of collimating pinholes by a photomultiplier. Then, the autocorrelation function plotted against time has given the diffusion coefficient as a slope.

The solution used is a phosphate buffered saline (PBS) at various pH to which human serum albumin (HSA) has been added. The additional macromolecules are polyvinylpyrrolidone (PVP) at several molecular weights. The PVP at the molecular weight of 360 000 causes an abnormally high diffusion coefficient when the blood substance is metabolically active and a transmembrane field is present. These are the conditions under which an increased rate of rouleaux formation was also observed by Rowlands *et al.* (1981). The only major difference between the two experiments is the particle concentration. In the light scattering experiments the concentration was $1{\cdot}8 \times 10^{-4}$ v/v, that is almost 28 times lower than that in Rowlands' experiments. Rowlands *et al.* (1981) obtained $\Xi = 3{\cdot}0$ and in a comparable case, our result was:

$$D/D_0 = 1{\cdot}56. \tag{64}$$

Table 2 shows all the results of measurements of the diffusion coefficient (in 10^{-10} cm^2/sec) in various situations.

TABLE 2

The values of diffusion coefficient D in 10^{-10} cm^2/sec *for various solutions*

Contents	PBS		PBS + PVP		
State	pH 7·4	pH 6·3	pH 7·4	pH 6·3	pH 7·4†
Metabolically active	15·9	16·5	23·5	19·5	21·4
Metabolically depleted	15·4	14·8	17·5	19·0	18·1
Metabolically repleted	—	16·2	22·2	19·3	20·6

† Restoration of the pH of the suspension at 7·4 after a measurement had been taken at pH = 6·3.

In spite of the seeming discrepancy between the results of the measurements in two different types of experiments (Rowlands *et al.* (1981) $\Xi = 3{\cdot}0$, light scattering $D/D_0 = 1{\cdot}56$), these numbers are in good agreement when the density corrections are made. Another correction we have to make is the dimensionality factor. Rowlands *et al.*'s experiments (1981, 1982) treated the observed solution as a two-dimensional fluid whereas the light scattering method accounts for all three dimensions. Therefore, the diffusion constant used by Rowlands after Swift & Friedlander (1964) has to be multiplied by a factor of two:

$$K' = \frac{4\pi kT}{3\eta}\Xi. \tag{65}$$

To compare the light scattering diffusion constant with the corresponding result of Rowlands (1981) we therefore require that:

$$2 \cdot \Xi - 1 = \frac{D}{D_0} - 1. \tag{66}$$

However, when the density variation is accounted for we expect that:

$$\frac{2\Xi - 1}{D/D_0 - 1} = \left(\frac{\rho_R}{\rho_D}\right)^{2/3} \tag{67}$$

where ρ_R denotes the density in Rowlands' experiment (1981) and ρ_D is the density in the diffusion experiment. Substituting the relevant numbers we obtain a remarkable agreement as the left hand side produces 8·9 and the right hand side gives 9·2 which indicates the compatibility of the two methods.

3. Conclusions

In this paper we have discussed and extended some important aspects of the Fröhlich theory of the long range coherence in biological systems. We have adopted the assumptions of the Fröhlich model as our basis and using our derivations supplemented the missing expressions for the dielectric constants. The Fröhlich long range potential has, therefore, been explicitly defined mathematically.

We have discussed the necessary conditions for this potential to become attractive. All relevant algebraic expressions for the dielectric constants, frequencies and coupling coefficients have been given. We have found that the population inversion of the cell's energy levels is possible if only the energy supply is maintained above a certain threshold level and if the phonon-heat bath coupling constant is large enough.

We have given a brief review of the diffusion process for particles with appreciable mutual interactions. We have stated the formula for the rate constant in such processes. Combining this result with the analytical expression for the Fröhlich potential we have obtained information about the diffusion constant in rouleaux formation. Our numerical estimates of the rate constant for the rouleaux formation provided us with the values of the Fröhlich potential parameter and a threshold condition for the appearance of an increased rate of rouleaux formation.

We have carried out an analysis of the density dependence of our diffusion constant and concluded that to a first order approximation, D is proportional to $\rho^{2/3}$.

We have reported some experimental work done by one of us on the diffusion coefficient of human erythrocytes with the use of quasi-elastic light scattering technique. The experimental findings reveal a marked difference in the diffusion coefficient between the metabolically active and metabolically depleted cells. The process of metabolic depletion appears to be reversible. The presence of a transmembrane potential has proven to be another crucial factor in the cell behaviour which agrees with the theoretical predictions.

Finally, we have applied the theoretically derived expressions to interpret both types of experiments. We have compared the light scattering results with the corresponding results reported by Rowlands *et al.* (1982) and attempted to explain a seemingly paradoxical difference in the values of diffusion coefficient. When the differences in densities of the solutions and the dimensionality are taken into account, both results agree to within an astonishing 5%.

We conclude that the two experimental results can be interpreted by the same theoretical model. Furthermore, the proposed theory seems to provide a satisfactory explanation of the process of rouleaux formation in both cases.

We hope that applications of our model may well exceed the scope we have touched upon in this work.

Transitions in microtubule C-termini conformations as a possible dendritic signaling phenomenon

Received: 3 March 2005 / Revised: 12 May 2005 / Accepted: 23 May 2005 / Published online: 24 September 2005
© EBSA 2005

Abstract We model the dynamical states of the C-termini of tubulin dimers that comprise neuronal microtubules. We use molecular dynamics and other computational tools to explore the time-dependent behavior of conformational states of a C-terminus of tubulin within a microtubule and assume that each C-terminus interacts via screened Coulomb forces with the surface of a tubulin dimer, with neighboring C-termini and also with any adjacent microtubule-associated protein 2 (MAP2). Each C-terminus can either bind to the tubulin surface via one of the several positively charged regions or can be allowed to explore the space available in the solution surrounding the dimer. We find that the preferential orientation of each C-terminus is away from the tubulin surface but binding to the surface may also take place, albeit at a lower probability. The results of our model suggest that perturbations generated by the C-termini interactions with counterions surrounding a MAP2 may propagate over distances greater than those between adjacent microtubules. Thus, the MAP2 structure is able to act as a kind of biological wire (or a cable) transmitting local electrostatic perturbations resulting in ionic concentration gradients from one microtubule to another. We briefly discuss the implications the current dynamic modeling may have on synaptic activation and potentiation.

Introduction

Microtubules (MTs) have long been known to play key roles in the functioning of eukaryotic cells. Cell division, for example, is accomplished by the dynamic reorganization of the cytoskeleton and the segregation of the chromosomes by mitotic spindles that are composed of MTs (Alberts et al. 2002). Whereas all living cells contain MTs in neurons they facilitate processes and interactions that extend over large (even macroscopic) distances. Elongated structural elements, for example the dendrites of large pyramidal cells of cerebral cortex, provide an environment where interactions that are electromagnetic in nature may propagate along the long axis of MTs aligned within them (Brown and Tuszynski 1999).

Recently, it has become apparent that neurons utilize MTs in cognitive processing. Both kinesin and microtubule-associated protein 2 (MAP2) were implicated in learning and memory (Wong et al. 2002; Khuchua et al. 2003; Woolf et al. 1999). Dendritic MTs, in particular, were implicated in these processes, and it is highly probable that precisely coordinated transport of critical proteins and mRNAs to the postsynaptic density via kinesin along MT tracks in dendrites is necessary for learning, as well as for long-term potentiation (LTP) (Kiebler and DesGroseillers 2000; Steward and Schuman 2001). As shown schematically in Fig. 1, presynaptic axon terminals make synaptic contacts onto postsynaptic spines. Within the shaft of the dendrite, MTs act as tracks for kinesin's processive movement (Alberts et al. 2002); thus enabling them to transport proteins such as receptors. MTs also transport mRNA that translates to proteins critical to synaptic activity. In general, actin participates in the dynamic changes of the dendrite and the formation of the spines. As for the interaction between the actin and MT as well as the possible role of actin in the signal processing, this is an interesting possibility but it is out of the scope of this paper and will be discussed elsewhere. Our computa-

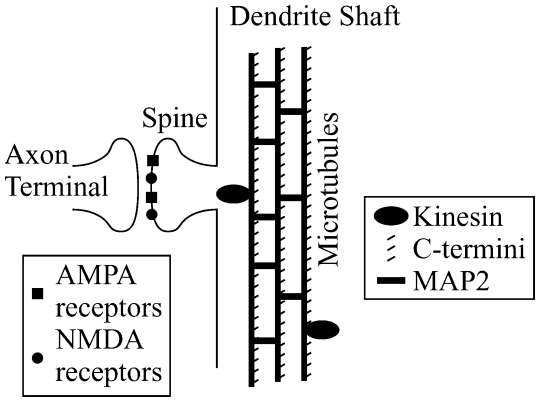

Fig. 1 Diagram of C-termini on the tubulin dimers of microtubules in relationship to incoming synapses. Axon terminals typically input to spines, many of which contain AMPA and NMDA glutamate receptors. Kinesin motors transport cargo along microtubules. C-termini states affect the transport of kinesin along microtubules and this affects transport of materials to active synapses

tional analyses reported in the present paper focus on the C-termini of those MTs whose biophysical properties have a significant influence on the transport of material to activated synapses; as one example, cytoskeletal signal transduction and processing, and, as another, synapses undergoing LTP.

When Nogales et al. (1998) determined a 3D-structure of tubulin, the C-termini could not be resolved because the C-terminus region is highly flexible and lies outside the globular domain of tubulin. However, molecular dynamics enables one to model conformation dynamics of the C-termini using their known amino acid sequences in conjunction with the available crystallographic structures of tubulin. We show some relevant results in the next section.

The C-termini of tubulin are located on the outside of the MT and hence they interact strongly with other proteins, such as MAP2 and kinesin (Sackett 1995). Indeed MAP2 binds to helices 11 and 12 near the C-termini of tubulin in MTs (Al-Bassam et al. 2002). While precise nature of the bond is not known at present, it is suspected to be ionic due to oppositely charged regions of tubulin and MAP2 in the binding areas. To the best of our knowledge, a single MAP2 binds one tubulin dimer. The processivity of kinesin appears to critically involve an interaction with the C-termini of tubulin, although MAP2 may temporarily uncouple to avoid interfering with the movement of kinesin along the MT (Thorn et al. 2000). Removal of the C-terminus of tubulin profoundly affects kinesin processivity; in particular cleavage by subtilisin results in a fourfold decrease of the rate of kinesin transport (Wang and Sheetz 2000).

In an effort to gain an insight into the role played by C-termini in the functioning of dendrites, we have developed a quantitative computational model based on the currently available biophysical and biochemical data regarding some key macromolecular structures involved (tubulin, its C-termini, and MAP2). Our model also accounts for the presence of ions in the surrounding aqueous environment. We start our modeling with the analysis of the possible conformations of the individual C-termini and calculate the resulting electric potential on the outside of the dimer. To elucidate the dynamic properties of C-termini and their interactions with MAP2 we study: (1) the relatively long-lived configurations of C-termini, (2) the interactions between C-termini and tubulin, (3) the interactions between nearest-neighbor C-termini, and (4) interactions between C-termini and MAP2 where we propose a model of wave propagation involving counterions that are weakly bound to MAP2.

Structural and electrostatic properties of tubulin including C-termini

In humans, tubulin exists in dozens of homologous isoforms some of which are preferentially expressed in the human brain (Lu et al. 1998). A 3D structure of tubulin was determined by Nogales et al. (1998) and later refined by Löwe et al. (2001) but several amino acids including some at the C-termini of the protein were not resolved, and hence these amino acid sequences were omitted from the (Protein Data Bank) PDB data files for tubulin (1TUB and 1JFF). However, we have created structure files that include the C-termini whose amino acid sequences correspond to those known for individual human tubulin isotypes. We have also performed computational experiments at physiological temperatures intended to find equilibrium conformations of tubulin's C-termini and these are shown later in the paper. The tubulin structure was a combination of 1JFF with a consistent set of structural elements from 1TUB for some regions absent in 1JFF. However, we must acknowledge the existence of serious limitations in the accuracy of computational studies of a protein as large and complex as tubulin.

An important physical property of proteins is their surface electric charge distributions, as these affect their interactions with other proteins and biomolecules. Fig. 2 illustrates the results of our visualizations based on the PDB file 1JFF. It shows a coarse-grained representation of the electric charge distribution on the tubulin dimer surface. The intention here is to show where charges of different signs are located, not necessarily how densely they are distributed at a given point. The fading of the font used represents the depth of view meant to express the 3D structure of the protein. This figure contains regions including the two C-termini that were not crystallographically resolved, but added here using relevant amino acid sequences. These C-terminal chains' conformations are purely artifacts of the process by which they were added and should not be interpreted as corresponding to any real conformation. The figure and the potential calculation were in part produced using MolMol (Koradi et al. 1996).

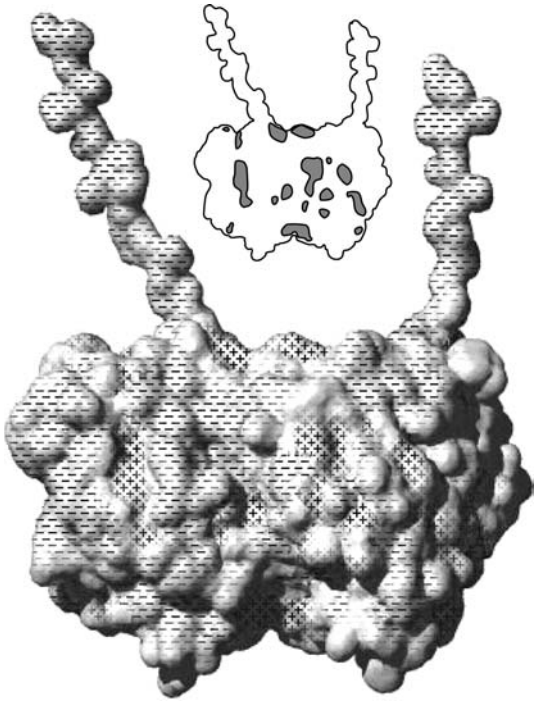

Fig. 2 A map of the electric charge distribution on the surface of a tubulin dimer with C-termini tails present (prepared in part with MolMol (Koradi et al. 1996)). *Pluses* represent the areas of positive charge while *minuses* represent the location of negative ones. The *symbols* do not correspond one-to-one to elementary charge values, only to the presence of charge of a given type

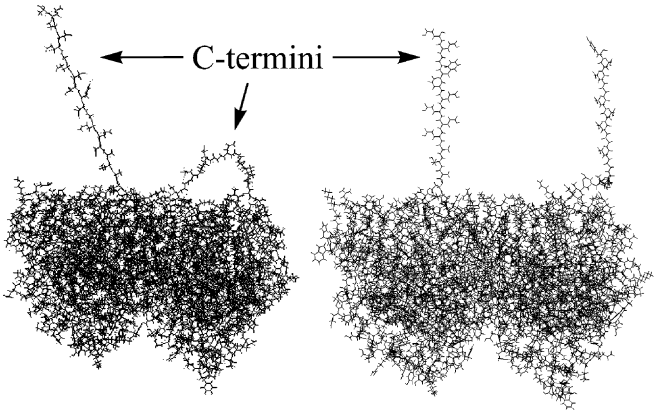

Fig. 3 A reconstruction of the surface of a tubulin dimer with two C-termini attached (based on the PDB and C-terminus sequence. The two states of the C-terminus shown are the result of MD simulation of this system

Frohlich Oscillations

The C-termini of tubulin are strongly negatively charged (having a net charge of up to 11 electrons each) and interact electrostatically with several other charged objects in their vicinity, namely: (a) the surface of the tubulin dimer (which is generally negatively charged, with as many as 16 negative charges per tubulin monomer, but which has a positively charged region(s) on its exposed surface that can bind a C-terminus), (b) with neighboring C-termini and (c) with adjacent proteins such as kinesin or MAP2.

Through the computer simulations that are later described in detail, we have found that the C-termini are likely to exist in two major conformational states: (a) a rather flexible conformation pointing away from the MT surface and subject to thermal fluctuations, or (b) a state in which the C-termini bind to the MT surface. Fig. 3 shows a tubulin dimer where two C-termini configurations are obtained from simulations (not described in this paper); in one of them, both C-termini point upright away from the surface while the other dimer shows one upright C-termini and one bound. It is feasible that bound conformations of C-termini form a regular arrangement on the surface of a MT. Interestingly, a recent paper by Makrides et al. (2003) reports that MAP (tau) binding to neuronal MTs produces a collective change in the MT lattice structure. Their result obtained using AFM (atomic force microscopy) techniques is consistent with our prediction of the existence of a collective state of the C-termini that are bound to the tubulin surface. However, we deliberately avoided any relation to conformational changes of the dimers themselves. This is because the time scale for the collective motions of the C-termini is much shorter than that for the bulk of the protein's conformational motions. Besides, dimer conformational changes (if any) are much smaller with respect to the degrees of freedom available for the C-termini. While this section has dealt with the preliminary application of molecular dynamics simulations to individual tubulin monomers and dimers, the next sections intend to explore the possibility of interactions among the many C-termini of a microtubule as well as between the C-termini and MAPs. Our intention is to examine whether: (a) collective conformational states of these structural elements may be generated, and (b) whether these states can exhibit nontrivial dynamics, e.g. wave propagation. As will be elaborated in the discussion, such collective states may be reversibly switched on and off; this might be of significance to dendritic information processing and axonal trafficking. However, due to the complexity and computational demands of this problem, we are now faced with a need to simplify the modeling effort.

Modeling the C-termini as charged rods

Based on the assumption that C-termini dynamics plays an important role in the functioning of a dendrite, we develop a simplified model of a C-terminus and its interactions with neighboring structures. Analysis of the model indicates the existence of two metastable states that were observed in the full MD simulation performed on a single dimer, and allows further investigation of the interactions with MAP2.

The proposed model of the C-termini microtubule network is schematically illustrated in Fig. 4 where the tubulin dimer is considered to be the basic unit. Each

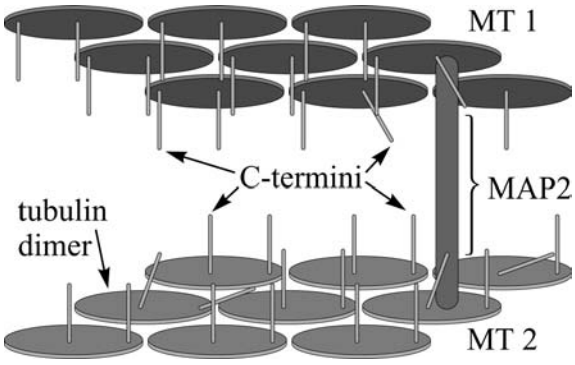

Fig. 4 A schematic diagram of portions of the two microtubules connected by a MAP2. Each portion shows the outer face of a tubulin dimer covered by two C-termini. Each C-terminus can be in one of two metastable states, perpendicular or parallel to the dimer surface

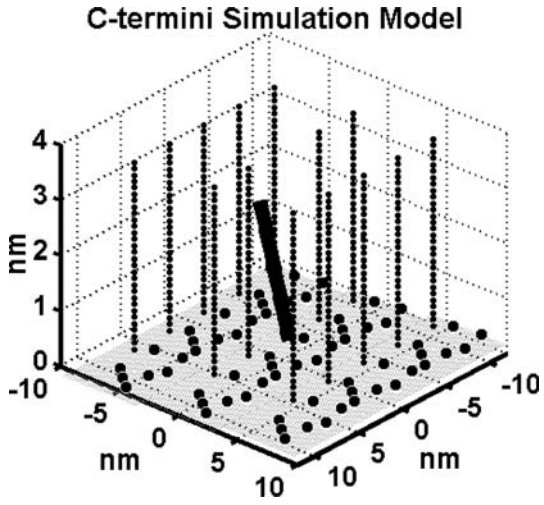

Fig. 5 A portion of the microtubule composed of a few tubulin dimers with their C-termini used as a model for the static simulation. Also shown are a few of the positively charged regions (*circles*) on the surface of a tubulin dimer. The test C-terminus is slanted (*bold*). (Axes are scaled in [nm])

dimer has two C-termini that may either extend outward from the surface of the protofilament or bind to it. The major goal here is to explore how MAP2 binding affects the states of the C-termini, which in turn may affect other sub-cellular processes, the processive motion of kinesin motor proteins transporting mRNA as they walk on the MT.

The most responsive structural elements of the system (i.e. elastic and electric degrees of freedom) can be best understood in terms of the conformational states of the C-termini. Each state of the unbound C-terminus is assumed to evolve such as to minimize the overall interaction energy of the system. Note that, while the exposed surface of the dimer is, on average, highly negatively charged, it exhibits local regions of positive charge that attract the C-termini as thermal fluctuations (or directed fields) may cause them to bend into and bind in what we call a 'down' state. The energy difference between the two metastable states is relatively small, on the order of few k_BT at room temperature, allowing for transitions between the two main conformational states to be thermally activated. We elaborate on this below.

In this preliminary analysis, we map the interaction energy of a C-terminus with its nearest neighbors to investigate its static properties; dynamic properties will be investigated later. Here, for simplicity, we model the C-terminus as a charged rod (of negligible width) that is attached at one end to the surface of the tubulin dimer, and can move otherwise above the surface as a rigid body (see Fig. 5). We describe its location in terms of spherical polar coordinates as: (θ, ϕ) (azimuth, elevation). The main contributions to the interaction energy of the test C-terminus are: (1) its nearest neighbors' C-termini, (2) the negative surface of tubulin dimer below and (3) the positive regions on the surface. Hence, we can describe the total energy of the ith test C-terminus as follows:

$$E_i^{\mathrm{tot}} = \sum_{j \in nn} E_{i,j}^{\mathrm{cc}} + E_i^{\mathrm{cd}} + E_i^{\mathrm{cp}} \qquad (1)$$

Debye length = charge carrier's net electrostatic effect in a solution

The different contributions to the interaction energy are now described explicitly. We use in our calculations the concept of Debye screening due to the presence of ions in a solution (Daune 1999). The electrostatic interaction energy between two C-termini labeled (i, j) can be approximated as:

$$E_{i,j}^{\mathrm{cc}}(\theta_{i,j}, \phi_{i,j}) = K\lambda^2 \int_0^L \int_0^L \mathrm{d}l_i \mathrm{d}l_j \frac{e^{-(D(\cdot)/\lambda_{\mathrm{D}})}}{D(\cdot)\varepsilon_{\mathrm{r}}(D(\cdot))}$$

$$\begin{aligned} D(l_{i,j}, \theta_{i,j}, \phi_{i,j})^2 &= \left(l_i \cos\phi_i \cos\theta_i + x_i - l_j \cos\phi_j \cos\theta_j - x_j\right)^2 \\ &+ \left(l_i \cos\phi_i \sin\theta_i + y_i - l_j \cos\phi_j \sin\theta_j - y_j\right)^2 \\ &+ \left(l_i \sin\phi_i - l_j \sin\phi_j\right)^2 \end{aligned} \qquad (2)$$

where ($x_{i(j)}$, $y_{i(j)}$) is the (fixed) binding location of the C-termini to the surface, $\theta_{i,j}$ is an abbreviation for (θ_i, θ_j), $D(\cdot)$ stands for the distance function, L is the length of the C-terminus, λ is the linear charge density, $K = (4\pi\varepsilon_0)^{-1}$, ϵ_{r} is the relative dielectric constant (which for short ranges in an aqueous solution is 1–80), and λ_{D} is the Debye screening length that depends on the ions and their concentrations in the surrounding solution.

The tubulin dimer has a complex surface both geometrically and electrostatically. For simplicity, we model it as a 2D rectangular area with a certain average charge density σ with several localized positively charged regions whose locations are based on the calculations described above, see Fig. 2. Considering the dimer and one of its C-termini, with the center of the dimer at the origin, the negative surface contribution to the interaction energy is given by:

$$E_i^{\mathrm{cd}}(\theta,\phi) = K\lambda\sigma \int_0^L \int_{-W/2}^{W/2} \int_{-H/2}^{H/2} \mathrm{d}l\,\mathrm{d}w\,\mathrm{d}h \frac{e^{-(D(\bullet)/\lambda_\mathrm{D})}}{D(\bullet)\varepsilon_\mathrm{r}(D(\bullet))}$$

$$D(l,w,h,\theta,\phi)^2 = (l\cos\phi\cos\theta - h - x_0)^2 + (l\cos\phi\sin\theta - w - y_0)^2 + (l\sin\phi + \Delta)^2 \quad (3)$$

where (x_0, y_0) is the binding location to the surface of the C-terminus, H, and W are the height and width of the dimer, respectively, and Δ a is the distance in the z-direction separating the C-terminus and the dimer surface. Similarly, the contribution due to positively charged regions (points) is given by:

$$E_i^{\mathrm{cp}}(\theta,\phi) = K\lambda q_\mathrm{e} \sum_{j=1}^{N_\mathrm{p}} \int_0^L \mathrm{d}l \frac{e^{-(D_j(\bullet)/\lambda_\mathrm{D})}}{D_j(\bullet)\varepsilon_\mathrm{r}(D_j(\bullet))}$$

$$D_j(l,\theta,\phi)^2 = (l\cos\phi\cos\theta - x_j - x_0)^2 + (l\cos\phi\sin\theta - y_j - y_0)^2 + (l\sin\phi + \delta)^2 \quad (4)$$

where N_p is the number of positive charges on the dimer surface, δ is a minimum z-displacement of a positive region with respect to the surface (the residue is, to some extent, exposed) and q_e is the electron charge.

Based on the above contributions, we calculated numerically the interaction energy surface as experienced by a C-terminus. The main assumptions behind this analysis are:

– The empirical estimate of the relative dielectric constant ε_r (Mallik et al. 2002) is linearly approximated by:

$$\varepsilon_r(d) = \begin{cases} (1 + 79 \cdot d)/1.7 & \text{if } d \leqslant 1.7\,\mathrm{nm} \\ 80 & \text{if } d > 1.7\,\mathrm{nm} \end{cases} \quad (5)$$

– Further effects of the ionic solution are taken into account only via the inclusion of the Debye–Huckel factors (Daune, 1999).

The governing equations were evaluated on a $\theta - \phi$ grid defining the inclination of the C-terminus. Fig. 5 depicts the simulation setup where a test C-terminus is rotating with two degrees of freedom (the base is fixed), θ, ϕ denoting the azimuth and elevation, respectively, and the rest of the environment is frozen, i.e. neighboring C-termini, and the dimer's surface, a negatively charged area with specific positive regions. The model parameters used for the numerical evaluation are given as follows. First, we have used the geometrical dimensions of the tubulin dimer as: $H = 8$ nm, $W = 6$ nm. Then, we assumed that approximately 2/3 of the net average charge of tubulin is exposed on the outer surface, which results in the surface charge density of: $\sigma = 12\mathrm{e}^{-}\cdot(4\ \mathrm{nm})^{-2}$. Next, a reasonable value of the linear charge density for the C-termini: $\lambda = 10\mathrm{e}^{-}/L$ (where L is the C-terminus length, $L = 3.5$ nm). The values of the displacement parameters were estimated at $\Delta = 4$ Å, $\delta = 1$ Å.

Figure 6 depicts the interaction energy for several elevation cuts (angles are given in the figure) at azimuth angles, whereas Fig. 7 shows a full surface plot. It transpires that the 'up-state' has the lowest energy. (It corresponds to the C-terminus being perpendicular to the tubulin's surface). However, the cone-angle created by the constraint $E - E_0 < 50$ meV (where $E_0 = E$ ($\phi = 90°$)) is about 40°. This means that the C-termini can move readily within this cone due to thermal fluctuations ($k_\mathrm{B}T$ is approximately 25 meV at physiological temperatures). But an important result is the existence of

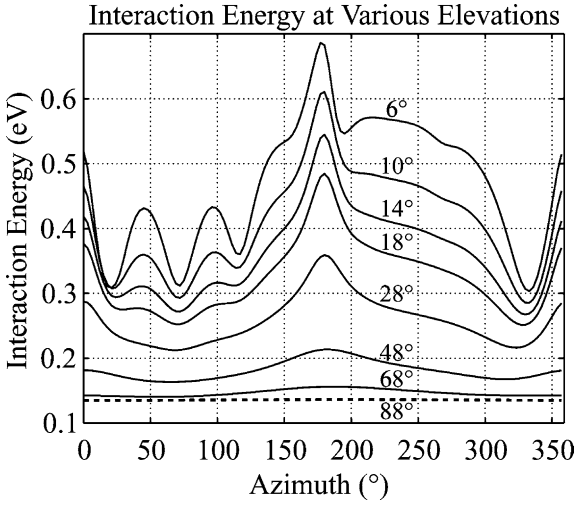

Fig. 6 Evaluation of (1) for the interaction energy between a test C-terminus and the environment vs. the azimuthal angle; each line in the figure describes an elevation cut; values are given

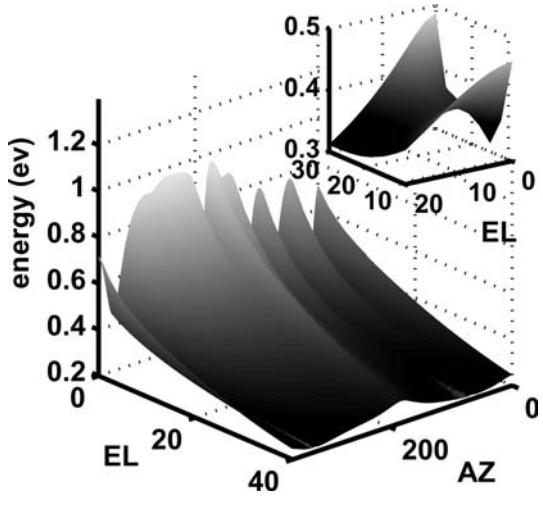

Fig. 7 Energy surface of the interaction between the test C-terminus and the environment. The grayscale is in [eV]. The *inset* shows a zoom of a saddle point on the surface

a local minima associated with the 'down-state' which is only 100 meV higher than the straight-up state, see Fig. 7. A saddle point between the two states is ~160 meV above the 'up-state'. What we deduce here is that, at least under the assumptions of the model, there are two metastable states with a moderate energy barrier separating them. The inset in Fig. 7 shows a close-up near the saddle point.

Finally, we wish to discuss ion condensation that may be expected to take place on MAPs and the C-termini of MTs due to their strong negative charge exposure to the aqueous environment. Many years ago, Manning (1978) postulated an elegant theory that polyelectrolytes may "condense" neutralizing ions from their surroundings. According to Manning's hypothesis, counterions condense along the polymer if a sufficiently high linear charge density is present on the polymer's surface. Thus, a linear polymer may be surrounded by counterions from the saline solution such that co-ions of the salt solution are repelled so that an ion depleted volume is created. The sum of surface charges and associated counterions depends on the counterion's valences and Bjerrum lengths. In general, depending on the charge density and the geometry of the charged surface exposed to ionic solutions (quasi-linear, cylindrical, spherical, etc) some of the ions condense on the surface binding very strongly to the opposite charges on the surface, while a number of ions remain fairly free to move about in the solution still being attracted to the surface. The proportion of the condensed ions to the surface charge can be evaluated for a given situation. The Bjerrum parameter is a phenomenological property of the ion's ability to compensate for the surface charges, and depends on temperature and the solvent. In 1926, Bjerrum developed a modification of Debye–Hückel ion-pair formation theory provided that the ions are small, of high valence, and that the dielectric constant of the solvent is small. The Bjerrum length is the distance at which the Coulomb energy of the screened charges equals $k_B T$, the thermal energy, creating an equilibrium from which the charges do not preferentially move. The cylindrical volume of ionic depletion outside the ion cloud surrounding the polymer serves as an electrical shield. Thus, the 'wire-like' behavior of such a structure is supported by the polymer itself, and the adsorbed counterions. For all practical purposes, these are bound to the polymer. The strength of this interaction is such that even under infinite dilution, counterions are still attracted to the polymer and do not diffuse away from the polymer. Although originally postulated for such polyelectrolytes as DNA, this theory applies to highly charged one-dimensional polymers such as the C-termini of microtubules or MAPs. In recent experiments (Stracke et al. 2002), it was demonstrated under the influence of externally applied electric fields that microtubules drift in the field direction, indicating that not all the protein charge is compensated by bound counterions.

Detailed description of the C-terminal model

In this section, we extend our model in order to simulate the dynamic behavior of a C-terminus. To enable exhaustive simulations, we model the C-terminus as a sequence of beads with flexible connections, instead of the rigid rod, in what is known as the bead-spring model, a common method for simulating polymers. The simulation takes into account the following types of interactions:

Electric field of the dimer

Since the tubulin surface is complicated we used a dense grid that models its charge distribution. The outer surface can be characterized as mainly negative with a few small positive pockets (by visual inspection of our earlier calculations we estimated the existence of 7 such pockets per dimer). The computation of the interaction between the C-terminus and the dimer's surface is highly intensive if done for each update of the position. For example, if we use a 2Å resolution, the number of grid points is (8/0.2)*(6/0.2) = 1,200, assuming a 6×8 nm^2 surface area. If we use a 10-bead model, then the number of point-to-point interactions becomes 12,000. A reasonable number of updates is 10^5–10^6, so this type of interaction becomes a serious bottleneck. To overcome this problem, we assumed that the surface is static and evaluated the field it exerts in a box of (6×8×6) nm^3 volume whose base is the surface. This can be done even in a finer grid than described earlier. Once we have the (static) field vector at the box grid points, we apply real-time linear interpolation for each update to obtain the field at the position of each bead. We assumed a negative charge of $-12e^-$ per tubulin monomer surface, and $+7e^-$ in positive pockets per dimer, hence the net negative contribution to the surface charge distribution is taken to be (−12–7/2) per monomer.

The bead-spring model

A C-terminus has a molecular weight of ~2 kD and is arranged as a long flexible tail. Instead of trying to model its entire secondary structure, we use an approximation where 1–2 amino-acids are modeled by a bead with an equivalent mass while the charge is distributed uniformly among the beads. To maintain the chain, we use the following interactions:

- Coulomb interactions between the electric charges
- The Lennard–Jones potential: Short range forces between all beads whose distance is shorter than a cut-off. This force is responsible for the strong short-range repulsion. The attractive part of this potential is truncated. The equation used is given below:

$$F_{\mathrm{LJ}} = 24(1/r)\left[2(\sigma/r)^{12} - (\sigma/r)^{6}\right] \quad \text{if } r \leqslant R_{\mathrm{c}} \tag{6a}$$

$$F_{\mathrm{LJ}} = 0 \quad \text{if } r > R_{\mathrm{c}} \tag{6b}$$

– FENE: Finite-extensible-nonlinear-elastic springs forces that enforce bond connectivity along the chain. This force is calculated between adjacent beads only, referred to as nearest neighbors (nn).

$$F_{\mathrm{fene}}(r) = \frac{KR_0^2 r}{\left(R_0^2 - r^2\right)} \quad \text{if } r < R_0 \tag{7}$$

Note that a singularity exists at $r = R_0$.

– Angular forces: These are the two types of forces that restrict the angle between every three adjacent beads and the planar angle involving every four adjacent beads, i.e. harmonic angular potential and harmonic dihedral potential. The harmonic cosine potential: (for simplicity, we give here the potential and not the force):

$$U_{\mathrm{angle}} = K_{\theta_a}(\cos(\theta) - \cos(\theta_0))^2 \tag{8}$$

where θ is the angle between every three adjacent beads.

The harmonic dihedral potential:

$$U_{\mathrm{dihedral}} = K_{\theta_d}(1 + \cos(n\varphi - \varphi_0)) \tag{9}$$

where for the quartet $(ijkl)$ we define $\varphi = (ijk)\angle(jkl)$, the angle between the plane spanned by (ijk) and the plane spanned by (jkl).

The other two contributions to the equation of motion are:

– Friction forces

$$F_{\mathrm{f}} = -m\Gamma v, \tag{10}$$

where v is the velocity vector and Γ is the friction coefficient.

– Random forces representing thermal fluctuations denoted by $W(t)$ and satisfying

$$\langle W(t)\rangle = 0, \quad \langle W_i(t)\, W_j(t')\rangle = 6k_{\mathrm{B}}Tm\Gamma\delta_{\mathrm{ij}}\delta(t - t') \tag{11}$$

This combination of friction and noise terms is described in the fluctuation–dissipation theorem and often referred to as Langevin dynamics. The initial conditions adopted in our simulations had C-termini in a straight conformation normal to the surface. We used 600 runs that lasted 500 ps each and they took up 400 ps for relaxation and 100 ps for stabilization of the various resultant conformations that were then statistically analyzed. A detailed description of the model parameters chosen for our simulations is given in Appendix A. Note that the external force is taken in the x-direction with a random projection [–0.2..0.2] in the y-direction. What our simulation indicates here is the ability of an ionic wave to trigger a corresponding wave of C-termini state changes from their upright to downward orientations (see Figs. 8, 9). In the next section, we address the related question whether or not an ionic wave can propagate along a MAP2 that interconnects two neighboring MTs.

In Figs. 9 and 10 we have presented the results of our calculations of the energy minimized positions of the individual beads representing the amino acids of the C-termini in two equivalent forms. The distributions shown in Fig. 10 (top) describe the minimal energy positions of beads representing the constituent residues of a C-terminus ranging from three to the end for each run after relaxation. The energy minimized value can come from each of the beads at positions from 3 to 11. The first bead is permanently connected to the surface and hence has no freedom to move. The surface is taken

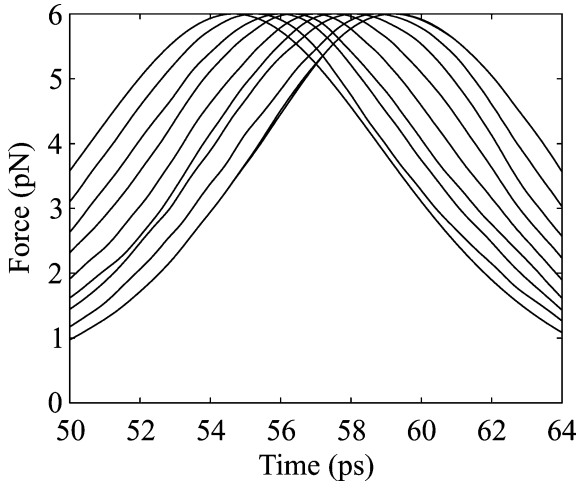

Fig. 8 Plot of the function $F(z(i), t) = \mathrm{amp}\ \mathrm{sech}\ (b(z(i) - vt))^2$ where $z(i)$ is the z-position of the ith bead

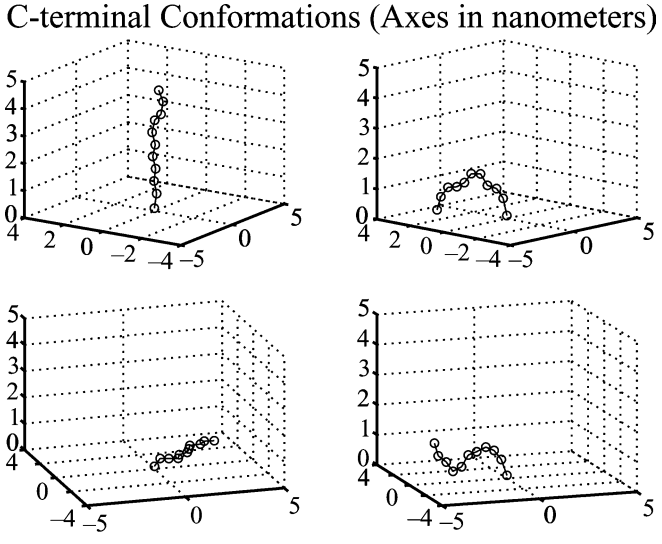

Fig. 9 Four C-termini conformations observed with the flexible model

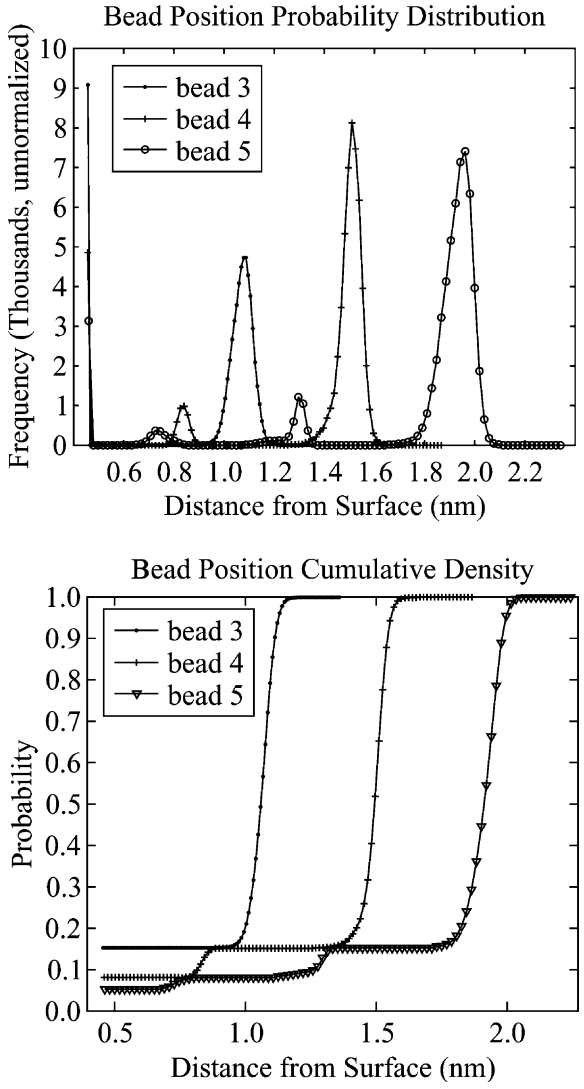

Fig. 10 Top: The histograms shown describe the minimal energy positions of beads representing a C-terminus ranging from 3 to 5 obtained at the end of each run after relaxation. The energy minimized value can come from each of the beads at positions from 3 to 11. The first bead is permanently connected to the surface and hence has no freedom to move. The surface is taken at $z = 0.45$ nm for technical reasons. **Bottom:** The cumulative sum of the probabilities corresponding to the same physical situation as described in Fig. 9 is just another way to present the results. It is shown that the probability of the down position which includes all cases of full or partial attachment is ~15%

to be at the vertical coordinate $z = 0.45$ nm for technical reasons. Figure 10 (bottom) shows the cumulative sum of the probabilities corresponding to the data shown in Fig. 9. It is shown that the probability of the down position which includes all cases of full or partial attachment is ~15%.

Model of an ionic wave propagation along MAP2

The next step in our investigation focuses on the characteristics of MAP2 and its ability to function as a 'wave-guide' that transfers the conformational change in a C-terminus state to an adjacent MT. Following the description of the MAP2 and its electrostatic properties, we describe a simplified model of the interaction between MAP2 and its ionic environment via counterions and their role in propagating the perturbation exerted by an adjacent C-terminus.

The 3D structure of MAP2 is unknown. However, MAP2 binding with MTs was investigated. The binding region is located at the C-terminus and the bond between MAP2 and a MT appears to be electrostatic in nature. Pedrotti et al. (1994) showed that MAP2 binds to MTs in a concentration-dependent manner. Once bound, a high NaCl concentration is not effective in reducing the concentration of MAP2 bound to MTs. During binding, $MgCl_2$ is ten times as effective as NaCl at decreasing MAP2 binding to MTs. The authors concluded that MAP2 may "screen" electrostatic repulsion between tubulin dimers.

Our estimates of charge on the surface of MAP2 are based on a published sequence (Tokuraku et al. 1999) in the Swiss-Prot database (entry P11137: MAP2_HUMAN). We found that the binding domain is composed of roughly the first 418 amino acids so we take the remaining 1,410 amino acids of MAP2b to constitute the projecting domain. Assigning a single positive charge to each Lys and Arg residue, snd and a negative ones to Asp and Glu with His being given an average value of $+1/2$ due to its isoelectric point and leaving the remaining residues neutral, we take the total negative charge of the projecting domain to be $-150\ e^-$ and its charge distribution to be very close to uniform.

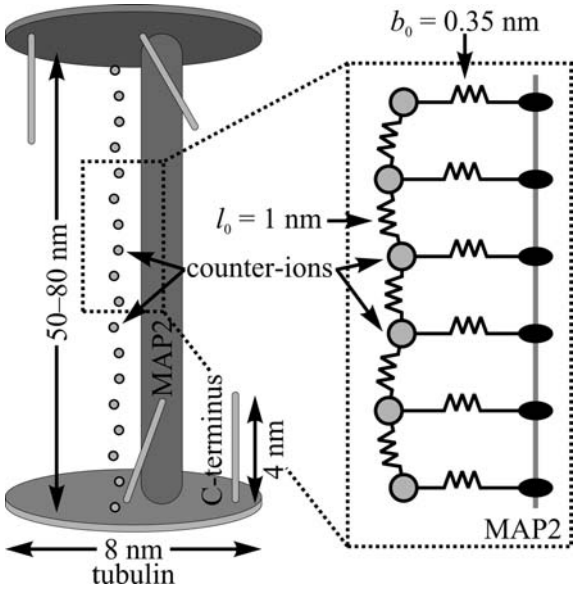

Fig. 11 A schematic model of the MAP2 interacting with positive counterions (*circles*). Also seen are two dimers at both ends of the MAP2 and a slanted C-terminus. The zoom region depicts the springs model used to describe the interactions between the MAP2 and the counterions

We are now able to extend our model to include MAP2 as a supporting structure (backbone) to which counterions are attached. We are aware of the still unresolved controversy regarding the characteristics of the binding between the projecting domain of MAP2 and an adjacent MT. While it is still to be determined if a single MAP2 makes direct physical contact with a MT, it is apparent to us that it at least reaches the immediate vicinity of a given MT. However, our model's results presented below are unaffected by the type of binding present as long as the distance between these two structures is on the order of 1 nm. To simplify the model we assume that the counterion attracting sites are equidistant and arranged in a straight chain along the MAP2. We envisaged that the counterions move only in a plane perpendicular to a cylinder representing the MAP2 (see Fig. 11). We show that a perturbation applied to the counterions at one end of the MAP2 will drive them out of equilibrium and initiate a wave that travels along the MAP2. Subsequently, we derive the equations of motion and investigate the properties of the traveling wave that emerges.

To facilitate the implementation of the model, we use the harmonic approximation and represent the chain as a 2D-spring system in which each counterion is strongly bound to a MAP2 site and weakly bound to its two nearest-neighbor counterions. The main justification for taking only the nearest-neighbor interaction into account is the strong screening effect imposed by the solution (see the previous section for discussion). In addition, we assume external forces of two kinds; the damping viscous force due to temperature fluctuations and a perturbation exerted by a C-terminus while changing its state (details given below). An additional constraint is provided by reflecting boundaries located approximately 0.2 nm from the MAP2 (representing a repelling force).

Our main focus in the following investigation is the characterization of the propagating perturbation along the MAP2. The results reported below were obtained from MD simulations of this model. The model Hamiltonian can be written as follows:

$$H = \frac{M}{2}\sum_i \dot{\mathbf{r}}_i^2 + \frac{1}{2}K^b \sum_i \left(|\mathbf{r}_i - \mathbf{b}_i| - b_0\right)^2 + \frac{1}{2}K^c \sum_i \left(|\mathbf{r}_i - \mathbf{r}_{i-1}| - l_0\right)^2 + W(\mathbf{r}) \tag{12}$$

where we have assumed a harmonic potential for the electrostatic interaction with K^b and K^c denoting the force constants of the MAP2–counterion and counterion–counterion interactions, respectively, $\mathbf{r}_i$ is the position of the counterion, $\mathbf{b}_i$ is the ith MAP2 binding site, b_0, l_0 are the equilibrium chain distances, M is the counterion's mass and $W(\mathbf{r})$ describes the site-dependent potential (which for the purpose of this calculation is ignored). Using the following notation, we obtain

$$\begin{aligned} \mathbf{u}_i^{\mathrm{CM}} &= \mathbf{r}_i - \mathbf{b}_i, \quad u_i^{\mathrm{CM}} = ||\mathbf{u}_i^{\mathrm{CM}}||, \quad \hat{\mathbf{u}}_i^{\mathrm{CM}} = \frac{\mathbf{u}_i^{\mathrm{CM}}}{u_i^{\mathrm{CM}}}, \\ \mathbf{u}_i^{\mathrm{CC}} &= \mathbf{r}_i - \mathbf{r}_{i-1}, \quad u_i^{\mathrm{CC}} = ||\mathbf{u}_i^{\mathrm{CC}}||, \quad \hat{\mathbf{u}}_i^{\mathrm{CC}} = \frac{\mathbf{u}_i^{\mathrm{CC}}}{u_i^{\mathrm{CC}}}, \end{aligned} \tag{13}$$

where the symbols CM and CC label 'counterion–MAP' and 'counterion–counterion' interactions, respectively. The corresponding equations of motion for the counterions are given as follows:

$$\begin{aligned} M\ddot{\mathbf{r}}_i = &-K^b\left(u_i^{\mathrm{CM}} - b_0\right)\hat{\mathbf{u}}_i^{\mathrm{CM}} \\ &- K^C\left[\left(u_i^{\mathrm{CC}} - l_0\right)\hat{\mathbf{u}}_i^{\mathrm{CC}} - \left(u_{i+1}^{\mathrm{CC}} - l_0\right)\hat{\mathbf{u}}_{i+1}^{\mathrm{CC}}\right] - \gamma\dot{\mathbf{r}}_i + \mathbf{f}_i \end{aligned} \tag{14}$$

where damping and the external force, $\mathbf{f}$, have been explicitly introduced. In order to solve these equations, we applied the velocity-Verlet algorithm for time integration (Swope et al. 1982).

Let us now describe the rationale and assumptions underlying the choice of parameters in the model, $K^{b(c)}$, b_0, l_0, M and γ. The equilibrium distance between counterions is dictated by our assumption about the average distance between binding sites. As discussed above, from the analysis of the residues of MAP2 we infer that there are approximately 150 electronic charges. Assuming that MAP2 is a 50-nm rod-like structure, we obtain a charge distribution of about $3e^-$ per nanometer along the MAP2 axis (length estimation is obtained from average measurements of the MAP2). Since our model actually represents a two-dimensional structure perpendicular to the MAP2 surface, we assume the average charge separation to be $l_0 = 1$ nm. The bond length for typical counterions in ionic solution is 2.5–4 Å; in our simulations we therefore used $b_0 = 3.5$ Å. The representative mass of the counterion chosen here is an average between sodium and calcium ions, $M = 30$ amu, or approximately 5×10^{-26} kg. The damping factor γ has units of amu ps^{-1}; in our simulations we have used $\gamma = 1$ amu ps^{-1} which is typical in molecular dynamics simulations. The MAP2-counterion bond force constant takes a typical value of $K_b = 100$ kcal mol^{-1} Å^{-2} and the counterion–counterion force constant is on the order of $K_c = 0.3$ kcal mol^{-1} Å^{-2}. The former estimate is comparable to the strength and distance involved in the formation of a monovalent ion's bond with a protein. The choice of the second force constant reflects a weak Coulomb interaction between adjacent counterions. At any rate, it is the ratio of these two constants that is more important in our calculations than their absolute values.

The interaction between the MAP2 and the C-terminus actually includes a layer of counterions surrounding each of these structures. In our model, the C-terminus is located 0.4 nm from the MAP2-base and is initialized at a given value of (θ, ϕ). It then falls at a certain angular velocity until it reaches the tubulin surface. We apply MD updating steps to the counterions only, since the C-terminus in this case merely serves as a

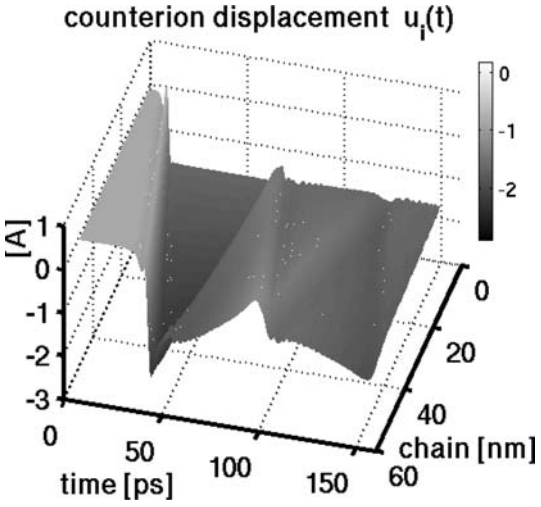

Fig. 12 Results of the MAP2 model simulation describing the counterions displacement (the chain-axis denotes the discrete indices of the counterions). The grayscale is given in [Å]

source of perturbation. In parallel, we evaluate the properties of the wave generated by this perturbation. A typical initial orientation is $\theta = 180°$, $\phi = 50°$ and the C-terminus collapses over a characteristic time of 10 ps.

The following figures show several properties of the wave propagation along the chain of $N = 50$ counterions. Figure 12 depicts the counterion displacement parallel to the MAP2, u_i, where i denotes the ith counterion. The counterions near the MAP2-base are attracted by the C-termini and the displacement is effectively negative. The wave propagates along the MAP2 and then is reflected back from the other end; this process may re-occur a few times. The amplitude of the reflected wave is attenuated and depends on the value of the damping factor γ. The asymmetry between the two edges is mainly an artifact of the experimental setup in which the C-terminus is located only at one end; hence the other end has fewer

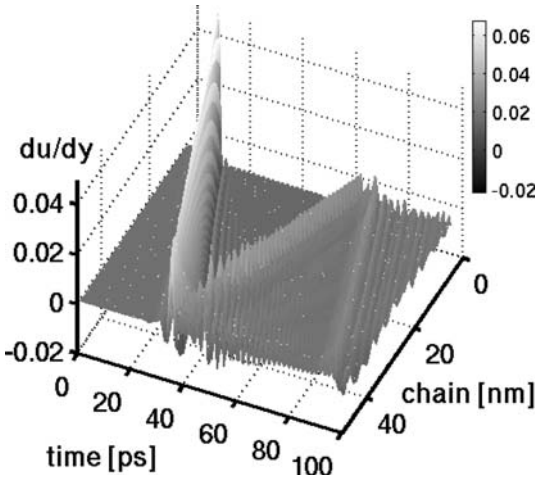

Fig. 14 Spatial derivative of the counterions displacement evaluated using (15b)

constraints and exhibits more fluctuations. The next two figures, Fig. 13 and Fig. 14, present the first derivatives of the displacement with respect to the time and space, respectively. More specifically, the temporal and the spatial derivatives are estimated from the simulation updating steps as follows:

$$\frac{\mathrm{d}u_i(t)}{\mathrm{d}t} \approx \frac{u_i(t+\Delta t) - u_i(t)}{\Delta t} \tag{15a}$$

$$\frac{\mathrm{d}u_i(t)}{\mathrm{d}y} \approx \frac{u_{i+1}(t) - u_i(t)}{\Delta y_i} \tag{15b}$$

where Δt is the simulation time step, Δy_i is the distance between two adjacent counterions and the spatial derivative is obtained only in the y-direction (parallel to the MAP2 axis).

The profiles of the displacements and their derivatives reveal the following interesting result. The projection of

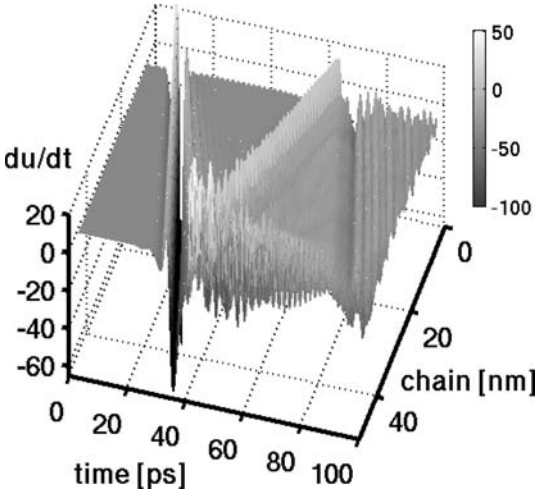

Fig. 13 Time derivative of the counterions displacement evaluated using (15a). The grayscale is given in units of [Å ps^{-1}]

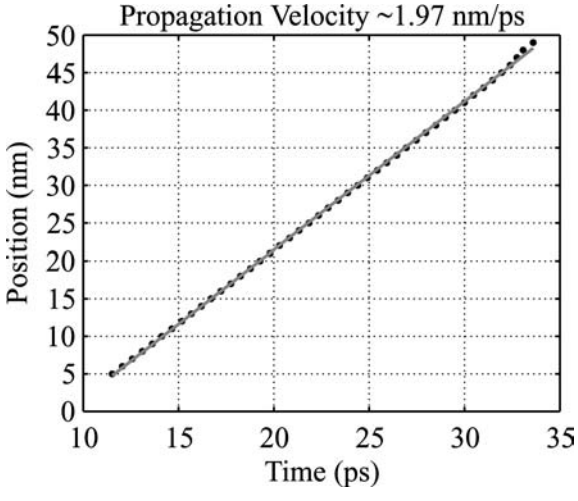

Fig. 15 Evaluation of the phase velocity of the wave propagation along the MAP2 using (16)

the initial perturbation along the MAP2 propagates almost as a "kink", mainly due to the large K_b/K_c ratio; only after the second reflection can one observe a significant spread of the packet. Determination of the phase velocity is done by evaluating the following quantity for all sites:

$$\{t_i: u_i(t) = u_0,\ u_i(0) = 0\} \tag{16}$$

i.e. we find the set of time values $\{t_i\}$ for which the displacement of the ith counterion is u_0 for the first time. We measure the first passage time for all sites from which the propagation velocity is evaluated. Figure 15 shows the results for the above parameters with a velocity estimation of $v_{ph} \approx 2$ nm ps^{-1}. Finally, it is worth mentioning that the velocity scales with the square root of K_c. More details of this analysis will be published separately.

Summary and discussion

In this paper, we have modeled static and dynamic properties of the C-termini of tubulin dimers that comprise neuronal microtubules. We have used various computational tools including molecular dynamics in order to explore the dynamic behavior of conformational states of a C-terminus of tubulin within a given microtubule and assumed that each C-terminus interacts via screened Coulomb forces with the surface of a tubulin dimer, with neighboring C-termini and also adjacent MAP2s. Each C-terminus was shown to either bind to the tubulin surface via one of the several regions we identified as positively charged or to explore the space available in the solution surrounding the dimer fluctuating above the tubulin surface with higher probabilities for conformations with a larger inclination angle. We found that the preferential orientation of each C-terminus is away from the tubulin surface but binding to the surface may also take place at a considerably lower probability. The static properties of the C-terminus were studied by analyzing the energy surface of a system composed of a test C-terminus modeled by a charged rod interacting with the tubulin dimers below and the neighboring C-termini. This analysis confirmed the hypothesis of two major states where the volume described by cone-angles above 50 degrees has energy differences of ~2KT at room temperature; we also found a clear barrier of ~6KT between the two major types of states. We further evaluated the statistical properties of the two major states by studying the dynamic properties of a polymer-like bead-spring model of the C-terminus. The results indicate that the system has indeed two major states with a strong bias towards the stretched-up state. In other words, the system tends to be mostly in the 'up-state' unless driven towards one of the surface binding sites where the probability of attraction increases. The statistical bias favoring the up-state versus the down state of C termini may be tipped depending on the actual physiological conditions, in particular the presence of local polarizing fields and/or screening effects. This may be affected by many processes, for example the effect of actin polymerization in the vicinity of a given microtubule or even by ordering of water molecules surrounding the MT surface.

Finally, we studied the properties of ionic wave propagation from one microtubule to another along MAP2. The trigger for this wave may be a near by C-terminus changing state or ionic flux, e.g. from an adjacent ion-channel. Under the noncondensed counterions assumption, we derived the equation of motion for a one-dimensional chain of counterions along the MAP2 main axis and evaluated the properties of such a wave. It was found that the wave may propagate at a speed of ~2 nm/ps (=2,000 m/s) with a small amplitude attenuation. The results of our model suggest that perturbations generated by the C-termini interactions with counterions surrounding MAP2 may propagate over distances greater than those between adjacent microtubules. Interestingly, a recent paper by Ripoll et al. (2004) has proposed an important integrative role for ion waves guided by protein polymers in providing a new means of signal transduction in eukaryotic cells. Our model offers a quantitative description of such a possibility in neurons.

Below, we briefly discuss the implications the current dynamic modeling may have on synaptic activation and potentiation. The results of the molecular dynamics modeling performed here raise the possibility of transmitting electrostatic perturbations collectively among neighboring C-termini and from C-termini located on one MT to those C-termini on another MT via a MAP2 that physically interconnects MT's in dendrites. Collective conformational states of C-termini and a transmission of perturbations among the C-termini was shown to be a viable mode of behavior in dendritic microtubules. This may suggest the possibility of a hitherto unexplored information processing mechanism operating at a subneuronal level is clear. For example, MAP2 and kinesin bind near to the C-termini on tubulin and the conformational states of C-termini affect this binding (Al-Bassam et al. 2002; Thorn et al. 2000). Hence these conformational states of the C-termini must at some point be taken into account in order to understand neural processing that depends on transport of synaptic proteins inside of neurons (see Fig. 1). In this connection, Kim and Lisman (2001) have shown that inhibition of MT motor proteins reduces an AMPA receptor-mediated response in hippocampal slice. This means that a labile pool of AMPA-receptors depends on MT dynamics, and MT motors determine the amplitudes of excitatory postsynaptic currents (EPSC).

Furthermore, a walking kinesin carries with it a protein or an mRNA molecule. Since kinesin binds to a MT on a C-terminus, as it steps on it, it brings the C-terminus to the MT surface and makes it ineffective in binding for the next kinesin over a period of time that it takes the C-terminus to unbind and protrude outside. From this, we can hypothesize that long stretches of

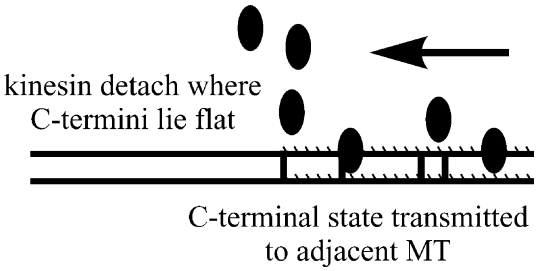

Fig. 16 C-termini that stand upright will increase kinesin processivity, whereas C-termini that lie flat will favor kinesin detachment. This could serve as a mechanism for releasing cargo near to activated synapses. The state of C-termini can be transmitted from one MT to a neighboring MT, in theory. Significant transport toward, and detachment near, active synapses could occur

C-termini in the upright position are more efficient at transporting kinesin and kinesin cargo while C-termini that lie flat may lead to a detachment of kinesin from the MT's (see Fig. 16). Thus, in considering the trafficking of many kinesins, collective conformational effects of C-termini become more and more important. While this is outside the scope of this paper, we may speculate even further and put forth a hypothesis that dendritic processing leading to axonal spikes at the axon hillock (an event not completely explained by membrane signaling) may be regulated or at least affected by the dynamic states of the C-termini in essence leading to a complex dynamic system within a neuron

Appendix A

The choice of model parameters

- The basic units in our simulation were selected as follows:
  - Mass: 1 amu = 1 D = 1.66×10^{-27} kg
  - Time: 1 ps (1×10^{-12} s)
  - Charge: 1 e^- (1.6×10^{-19} C)
  - Length: 1 nm (hence, velocity is 1 nm/ps)
  - Energy: kJ/mol
  - Force: kJ/(mol · nm)
- The mass of the molecular chain of beads is estimated as 2 kD (summing up the amino acids of the C-terminus of a given human tubulin isotype), or 2000 unit masses. For simplicity we assume identical beads, i.e. for N-beads model the weight of each bead is 2 kD/N. We actually take N = 11, however the first bead is totally attached to the surface.
- The net charge of the C-terminus is assumed to be −10e, again taken from the same isotype of tubulin.
- The nominal length of the C-terminus is taken to be $L = 4.5$ nm.
- The Lennard–Jones parameters are:
  - $\epsilon = 1$ (however recall the truncation)
  - $\sigma = 0.45$ (in nm units)
  - $R_c = 2.0^{1/6}\sigma$
- FENE parameters:
  - $K = 20$–30
  - $R_c = 1.5\sigma$
- Harmonic angle force parameters:
  - $K_{\theta_a} = 40$ (the force constant)
  - $\theta_0 = 135°$ or $3\pi/4$
- Dihedral harmonic angle force parameters:
  - $K_{\theta_d} = 4$ (the force constant)
  - $\phi_0 = 0°$ (or π)
  - $n = 2$ multiplication factor
- The friction coefficient used: $\Gamma = 0.03$
- The noise was taken from a (3D) uniform distribution $[-W,...,W]$ $W = 20$;

Note that the friction coefficient, Γ, enters the equation of motion as part of the fluctuation-dissipation terms in the Langevin dynamics. We use the random and friction forces to represent a virtual solution without explicitly taking into account the particles in the solution. The actual parameters of the simulation are determined from the (room) temperature, the Lennard–Jones constants and the bead mass. The friction is determined as a function of the system's time unit and the time steps of the numerical integration. In our case, we were interested in maintaining the higher vibrational frequencies, so the decay time was kept longer (determined from friction). The amplitude of the stochastic force then follows the Langevin constraints.

External force representation

The external force is simulated as a traveling localized wave with a certain amplitude, as follows: $F(z(i), t) =$ amp $\mathrm{sech}(b(z(i) - vt))^2$ where $z(i)$ is the z-position of the ith bead

Figure 8 shows the actual force on each one of the beads. The parameters of the wave were taken to be:

- $v = 0.8$ [nm/ps]
- amp = 6 [kJ mol^{-1} nm^{-1}]
- $b = 0.25$

Transmission of the Quantum Interaction of Erythrocytes

LIONEL S. SEWCHAND, DELIA ROBERTS, AND STANLEY ROWLANDS*

Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received January 22, 1982; Accepted June 29, 1982

Abstract

The previously demonstrated long-range quantum mechanical interaction between human erythrocytes suspended in plasma also occurs with artificial media. Certain macromolecules dissolved in phosphate-buffered saline will transmit the interaction provided their concentration is above a minimum. Extended macromolecules transmit the interaction, whereas a compact macromolecule (albumin) does not.

Index Entries: Erythrocytes, quantum interaction between; quantum mechanics, and erythrocyte interactions; macromolecules, and quantum erythrocyte interactions; ultra-long-range force, between erythrocytes.

Introduction

We have shown that human erythrocytes interact when less than a few micrometers apart (*1–3*) and that this interaction has features in common with Fröhlich's (*4, 5*) theory of ultra-long-range coherent quantum mechanical interactions in biological systems. The electric field of the membrane potential is about ten million volts per meter, which polarizes the molecules constituting the membrane. The polarized molecules interact, giving rise to modes of vibration that Fröhlich (*5*) calculates to have frequencies of the order of 10^{11} Hz, at which frequency quantum mechanical properties become significant. In the very strong electric field, conformational change in membrane molecules and the readjustment of counterions will give rise

0163-4992/82/1200-0253$02.00

to metastable states of polarization that are analogous to the states of "population inversion" in the photon laser, though within the membrane the quantum particles are phonons. The theory asserts that if the membrane is supplied with metabolic energy above a minimum level, membrane phonons will trigger into a laser-like coherent mode of vibration that can give rise to forces between membranes, organelles, and macromolecules extending over a range of several micrometers (*5*).

We made measurements of the Brownian movement of human erythrocytes in blood that showed that the movement is no longer random when two erythrocytes are closer than three cell radii (*2, 3*). The interaction disappears when the cells are killed and it disappears *reversibly* when the membrane potential is abolished or when the cells are metabolically depleted. Moreover, there is some evidence from experiments on interspecies erythrocyte rouleau formation (*6*) that the interaction is specific (*2, 3*). At low frequencies, ionic screening would limit the range of a polar-wave interaction to a few nanometers, but Fröhlich demonstrates (*5*) that at 10^{11} Hz ionic screening is insignificant up to distances of micrometers. Pohl (*7, 8*) has shown that dividing cells will attract $BaTiO_3$ particles (dielectric constant, 4000) more readily than $BaSO_4$ particles (dielectric constant 11). He names the process "microdielectrophoresis" (*9*), and attributes the interaction to cellular electromagnetic vibrations of the Fröhlich type, but at a lower frequency. With erythrocytes (murine) he found no interaction. These experiments of Pohl (*7*) were done with cells suspended in artificial media of very low salt concentration, which enhances electromagnetic transmission. Our experiments were done with the erythrocytes suspended in their own plasma. When the cells were suspended in Ringer-Locke solution or phosphate-buffered saline (high salt content similar to that of plasma) there was no interaction. In the experiments described in this paper, we have tested the hypothesis that macromolecules are necessary to transmit the quantum interaction of human erythrocytes. The implication it that this interaction is not a direct polar wave attraction of the type demonstrated by Pohl (*7, 8*).

Methods

The methods and the Brownian theory (*10*) employed in the calculations have been fully described (*3*). The observed process is Brownian movement of erythrocytes, on which the Fröhlich interaction is superimposed. Provided there is an adequate concentration of certain macromolecules in the suspending medium, red cells that come into contact form themselves into easily recognized columns of cells called rouleaux. The macromolecules under study are polyvinylpyrrolidone (PVP-360, average molecular weight 360,000; Sigma Chemicals Co., St. Louis, MO), dextran (Dextran 70, molecular weight 60,000–90,000, ICM, Cleveland, OH), human fibrinogen prepared by the Cohn fractionation method, and human serum albumin (Connaught Laboratories, Willowdale, Ontario). With the exception of albumin, the macromolecules are known rouleau-inducing agents. The macromolecules were made into solutions of various concentrations in phosphate-buffered saline (PBS: composition 150 m*M* NaCl, 7.3 m*M* Na_2HPO_4, 2.8 m*M*

NaH_2PO_4, 2.2 m*M* $CaCl_2$, 4.6 m*M* $MgCl_2$, 310 mosmol, pH 7.4 at 22°C). The viscosity of the solutions was measured with a cone and plate viscometer (Synchro-Lectric, Brookfield, Stoughton, MA). At the start of an experiment the solution was filtered through a 0.3 μm Millipore filter and human blood from a finger prick was added to give a cell concentration (v/v) of ~0.2%. The suspension was stirred and quickly transferred to a siliconized (Dow Corning, Midland, MI: Sylgard 184 or R4-3117) hemacytometer chamber (Spencer Bright-Line, American Optical Corp., Buffalo, NY). The chamber was sealed with silicone grease to prevent evaporation and photographed with a time-lapse ciné-camera on an Ortholux microscope (Wild-Leitz, Rockleigh, NJ) at about 60× magnification. An exposure was taken every 15 s for 1 h.

Analysis of Results

The observed process is an aggregation of cells undergoing Brownian movement on which is superimposed a specific interaction at a distance. The cells sediment to the floor of the chamber and if the motion is purely Brownian the kinetics of rouleau-formation is given (*3*, *10*) by

$$\frac{1}{N_t} - \frac{1}{N_o} = \frac{2kT}{\eta} t \qquad [1]$$

where k is Boltzmann's constant, T is the absolute temperature, and η is the viscosity of the solution. The developed ciné-film was projected with a Photo-optical Data Analyser (Model 224A, L-W International, Woodland Hills, CA) and in the earliest frame at which the cells had settled the total number of cells and rouleaux (N_o) was counted in an area defined by the hemacytometer grid. The count was repeated (N_t) every fifth frame (75 s) and the regression of N_t^{-1} on t was computed. Correlation coefficients averaged 0.98.

Equation [1] is derived on the assumption that the diffusion coefficient is given by the Stokes-Einstein relation

$$D = \frac{kT}{6\pi\eta r} \qquad [2]$$

where the denominator is the Stokes' drag coefficient

$$\mu = 6\pi\eta r \qquad [3]$$

We have done an extensive series of measurements on the drag coefficients under the conditions of our experiments (*2*, *3*, *11*,). These demonstrate (*3*) that, in plasma, the experimental value is 1.78 ± 0.06 (SEM) times greater than the theoretical value, and they imply that cells in contact with a surface experience an added hydrodynamic drag (*11*). Accordingly, the rate constant in Eq. [1] has to be divided by the ratio of the experimentally determined to the theoretical drag coefficient. The drag coefficient is measured in each experiment from the Brownian movement of isolated cells (*2*, *3*) and for each experiment a Brownian motion rate

constant is calculated. This is the factor $2kT/\eta$ in Eq. [1] corrected for the additional hydrodynamic drag. For a viscosity of 1.7×10^{-3} Pas, this rate constant has a value of $2.6 \times 10^{-18} m^3 s^{-1}$. For convenience we use an interaction coefficient Ξ which we define to have a value of unity when representing the Brownian motion rate constant. Experiments on dead cells and microspheres (*2, 3*) demonstrate values for Ξ that do not differ significantly from unity. It is shown in reference (*3*) that if r is the erythrocyte radius, then $Z = \Xi r$ where Z is the radius of the zone of attraction around the erythrocyte.

Results

The results are given in Table 1. Concentrations of macromolecules are given in column 1 and the viscosities of the suspending media in column 2. The measured drag coefficients in column 3 are used to calculate the Brownian motion rate constant as explained under Methods. The interaction coefficients (Ξ column 4) are expressed as multiples of this Brownian motion rate constant. If $\Xi > 1$ an attractive interaction is implied and $\Xi < 1$ implies a repulsion. It will be seen that with

[a]Standard deviation.

PVP concentration ≥ 0.1 g%, Dextran ≥ 2.0 g%, and fibrinogen ≥ 0.3 g%, Ξ is greater than one. The concentrations of fibrinogen that showed an interaction were in the physiological range, whereas albumin at physiological concentrations gave no indication of an attraction.

In the previously described experiments (*3*) that were all done in plasma, rouleaux formed even when the cells were metabolically depleted or with a zero membrane potential. The counts of (N_o) and (N_t) were unequivocal, although the magnification and resolution used was low to get sufficient cells in the field of view for statistical analysis. With low concentrations of PVP, dextran, and fibrinogen, and with all concentrations of albumin, rouleaux do not form, but a few cells stick together. These are identified by running the film quickly back and forth to check that they indeed remain together though human error may occur because the counting process is long and tedious. For instance, we did pairs of experiments at six different concentrations of dextran between 0.1 and 1.0 g%, but the values of Ξ were distributed randomly. Hence the presentation of these results in the table as a mean and standard deviation. It is possible that there is a threshold concentration above which the quantum interaction appears as a step function. This hypothesis could only be tested by many more experiments, work that will not be done until automated methods of film analysis are available.

The drag coefficients should, of course, change uniformly as the viscosity and the density of the suspending medium increases, but this was not so. In early experiments with plasma we encountered difficulty in getting uniform drag coefficients, but the problem was overcome (*3, 11*). Further work on surface interaction when employing solutions other than plasma should improve the accuracy of the results. Nevertheless, it is important to remember that the drag coefficient was *measured* in each experiment and that the interaction coefficient is a measure of any deviation from the *observed* Brownian motion of isolated cells.

Discussion

Rowlands et al. (*1–3*) have shown that normal human red cells in their own plasma form rouleaux significantly faster than Brownian motion predicts. Varying the membrane potential and the cellular ATP content shows that the interaction is compatible with the major predictions of Fröhlich's theory (*4, 5*) of coherent excitations in biological systems. Cells suspended in phosphate-buffered saline do not interact. The present results show that extended macromolecules must be present in sufficient concentration in the suspending medium, a point that was not predicted by Fröhlich's theory in its present form. PVP and dextran are electrically neutral and fibrinogen carries a net negative charge. Albumin, a compact globular molecule, does not transmit the interaction even when its concentration is at or above the upper limit of normal in plasma. This suggests that the secondary or tertiary structure of the macromolecule determines whether or not it will transmit the Fröhlich interaction.

Human erythrocytes, in addition to having a membrane potential, carry a negative surface charge (*12, 13*) that keeps the membranes apart when the cells are sus-

pended in isotonic solutions. The surface charge is neutralized by counterions up to very short distances of approach, quite invisible in our microscope, of necessity used at low magnification. Brownian movement can overcome a small repulsion and two such erythrocytes may stick, but if they do not, Brownian motion will cause them to separate. This process is monitored by running the ciné-film back and forth (see Results). Nevertheless, with the experiments performed as at present, firm conclusions cannot be drawn from the magnitude of values of the interaction coefficient which are substantially less than unity as exemplified by the results for low concentrations of dextran.

In the plasma experiments (*2, 3*) there was a considerable spread in the values for Ξ for normal cells. This is not unexpected. There is a considerable spread in the area and volume of the erythrocytes in a single sample of human blood (*14*) and an even larger spread in the membrane permeability for individual cells to certain nonelectrolytes (*15*). Therefore, the Fröhlich force is unlikely to be identical between every pair of erythrocytes. And so the variations in the values of Ξ for PVP $\geqslant 0.1$ g% probably reflect the variations noted in the plasma experiments (*3*).

In spite of the reservations discussed above, it can be concluded that the quantum mechanical interaction between human erythrocytes can only be transmitted in the presence of a sufficient concentration of extended macromolecules. Pohl (*7, 8*) has demonstrated an attractive force toward mitotic cells in suspending media devoid of macromolecules, but only if the medium has a very low ionic strength. He did not find an effect with murine erythrocytes.

Our experiments were done at physiological ionic strengths and indeed the original experiments were done in plasma itself (*1–3*), so there is no incompatibility between Pohl's findings and our own. Fröhlich has reviewed (*5*) the evidence for the occurrence of vibrations of the predicted frequency in microorganisms and in cells in tissue culture. Pohl's work and ours demonstrate the predicted ultra-long-range interaction and so all the major features of Fröhlich's theory of coherent excitations in biological systems have been confirmed.

Abstract

Tubulin heterodimers are the building blocks of microtubules and disruption of their dynamics is exploited in the treatment of cancer. Electric fields at certain frequencies and magnitudes are believed to do the same. Here, the tubulin dimer's response to external electric fields was determined by atomistic simulation. External fields from 50 to 750 kV/cm, applied for 10 ns, caused significant conformational rearrangements that were dependent upon the field's directionality. Charged and flexible regions, including the α:H1-B2 loop, β:M-loop, and C-termini, were susceptible. Closer inspection of the α:H1-B2 loop in lower strength fields revealed that these effects were consistent and proportional to field strength, and the findings indicate that external electric fields modulate the stability of microtubules through conformational changes to key loops involved in lateral contacts. We also find evidence that tubulin's curvature and elongation are affected, and external electric fields may bias tubulin towards depolymerization.

Introduction

α- and β- tubulin heterodimers spontaneously assemble end to end to form protofilaments, and the helical arrangement of 13 protofilaments constitutes microtubules that are central to cellular rigidity, division, motility, and trafficking of intracellular proteins [1–4]. As the driving force for sister chromatid segregation in mitosis, microtubules have long been targeted by chemotherapies using pharmacological agents that stabilize MTs such as paclitaxel, and those that destabilize them such as vincristine, and vinblastine [5,6]. More recently, microtubules have become the target of a novel treatment modality: electric fields. Alternating electric fields at 2.5 V/cm with a frequency of 100–300 kHz, known as Tumor Treating Fields (TTFields), disrupt microtubules *in vitro*. While no definitive mechanistic model of their action has been established, a putative explanation claims that this is due to the microtubules' large intrinsic charge and dipole [7–10] which interacts with electric fields and their gradients. In a major development in the area of cancer therapy, Optune®, a device for administering the fields to patients, was recently approved by the FDA to treat glioblastoma [11–13].

Compared to TTFields, external electric fields (EEFs) of much greater strengths but shorter timescales can also eliminate cancer cells *in vitro* and *in vivo*. Nanosecond pulsed electric fields

(nsPEFs)—static EEFs of tens of kV/cm that are applied repeatedly over nanosecond durations [14,15]—have demonstrated anti-cancer potential against Jurkat and HL-60 cells *in vitro* at 300 kV/cm [15], papillomas and squamous cell carcinoma *in vivo* at 40 kV/cm [16], and many other cancer models [17–23]. Several mechanisms have been proposed to explain nsPEFs' effects, but their creation of nanopores, which allow an influx of Ca^{2+} from extracellular and intracellular sources, and reduction of mitochondrial membrane potential have received the most attention [14,24,25].

More recent investigations have demonstrated that nsPEFs affect the cytoskeleton. Nanosecond pulsed electric fields cause a breakdown of actin filaments with concomitant cell rounding [26–29] and 44 kV/cm pulses induce microtubule clearance in U87 human glioblastoma cells within minutes, all without observable Ca^{2+} influx and/or osmotic swelling [30]. These findings of microtubule breakdown [30], in conjunction with those of Kirson et al. [31] in TTFields, suggest that EEFs may destabilize microtubules directly in addition to various indirect effects that have been proposed [8].

Other investigations of tubulin in EEFs have found that microtubules can be aligned with an applied electric field [32,33] and that EEFs reduce the Young's modulus of a tubulin heterodimer [34]. Despite these earlier findings, the precise atomic-level details of a single dimer's response to EEFs are unknown. Therefore, we performed an investigation of these effects through Molecular Dynamics, applying EEFs along multiple directions (Fig 1) at time scales and field strengths consistent with nsPEFs (36–38), the results of which are important for understanding macroscopic observations like nsPEF-induced depolymerization. Notably, the α:H1-B2 loop and β:M-loop, that are integral to lateral contacts between protofilaments, are especially susceptible to the influence of electric fields, and the bend angle and elongation of tubulin are affected, which may accelerate the depolymerization process.

Results and discussion

Tubulin's structure and dynamics are affected by EEFs

Structural change as measured by root mean standard deviation. We first investigated large-scale EEF-induced changes to tubulin's root mean standard deviation (RMSD) and dipole magnitude. By both measurements, a 750 kV/cm EEF caused significant structural changes in all directions tested (Fig 2). Most of the change in RMSD was in loops and turns. As expected, we found that rigid structures like alpha helices and beta sheets remained relatively fixed, with an RMSD for alpha carbons close to 1 Å, whereas other structural motifs were more sensitive to the EEFs and exhibited an RMSD of 5–6 Å. By comparison, the same flexible motifs showed an RMSD of around 2–3 Å in the dimer unexposed to an EEF. These more-flexible residues were classified as, in order of prevalence, coils, hydrogen bonded turns, and 3_{10} helices (Fig 2B and Fig 2E). The relaxation time was less than 30 ns, when the EEF was applied along the dimer's transverse axis (Fig 2A), but lasted longer when applied along the longitudinal axis (Fig 2D). Microtubules clearance is observable in nsPEFs applied at 10 Hz, or with 100 ms between their application, which means that there is likely sufficient time for total relaxation in a single dimer between pulses.

Increase of dipole moment by EEFs. In all but the negative transverse direction, or opposite the dimer's dipole, the EEF doubled the magnitude of tubulin's dipole moment (Fig 2C and Fig 2F). Increases in dipoles were longer lasting when the EEF was applied along the longitudinal versus transverse axis, a finding similar to our results in RMSD (Fig 2C and Fig 2F). This effect is explainable by coupling of charged residues with the EEF, in which the dimers' natural charge distributions were exaggerated (in all but the negative transverse simulation). Atomistic simulations of insulin and lysozyme in EEFs have demonstrated that protein dipoles

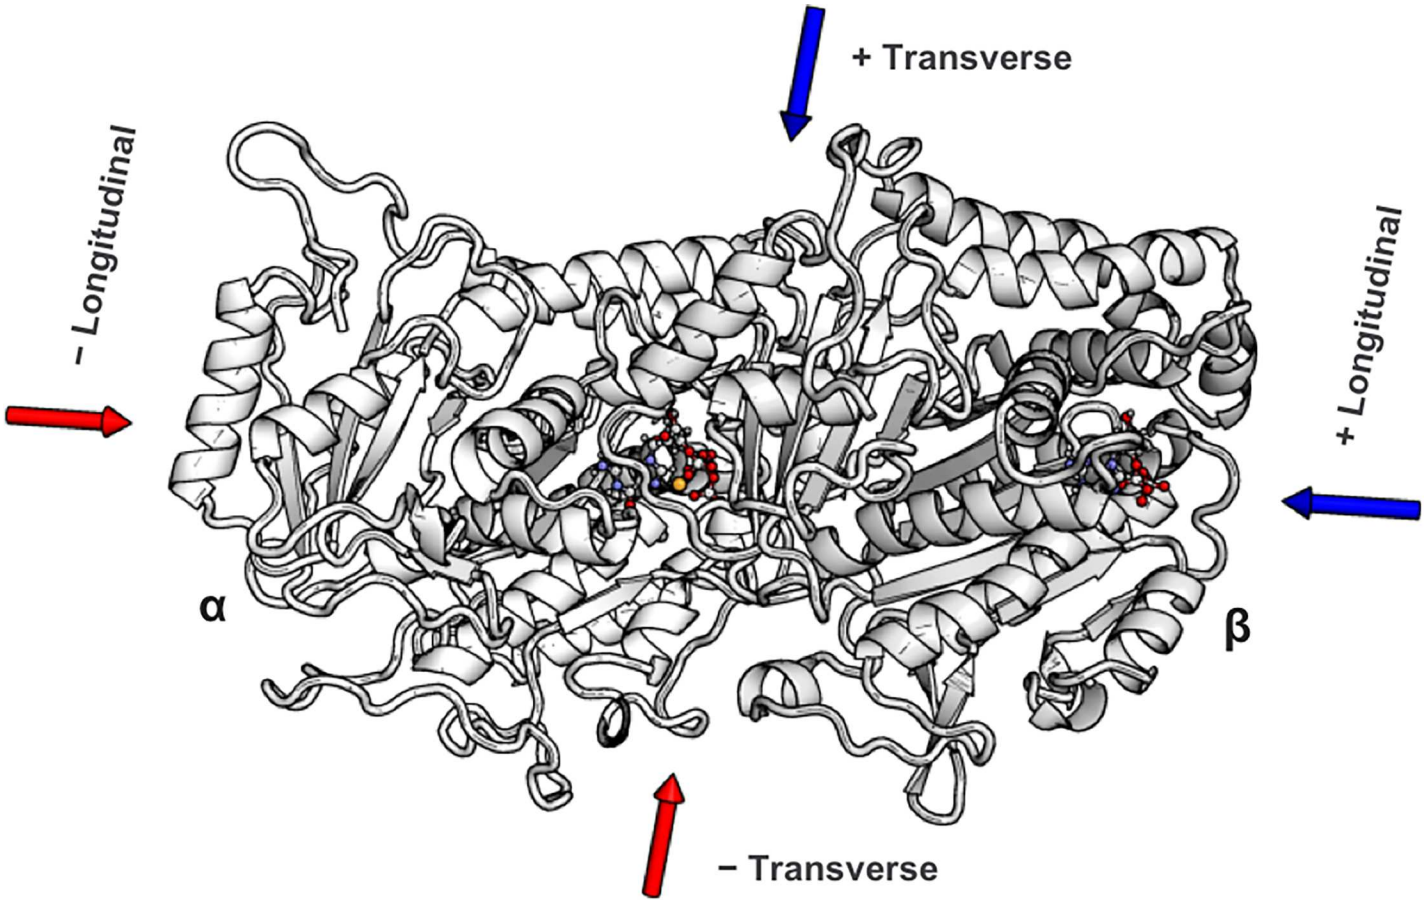

Fig 1. Directionality of the applied electric fields. Electric fields were applied along the direction of the dipole (transverse axis) and along the vector between the beta and alpha monomers' center of mass (longitudinal axis), both in reference to the equilibrated dimer's initial position.

are affected by the localized rearrangement of charged sidechains and loops [35–37]. Additionally, Ojeda-May et al [38] and Budi et al [36] found that EEFs can convert beta sheets to alpha helices or destabilize alpha helices, respectively, but we observed neither in the 750 kV/cm EEFs studied here (S1 Fig).

Rearrangement is greatest in the α:H1-B2 Loop, β:H6-H7 Loop, and C-termini

Charged, flexible regions undergo large per-residue displacement. To gain a better understanding of EEFs' effects on the tubulin dimer, we superimposed final structures, after 10 ns of EEF exposure in opposite directions, and calculated displacement on a residue-by-residue basis. In flexible regions, structural rearrangement was dependent upon the residue's root mean square fluctuation (RMSF) (S2 Fig) and charge; positive and negative residues move towards the EEF's anode and cathode, respectively. There was overlap in the affected regions within dimers in the transverse and longitudinal EEFs. After exposure to EEFs along the dimer's transverse axis (Fig 3B), displacement was greatest in the α:H1-B2 loop (Fig 3D), α:H4-B5 loop, β:H6-H7 loop (Fig 3C), β:M-loop, and C-termini of both monomers (Fig 3E). Similarly, the longitudinal EEFs greatly affected the α:H1-B2 loop (Fig 4C), β:H6-H7 loop, β:M-loop (Fig 4E), and both C-termini (Fig 4D).

C-termini exposed to EEFs showed large movements relative to those that were unexposed, but the extent of their rearrangement was dependent on the field's direction. While the C-termini of the α-monomer and β-monomer shifted inwards in the positive and negative longitudinal EEF, respectively, neither were significantly displaced when the EEF was applied along the opposite, outward direction (Fig 4B). This, plus other research indicating that there are frequent interactions between each monomer's C-terminus and the other's H11 [39], suggests that the C-termini take an "inward" trajectory from a position on the surface of the dimer. In opposition to this movement is the attraction between the negative C-termini and the dimer's positively charged surface. Our equilibrated structure contained salt bridges from α:311K to α:447E and β:292K to β:445E (S3 Fig); the C-termini would necessarily need to escape their attraction to the dimer's positive surface along an inward low-energy path and the EEFs' direction influences whether they reach such an extended state.

EEF-induced modulation of C-termini would have biological relevance because of effects on the dynamics of kinesin [40], dynesin [41], and other microtubule-associated proteins, all of which directly interact with the C-termini of microtubules. In fact, post-translational modifications and removal of the C-termini have already been implicated in changes to motor protein velocity and processivity [41,42]. The interaction between the C-termini and EEFs may be further complicated by post-translational modifications. One such modification is polyglutamylation, which is common to cancer cells, and would result in the addition of negatively charged glutamate amino acids to the already negatively charged C-termini [43] making the latter protrude even more from the mostly negatively charged surface of microtubules. Further investigations of the C-termini's response to EEFs are needed to characterize their transition between contracted and extended states [44] and whether such changes affect the dynamics of microtubule-associated proteins.

Per-residue fluctuations are augmented in EEFs. We also investigated how EEFs affect residue fluctuations. We calculated change in RMSF as $\Delta RMSF = RMSF_{EEF} - RMSF_{AMB}$ where $RMSF_{EEF}$ represents fluctuations of each residue in the dimer exposed to an EEF and $RMSF_{AMB}$ denotes fluctuations in dimer unexposed to an EEF. Therefore, a residue with a large positive $\Delta RMSF$ experienced a significant increase in its fluctuation in an external electric field (relative to the same residue in the dimer unexposed to an external electric field); conversely, a residue with a large negative $\Delta RMSF$ was found to have stabilized by the field. The results (Fig 5 and S4 Fig) further demonstrate the interaction between EEFs and the α:H1-B2 loop, α:H10-B9 loop, M-loop, and C-termini. For these regions, the EEFs' influence on $|\Delta RMSF|$ was consistent, regardless of the direction in which the EEF was applied, but whether $\Delta RMSF$ was positive or negative was variable. For example, there was an increase in fluctuation for the M-loop in both the positive transverse and, especially, negative longitudinal directions. But the same loop showed reduced fluctuation in the negative transverse and positive longitudinal directions. The directional dependence was most apparent in the α:H1-B2 loop which, for three of the four directions tested, experienced the greatest increase in fluctuation among all internal structures, yet was rigidified in the positive transverse EEF.

EEF perturbation results are consistent at lower magnitudes. Given its notable susceptibility to 750 kV/cm EEFs, measurable by both displacement and $\Delta RMSF$, we examined the robustness of α:H1-B2 loop's response to EEFs of lower strengths. We ran 10 ns simulations of EEFs applied along the positive and negative transverse directions at 50, 100, and 200 kV/cm

Positively and negatively charged residue side chains are represented by light-blue and yellow sticks, respectively.

https://doi.org/10.1371/journal.pone.0202141.g003

and then visualized the average positions of the loop over the last 5 ns (Fig 6B). We also characterized the loop's movement using measurements of two charged amino acids—greater distances between α:40K and α:H3 (Fig 6C) and α:47D and α:H3 (Fig 6D) correspond to outward movements of the first and second half of the α:H1-B2 loop, respectively. Inspection of the α:H1-B2 loop's response to lower strength EEFs revealed a change in conformation that was proportional to field strength. The greatest effect was observed in the movements of α:40K.

As a positively charged residue, α:40K was more frequently in an "outward" conformation in a positive transversal field and vice versa, even at 50 kV/cm (Fig 6C). Conversely, the negatively charged α:Asp47 was more likely to be in an "inward," closer to the dimer conformation in a positive transverse EEF. Given the field magnitudes and exposure duration tested here, the results indicate that nsPEFs induce rearrangement in the α:H1-B2 loop. The findings are relevant to a mechanistic explanation of the breakdown of microtubules under the influence of EEFs.

A tubulin dimer in a microtubule is held in place through loop-loop interactions. A dimer within a microtubule has both longitudinal and lateral contacts with its own and adjacent protofilaments, respectively [4,45,46]. In the energetically favorable B-lattice confirmation, lateral contacts between the α monomers of two protofilaments include hydrogen bonds between the H1-B2 loop on one side and the M-loop on the other [47,48]. Similarly, lateral contacts between β monomers include hydrogen bonds between the M-loop of one dimer and the H1-B2 loop of the other [2,4,47]. Given that these regions are susceptible to EEFs, we conjecture that this induced rearrangement may promote microtubule catastrophe.

Tubulin's essential dynamics are affected by EEFs

Beyond the per-residue effects of EEFs, we asked whether the lower-frequency motions of tubulin were also affected. Specifically, intradimer curvature and elongation are two modes that are biologically relevant for the polymerization and depolymerization of microtubules [49,50]. These two essential modes in microtubule dynamics were calculated over the last 5 ns of exposure to 750 kV/cm EEFs for all field directions (Fig 7). The negative transverse EEF promoted the greatest change in curvature, with the mean bend angle at 5.9˚ and 8.2˚ for the unexposed and negative transverse EEF, respectively (Fig 7B). Furthermore, EEFs in all four directions promoted elongation, though the greatest increases were in the longitudinal EEFs (Fig 7D).

The curvature of tubulin has long been linked to the dynamics of microtubules. The straight conformation is found in zinc-induced protofilament sheets [52] and are characteristic of stable microtubules [2], while the curved conformation is found in depolymerization peels, which are sometimes referred to in the literature as "ram's horns" [4,53]. A recent model, based on structures produced with cryo-electron microscopy, proposed that the curved dimer conformation is an energetically preferred state that alleviates the strain of elongation produced during the depolymerization process [4]. Given our findings that EEFs can bias tubulin dimers towards bent (Fig 7B) and elongated conformations (Fig 7D), we posit that modulation of essential dynamics is another means by which nsPEFs affect microtubule stability.

https://doi.org/10.1371/journal.pone.0202141.g004

While our model investigates the effects of EEFs on a single tubulin dimer, other groups have proposed that nsPEFs' effects on the cytoskeleton are due to electrophoresis of the large, negatively charged microtubules [30]. In other words, microtubule breakdown in nsPEFs stems from macro-scale forces, because an unaligned microtubule experiences a lateral electrophoretic force in electric fields [54], and the breakdown of loop-loop interactions occurs secondarily. We did observe an increase in the mean squared displacements of dimers that were proportional to the EEFs' magnitude (S5 Fig), but insight into large-scale, electrophoretic breakdown of microtubules would require either a macroscopic model of microtubule networks or an *in vitro* experiment on microtubule buckling in a range of external electric fields. Relatedly, buckling during the alignment process appears to be modulated by loop-loop interactions between adjacent protofilaments, as evidenced by microtubule response to acetylation of α:40K [55]—so EEF-induced changes in loop-orientation may affect microtubules' plasticity and resistance to buckling at the level of the dimer. Future experiments may further this work by increasing tubulin's number—by simulating either a full or partial cross-section of a microtubule with lateral contacts [48]—or by investigating the effects of hydrolysis of GTP on the dimer's response to EEFs.

Conclusions

In this paper, we have reported on our computer simulations of the effects of externally applied alternative electric fields on the structure and dynamics of tubulin dimers. This was motivated by several experimental observations concluding that microtubules become unstable when exposed to sufficiently strong electric fields. In our simulations, we have observed displacement in the charged and flexible regions of tubulin, including the α:H1-B2 loop, β:M-loop, and C-termini. The changes to the α:H1-B2 loop were persistent at lower magnitude EEFs, and there were also detectable perturbations to tubulin's curvature and elongation. Based on these observations, we propose a mechanistic explanation of the microtubule breakdown in EEFs, which is most likely to involve promotion of depolymerization through weakened lateral bonds and increased dimer strain. Finally, we have found significant effects of the field's orientation on the conformational rearrangements of tubulin dimers, an observation that should encourage an experimental validation.

Materials and methods

We created a 3D model of a tubulin heterodimer by modifying a crystal structure of tubulin bound to Taxol: PDB ID: 1JFF [56]. Preparing this structure for computer simulations, we removed Taxol, added missing residues α:1, α:35–60, α:440–451, β:1, and β:428–445, and energy minimized using Modeller [57].

Note that the residue indices referenced here are ungapped and therefore differ from those reported by Löwe et al [56]. The final structure included the dimer's C-termini and consisted of 451 residues in α-tubulin plus GTP and one Mg^{2+} atom, both of which are bound to α-tubulin, and 445 residues in β-tubulin plus GDP, which is bound to β-tubulin. We included missing hydrogen atoms and delta protonated histidine residues with psfgen [58]. We then solvated the dimer in TI3P3 water atoms in a rectangular box with 20 Å of padding along each axis using VMD's Solvate plugin. This box sizing was chosen with consideration of C-terimini movements to prevent interaction with the dimer's image. To neutralize the dimer and

produce a NaCl molarity of 150mM, we added 185 Chloride and 240 Sodium ions *via* VMD's Autoionize plugin; ultimately, the periodic cell was 110 x 150 x 110 Å along the x, y, and z axes, respectively, and contained 164,493 water atoms.

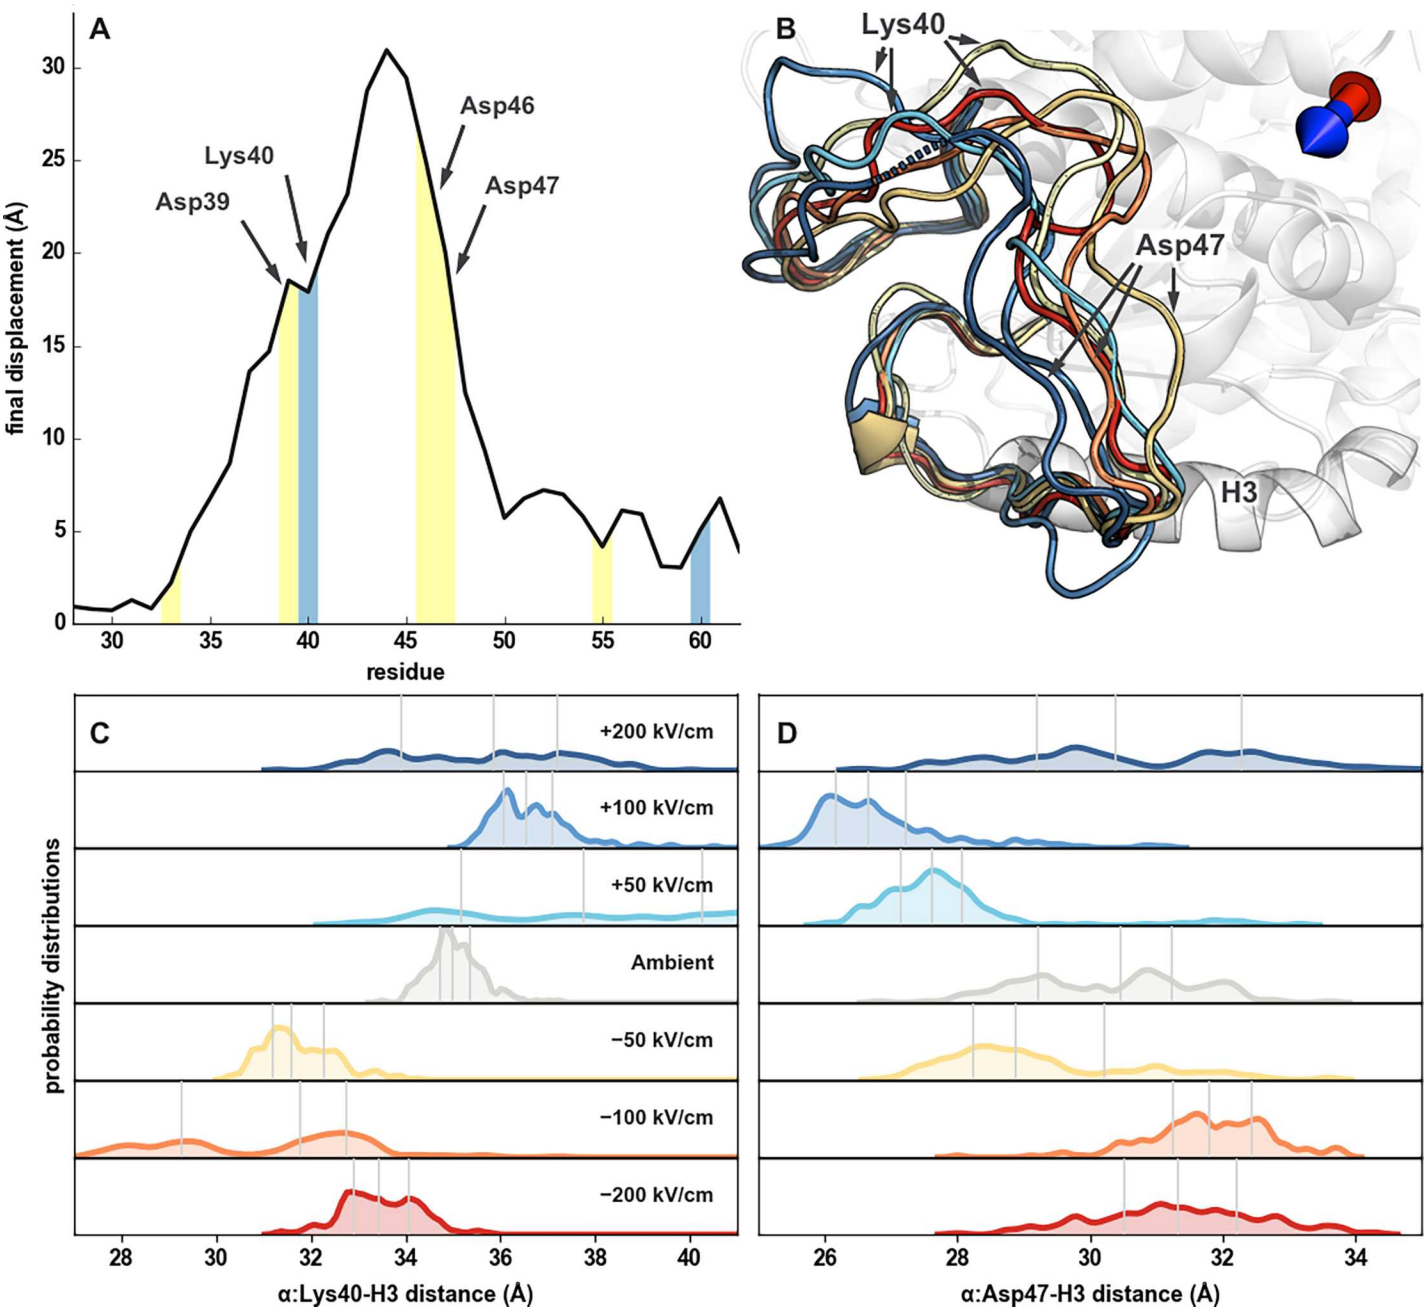

Fig 6. α:H1-B2 Loop's response to transverse external electric fields. Negatively and positively charged residues are highlighted with yellow and light-blue, respectively. (B) Average positions of the α:H1-B2 loop, during the final 5 ns of EEF application, along the transverse direction. Loop colors of dark blue, blue, light blue, yellow, light orange, orange, and red correspond to +200, +100, +50, 0, -50, -100, and -200 kV/cm field strengths, respectively. The positive and negative EEF directions are indicated with a blue and red arrowhead, respectively. (C, D) Probability distributions for the distance between α:40K and α:H3 and between α:47D and α:H3, using snapshots from the final 5 ns of EEF exposure, correspond to outward movement of the first and second half of the α:H1-B2 loop, respectively. Quartiles for distance measurements are indicated with vertical gray lines.

https://doi.org/10.1371/journal.pone.0202141.g006

Long-range electrostatics effects were treated with Particle-Mesh Ewald sum and a 12 Å cutoff [59]. We applied rigid bonds to hydrogen bonds, used a 2 femtosecond timestep, and saved frames to trajectories every 25 ps. We energy minimized the solvated structure for 25 ps,

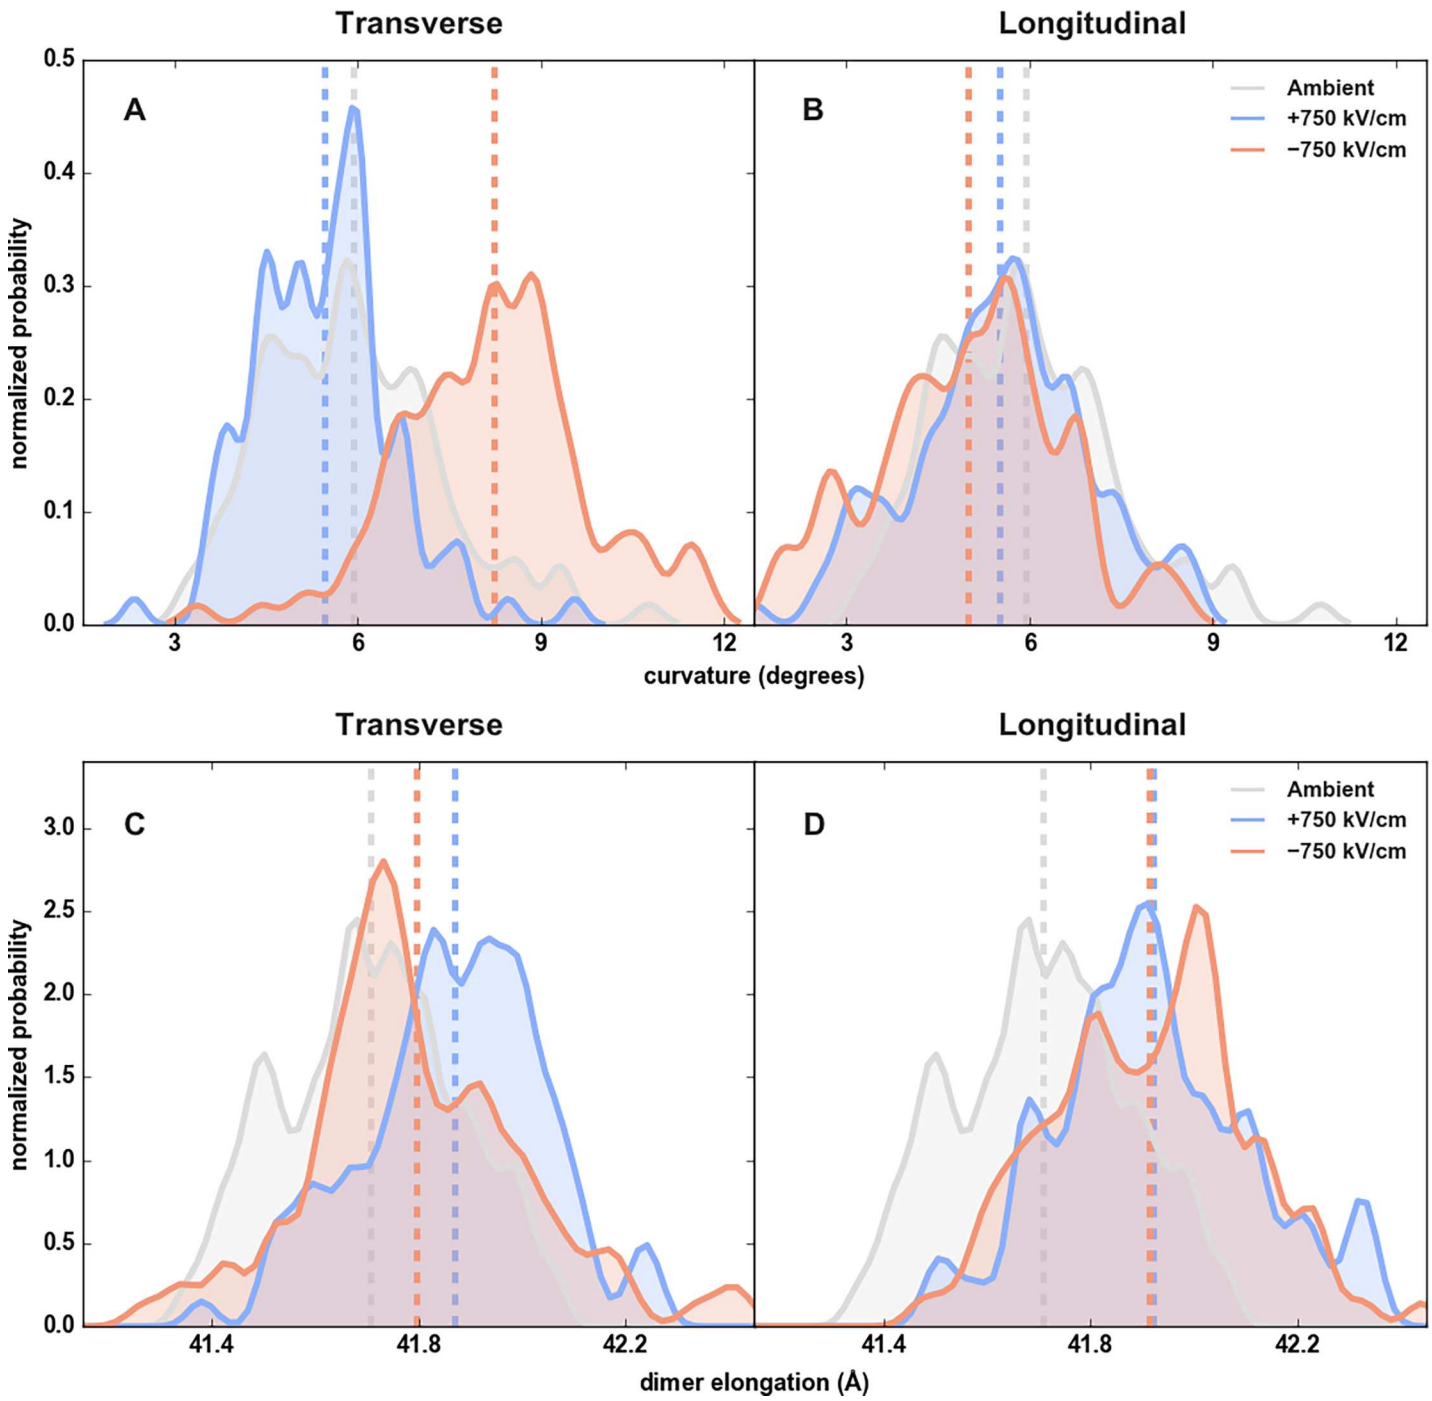

Fig 7. Tubulin essential dynamics in an external electric field. (A, B) Normalized probability distributions of tubulin's curvature and dimer elongation for the last 5 nanoseconds of EEF application. Curvature was calculated by the method presented in [51]. Elongation was measured as the distance between the center of mass of each monomer's alpha helices. Mean curvature and compaction are shown by dashed lines.

https://doi.org/10.1371/journal.pone.0202141.g007

equilibrated it for 500 ps in an NVT ensemble, then equilibrated it for 1 nanosecond in an NPT ensemble. Because of 1JFF's unfavorable initial conformation, we performed extensive additional energy minimization of the dimer by running it for an additional 100 ns in an NPT ensemble until convergence was definitive in RMSD. All simulations were run with the

CHARMM36 force field [60]. Notably, CHARMM36 is a non-polarizable force field in which dipoles are measured purely by the distribution of fixed charges. In future studies, electronic polarization by the EEF and or other modalities could be accounted for with a polarizable force field like Drude-2013 or AMOEBA-2013 [61–63]. NAMD 2.10 [64] was used to run the simulations on clusters of 64 nodes, each containing 16 cores, connected by Infiniband in a BlueGene/Q cluster. We ran equilibration and production simulations at 310˚K and coupled them to a Nosé-Hoover-Langevin piston for pressure control and used Langevin dynamics for temperature control.

We simulated static electric fields with the External Electric Field module of NAMD and applied them along four directions that we define as the positive and negative of the transverse and longitudinal axes, respectively (Fig 1). The positive transverse direction was that of the dimer's dipole moment at the start of the production runs while the negative transverse direction was its negative. The positive longitudinal direction was along the vector formed from the beta to the alpha monomers' center of mass at the beginning of the production runs; here again, the negative longitudinal vector was its negative. In addition to the control run, we ran simulations of EEFs at 750 kV/cm along each of the four major directions; we chose this initial magnitude based on other Molecular Dynamics studies of proteins in EEFs found in the literature [35,65,66]. We performed each production run for 50 ns and applied the EEFs between the 10 and 20 ns time points (using a 10 ns duration that is typical of nsPEFs [30]). Additionally, we simulated lower strength fields at 200, 100, and 50 kV/cm along the two transverse directions for 10 ns using the positions and velocities of the ambient production run at the ten-nanosecond mark for the first frame.

Analysis was performed with modules and scripting in VMD [58]. Per-residue displacement, referred to here as "final displacement," was calculated as the distance between alpha carbons after superimposing heterodimers exposed to two EEFs of opposite directionality, which is loosely based on the concept developed by Hekstra et al [67]. Tubulin's intradimer curvature (or bend angle) was calculated by the method described by Pecquer et al [51] and characterized by Peng et al [53]. Briefly, we calculated curvature as the intersection angle between the two best fit lines—created with the atoms of α:H7 and β:H7—from the Taxol bound tubulin dimer, PDB ID: 1JFF, and the dimer under study, after superimposing the two structures by the atoms of their α:H7s. We measured dimer elongation as the distance between the centers of mass from all alpha helices atoms in the α and β monomers, using atoms classified as belonging to alpha helices in the initial equilibrated structure.

Supporting information

S1 Fig. Secondary residue classifications in a 750 kV/cm EEF. (A, B) The total number of residues that are classified as alpha helices or beta sheets during the application of 750 kV/cm EEFs of four directions: positive transverse, negative transverse, positive longitudinal, and negative longitudinal.
(TIFF)

S2 Fig. Final displacement in a transverse external electric field and RMSF. Final displacement, measured as the distance between residues after 10 ns exposure to a positive and negative transverse EEF (black). Cα RMSF per residue of a tubulin heterodimer, from the 10 to 20 ns time frame, without exposure to an EEF (blue).
(TIFF)

S3 Fig. Salt bridges between the C-termini and the dimer surface. Representative salt bridges experienced by the C-termini when in a contracted state (lying along the dimer's surface).

A distance cutoff of 3.2 Å and the positions of the initial frame, after equilibration, were used to identify possible salt bridges.
(TIFF)

S4 Fig. Visualization of change in per-residue RMSF. Same as Fig 4 but with ΔRMSF of each residue mapped onto the structure. Red and blue indicate an increase and decrease in RMSF, respectively. Field directions are indicated with arrows.
(TIFF)

S5 Fig. Mean standard displacement of tubulin in a transverse external electric field. Mean standard displacement ($Å^2$) of tubulin from the start to the end of the application of a transverse EEF.
(TIFF)

Author Contributions

Conceptualization: Joshua J. Timmons, Jordane Preto, Jack A. Tuszynski, Eric T. Wong.

Data curation: Joshua J. Timmons.

Formal analysis: Joshua J. Timmons.

Investigation: Joshua J. Timmons.

Methodology: Joshua J. Timmons, Jordane Preto, Jack A. Tuszynski.

Resources: Jack A. Tuszynski.

Supervision: Jack A. Tuszynski.

Validation: Jordane Preto.

Writing – original draft: Joshua J. Timmons.

Writing – review & editing: Jordane Preto, Jack A. Tuszynski.

Two Fermions in a Double Well: Exploring a Fundamental Building Block of the Hubbard Model

Simon Murmann,* Andrea Bergschneider,* Vincent M. Klinkhamer, Gerhard Zürn, Thomas Lompe,† and Selim Jochim
Physikalisches Institut der Universität Heidelberg,
Im Neuenheimer Feld 226, 69120 Heidelberg, Germany

We have prepared two ultracold fermionic atoms in an isolated double-well potential and obtained full control over the quantum state of this system. In particular, we can independently control the interaction strength between the particles, their tunneling rate between the wells and the tilt of the potential. By introducing repulsive (attractive) interparticle interactions we have realized the two-particle analog of a Mott-insulating (charge-density-wave) state. We have also spectroscopically observed how second-order tunneling affects the energy of the system. This work realizes the first step of a bottom-up approach to deterministically create a single-site addressable realization of a ground-state Fermi-Hubbard system.

arXiv:1410.8784v2 [cond-mat.quant-gas] 17 Feb 2015

In the presence of strong correlations, the understanding of quantum many-body systems can be exceedingly difficult. One way to simplify the description of such systems is to use a discrete model where the motion of the particles is restricted to hopping between the sites of a lattice. The paradigmatic example for this approach is the Hubbard model, which reduces the physics of a quantum many-body system to tunneling of particles between adjacent sites and interactions between particles occupying the same site. While this model captures essential properties of electrons in a crystalline solid and provides a microscopic explanation for the existence of Mott-insulating and antiferromagnetic phases, many questions about this Hamiltonian — such as whether it can explain d-wave superfluidity — are still unanswered [1].

A promising approach to answer these questions is to use ultracold atoms trapped in periodic potentials as quantum simulators of the Hubbard model [2–8]. Such experiments have been performed both in large- and small-scale systems. Degenerate gases loaded into optical lattices have been used to observe the transition to the bosonic [9, 10] and fermionic Mott insulator [3, 4]. The first observation of second-order tunneling was achieved in a small-scale system by studying the tunneling dynamics of bosonic atoms in an array of separated double wells [11, 12]. In a recent experiment, these two regimes have been connected by splitting a fermionic Mott insulator into individual double wells. In this way, the strength of the antiferromagnetic correlations in the many-body system could be determined by measuring the fraction of double wells with two atoms in the spin-singlet configuration [13]. But despite the observation of antiferromagnetic correlations[13, 14] current experiments using fermionic atoms have so far failed to reach temperatures below the critical temperature of spin ordering [15, 16].

Recently, new experimental techniques have been developed which allow for the deterministic preparation of few-particle systems in the ground state of a single potential well [17–19]. This makes it feasible to use ultracold atoms to study many-body physics in a bottom-up approach, i.e. to start from the fundamental building block of the system and watch how many-body effects emerge as one gradually increases the system's size [20]. Here we report on the realization of the fundamental building block of the Fermi-Hubbard model at half filling, which consists of one $|\uparrow\rangle$ and one $|\downarrow\rangle$ particle in a spin-singlet configuration in a double-well potential.

By starting from this two-site realization of the Hubbard model, we can test our building block in a regime where the model can still be easily solved. In the Hubbard regime, the spatial wave function $|\Psi\rangle$ of this two-particle system can be written in the basis $\{\,|LL\rangle\,,|LR\rangle\,,|RL\rangle\,,|RR\rangle\,\}$. These basis states are all possible combinations of the localized single-particle states $|L\rangle$ and $|R\rangle$ of one particle in the ground state of either the left or the right well. In this basis, the spatial part of the Hamiltonian is

$$H = \begin{pmatrix} U+2\Delta & -J & -J & 0 \\ -J & 0 & 0 & -J \\ -J & 0 & 0 & -J \\ 0 & -J & -J & U-2\Delta \end{pmatrix}, \qquad (1)$$

with the tunneling matrix element J, the on-site interaction energy U and the energy tilt 2Δ between the wells. Diagonalizing this Hamiltonian leads to three eigenstates ($|a\rangle$, $|b\rangle$ and $|c\rangle$) which are symmetric and one eigenstate ($|d\rangle$) which is antisymmetric with respect to particle exchange (Fig 1b).

To prepare our double-well system, we start with two ^{6}Li atoms in different hyperfine states in the motional ground state of a single optical microtrap [17] (Sec. I of the Supplemental Material [21]). We then slowly ramp on a second potential well and thereby deform our single trap into a double-well potential. During this process, we keep the coupling between the wells negligible and thus initialize the system in state ($|LL\rangle$) where both atoms reside in the ground state of the left well. This state is the

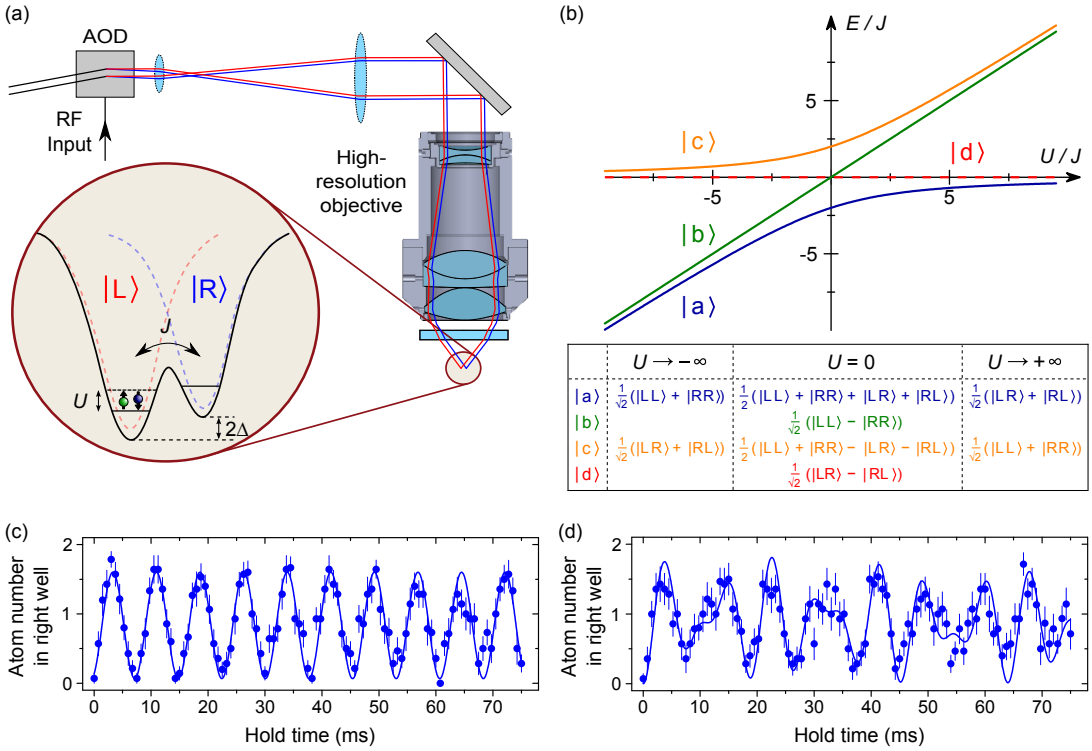

FIG. 1. Experimental realization and eigenenergies of the two-site Hubbard model. (a) Experimental setup: The double-well potential is created by focusing two laser beams with a high-resolution objective. By independently controlling the intensity and position of the two laser beams with an acousto-optic deflector (AOD) we can tune the tunnel coupling J and the tilt Δ between the two wells. (b) Energies of the four lowest two-particle eigenstates in a symmetric double-well potential as a function of the on-site interaction energy U. (c, d) Tunneling of two particles in the double well. The data show the time evolution of the particle number in the right well after initializing the system with both particles in the left well and abruptly switching on the tunnel coupling J between the two sites. For $U \approx 0$ and $\Delta \approx 0$ (c), we can extract the value of the tunnel coupling by fitting the data with a damped sine wave. For intermediate interaction strength ($U \approx J$) (d), we observe correlated tunneling of the two particles, which shows good agreement with the prediction from the Hubbard model (solid line). The error bars denote the 1σ statistical uncertainty.

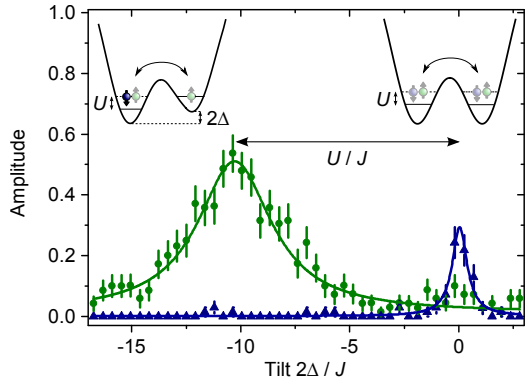

FIG. 2. Single-particle and pair tunneling as a function of the tilt Δ at an interaction energy of $U/J = 10.05 \pm 0.19$. The data points show the time-averaged probability of finding a single particle (green circles) or a pair of particles (blue triangles) in the right well after initializing the system with two atoms in the left well and switching on the tunneling. Pair tunneling is resonant in a symmetric double well, while conditional single-particle tunneling occurs for a tilt of $-2\Delta = U$. The error bars denote the 1σ statistical uncertainty.

starting point for all our measurements. We can prepare it with a fidelity of more than 90 %. The predominant error is that there is only one atom in the trapping potential, while the probability to start with three atoms is $\lesssim 1\,\%$.

Since the spatial wave function of the initial state is symmetric with respect to particle exchange, the spin wave function of the two fermions is in a singlet configuration. In the experiments presented here, we do not couple the position and the spin of the particles and therefore restrict the spatial wave function of the system to the symmetric eigenstates $|a\rangle$, $|b\rangle$ and $|c\rangle$.

In a first set of experiments, we study the tunneling dynamics of the two particles in our double-well potential to characterize the Hubbard parameters J, U, and Δ of our system. To do this, we initialize the system in state $|LL\rangle$ and abruptly reduce the height of the potential barrier, which allows the atoms to tunnel between the wells. To observe the resulting dynamics, we let the system evolve for different durations and then freeze the spatial distribution of the atoms by quickly increasing the barrier height. We then count the number of atoms in one of the wells by recapturing them into a magneto-optical

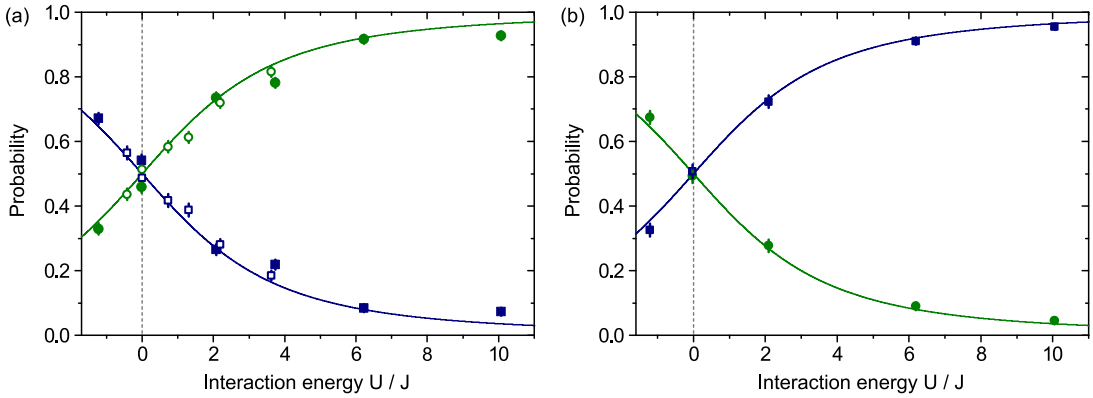

FIG. 3. Occupation statistics as a function of interaction strength. The relative probabilities of measuring both particles in the same well (P_2, blue squares) or in different wells (P_1, green circles) are shown as a function of the on-site interaction energy U. Open (filled) symbols indicate a tunnel coupling of $J/h \simeq 142\,\mathrm{Hz}$ ($J/h \simeq 67\,\mathrm{Hz}$), the solid lines show the prediction of the Hubbard model. (a) For the ground state $|a\rangle$, double occupancy is suppressed for increasing repulsive interactions. This indicates the crossover from a metallic to a Mott-insulating regime. For attractive interactions, double occupancy is enhanced, which we interpret as the onset of a charge-density-wave regime. (b) For the excited state $|c\rangle$, we observe the crossover to the charge-density-wave regime for strong repulsive interactions. For both measurements, the data have been corrected for the effect of the finite fidelities of preparation and detection (Sec. VII and Fig. S5 of [21]). The error bars denote the 1σ statistical uncertainty.

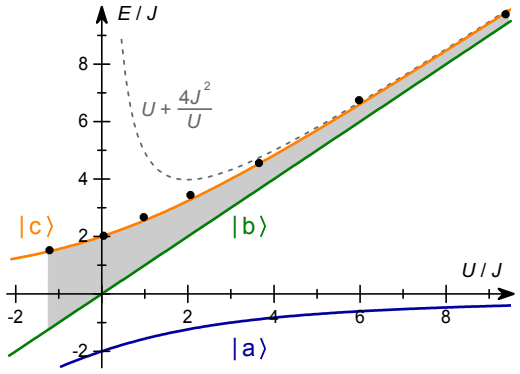

FIG. 4. Transition from first-order to second-order tunneling. To directly measure the influence of the tunnel coupling on the energy of the system, we determine the energy difference $E_{\mathrm{bc}} = E_{\mathrm{c}} - E_{\mathrm{b}}$ (shaded region) between state $|c\rangle$ (orange) and state $|b\rangle$ (green) using trap modulation spectroscopy. To compare our results to the eigenenergies of the Hubbard model (Fig. 1b), we plot the sum of E_{bc} and the energy of state $|b\rangle$ ($E_{\mathrm{b}} = U$). The error bars for the 1σ statistical uncertainties (Sec. VIII of [21]) are smaller than the symbols of the data points. For $U = 0$, we observe that $E_{bc} \approx 2J$, which is consistent with single-particle tunneling. For increasing repulsion, first-order tunneling is suppressed and E_{bc} converges to the superexchange energy $4J^2/U$ (see dashed line).

trap and measuring their fluorescence [28] [17] (Sec. III of [21]).

For a noninteracting system and a small tilt of the double well ($|\Delta| \lesssim J$), we observe long-lived tunneling oscillations whose frequencies we can set by tuning the barrier height (Sec. V.A, Fig. S1 and Fig. S2(a) of [21]). As an example, a typical oscillation for $\Delta \simeq 0$ with a frequency of $2J/h \simeq 134\,\mathrm{Hz}$ is shown in figure 1c. To calibrate Δ, we measure the oscillation frequency for different tilts and find good agreement with the effective coupling strength $J_{\mathrm{eff}} = \sqrt{J^2 + \Delta^2}$ of a two-level system (Sec. V.B and Fig. S2(b) of [21]).

For an interacting system, the interaction energy creates an effective detuning for the tunneling of a single particle. In the limit of strong interactions and a symmetric double well ($U \gg J$ and $\Delta = 0$), the atoms can therefore only tunnel as pairs [29]. However, we can restore single-particle tunneling by setting a tilt that compensates for the interaction shift [11]. This allows us to calibrate the on-site interaction energy U by measuring the strength of single-particle tunneling as a function of the tilt Δ for different interaction strengths (Fig. 2). We find good agreement with a calculation of the interaction energy of two particles in the single well [25] (Sec. V.C and Fig. S3 of [21]).

Using the parameters determined from these measurements, the two-site Hubbard Hamiltonian (Eq. 1) fully describes the oscillations of two interacting particles in our double well (solid line in Fig. 1d).

To use our system as a fundamental building block of the Hubbard model, we must be able to prepare the particles in the ground state of the symmetric double well. To achieve this, we first initialize the system with both atoms in the left well and a tilt $\Delta \ll 0$. Then, we adiabatically change the tilt to bring the system into the ground state of the symmetric double well [30] (Sec. VI and Fig. S4 of [21]) [31].

To show that our fundamental building block already contains the physics that is responsible for the formation of ordered phases in a many-body system, we first measure the influence of the interaction energy U on the distribu-

tion of the two particles between the wells. We therefore determine the probabilities $P_1 = |\langle\Psi|LR\rangle|^2 + |\langle\Psi|RL\rangle|^2$ of finding the two particles on different sites (single occupancy) and $P_2 = |\langle\Psi|LL\rangle|^2 + |\langle\Psi|RR\rangle|^2$ of finding both particles on the same site (double occupancy) by measuring the probabilities of having 0, 1 or 2 atoms in one of the wells (Sec. VII of [21]).

In a noninteracting system ($U = 0$), the spatial wave function of two particles in the ground state is an equal superposition of the basis states $|LL\rangle$, $|LR\rangle$, $|RL\rangle$, and $|RR\rangle$. This leads to equal probabilities P_1 and P_2 which we observe in our measurements (Fig. 3a).

In a system with strong repulsive on-site interactions, it is energetically unfavorable to have two atoms occupying the same site. The ground state of our system then becomes a two-particle analog to a Mott-insulating state which we observe as a reduction of double occupancy. For attractive interactions we observe an increase in double occupancy that marks the onset of a paired state. We interpret this state as the two-particle limit of the cold gas analog of a charge-density-wave state as described in [32]. We perform these measurements for two different barrier heights. For the larger barrier height ($J/h \simeq 67\,\mathrm{Hz}$), we find good agreement with the prediction of the Hubbard model (Fig. 3a). For the smaller barrier height ($J/h \simeq 142\,\mathrm{Hz}$), we observe a small deviation from the theoretical expectations which might indicate that our system is approaching the limits of the Hubbard approximation.

Since in our isolated, two-particle system excited states are stable against relaxation, we can also prepare the system in the highest-energy eigenstate $|c\rangle$ (Fig. S4 of [21]). When measuring the occupation statistics of this state as a function of interaction strength, we find that the number of doubly occupied sites is enhanced for repulsive interactions (Fig. 3b). This allows us to study the charge-density wave regime in a system with repulsive interactions.

In our final measurement, we directly probe the effect of the tunnel coupling on the energy of the system by trap modulation spectroscopy (Sec. VIII of [21]). For this, we initialize the system in state $|c\rangle$ and measure the energy difference to state $|b\rangle$ as a function of interaction strength. For $U = 0$, the atoms are delocalized over the wells by single-particle tunneling. This leads to a change in the kinetic energy of the system that is proportional to the tunnel coupling J (Fig. 4). As we increase the interactions, the system enters the insulating regime and first-order tunneling is suppressed. However, second-order tunneling is still possible and we observe a crossover to a new energy scale given by the superexchange energy $4J^2/U$. This energy is directly responsible for the appearance of spin order in the ground state of the Hubbard model [33].

By combining a series of isolated double wells we can realize a dimerized lattice [13] where each dimer contains two fermions in a spin-singlet configuration with high fidelity. By adiabatically lowering the barriers between the double wells, we can then prepare a low-entropy state in a homogeneous lattice. Since our systems can be prepared with arbitrary filling factors they are also ideally suited to study the effects of hole doping. Additionally, the tunability of our potential allows us to explore finite-size lattices with arbitrary geometries [34] and introduce controlled disorder into our system. Finally, our experiments provide a starting point for scalable quantum computation with neutral atoms [35–38].

SUPPLEMENTAL MATERIAL

I. PREPARATION OF TWO FERMIONS IN A MICROTRAP

We start our experiments by preparing two ^{6}Li atoms in the $|F = 1/2, m_F = +1/2\rangle$ and $|F = 1/2, m_F = -1/2\rangle$ hyperfine states – labeled $|\uparrow\rangle$ and $|\downarrow\rangle$ – in the motional ground state of an optical microtrap. To do this we follow the procedure established in Serwane et al.[17]. We first prepare a two-component Fermi gas consisting of $N_{|\uparrow\rangle} \approx N_{|\downarrow\rangle} \approx 2.5 \times 10^4$ atoms in a crossed-beam optical dipole trap at a temperature of $T \approx 250\,\mathrm{nK}$. This dipole trap acts as a reservoir from which we load about 1000 atoms into our microtrap, which is created by focusing a far red-detuned laser beam ($\lambda = 1064\,\mathrm{nm}$) with a custom-designed high-resolution objective (NA = 0.55)[22]. We then apply a magnetic field gradient to deform the trapping potential until only a single bound state remains in the microtrap. This spilling technique allows us to prepare systems of one $|\uparrow\rangle$ and one $|\downarrow\rangle$ atom in the ground state of the trap with a typical fidelity above 90%.

To characterize our microtrap, we have measured its trapping frequencies using modulation spectroscopy. We find trap frequencies of $\omega_{\mathrm{ax}} \approx 2\pi \times 2.5\,\mathrm{kHz}$ and $\omega_{\mathrm{rad}} \approx 2\pi \times 16.5\,\mathrm{kHz}$ at an optical power of $P \approx 393\,\mu\mathrm{W}$, which is in good agreement with our expectations for a cigar-shaped dipole trap with a waist of $w_0 \approx 1.66\,\mu m$ and an aspect ratio $\eta \approx 7$.

II. CREATION OF THE DOUBLE-WELL POTENTIAL

To form a double-well potential, we create two microtraps which are partially overlapping. We achieve this by using an acousto-optical deflector (AOD) to create two separated laser beams that are incident upon the objective under slightly different angles, which the objective translates into a spatial separation of the two foci in the focal plane. To control the spacing and the tilt of the resulting double-well potential we tune the relative angle and intensity of the two trapping beams. We do this by changing the frequencies and amplitudes of two RF-signals driving the AOD. To obtain a tunnel coupling which is on the order of 100 Hz at our typical light powers of $200\,\mu\mathrm{W}$, we set the frequencies to values of 32 MHz and 38 MHz which corresponds to a spacing of the double well of $d \approx 2\,\mu\mathrm{m}$. To tune the strength of the tunnel coupling during our experiments, we change the overall depth of the potential which we control by actively stabilizing the overall light power P_{tot} of the trapping beams. At these trap parameters, the individual wells have a depth of approximately $h \times 30\,\mathrm{kHz}$ and the height of the potential barrier between them is approximately $h \times 5.4\,\mathrm{kHz}$. To compare our double well to optical lattice experiments, we can define an effective lattice wavelength $\lambda_{\mathrm{eff}} = 2d$ and calculate the recoil energy $E_{\mathrm{rec}} = h^2/2m\lambda_{\mathrm{eff}}^2 \approx h \times 2.1\,\mathrm{kHz}$, where h is the Planck constant and m is the mass of ^{6}Li.

III. SITE-SELECTIVE ATOM NUMBER DETECTION

Since our experiment allows us to independently address the individual wells of our potential, we can perform site-selective atom-number detection by switching off one of the wells and measuring the number of atoms in the remaining well.

To do this, we first decouple the wells by rapidly increasing the height of the potential barrier within 2 ms. This ramp is fast compared to the time scale of the tunnel coupling but slow enough to avoid heating of the atoms into higher trap levels. Then we slowly turn off one of the wells while keeping the overall light power constant. During this process, the atoms in this well are adiabatically transferred into excited states of the remaining well. Therefore, we use the spilling technique introduced above to remove all atoms from these highly excited states.

To count the number of atoms in the remaining well, we release the atoms from the microtrap, recapture them in a magneto-optical trap and measure their fluorescence with a CCD camera (Andor iXon DV887) for an exposure time of 1 second [17].

IV. THE TWO-SITE HUBBARD MODEL

To experimentally realize the Hubbard model, our double-well system has to fulfill the tight-binding approximation and the single-band approximation.

In a lattice potential, the wavefunction of a single particle can be described as a superposition of localized wavefunctions centered on the individual sites of the lattice. In the limit of tight binding, the overlap between wavefunctions located on different sites is small and they can be approximated by the eigenstates of the individual wells. In this case, the tunnel coupling J between adjacent sites is much smaller than the lowest excitation energy on the individual wells. Since in our double well, the tunneling constant J is approximately $h \times 100\,\mathrm{Hz}$ and the axial trap frequency ω_{ax} in each well is about $2\pi \times 1\,\mathrm{kHz}$, the tight-binding approximation is well fulfilled in our system.

In the single-band approximation, one only considers the motion of the particles in the lowest Bloch band, which is composed of the ground states of the individual wells. To fulfill this approximation, all energy scales in the system have to be much smaller than the band gap to the first excited band. In our double-well system, we initialize both atoms in the ground state of one well (see Sec. I) and limit the interaction energy U to values smaller than the lowest excitation energy of the single wells during all our experiments. For all but the largest values of the interaction energy we estimate the wavefunction overlap

between two interacting particles localized in a single potential well and the respective non-interacting ground state to be above 97 %. For the largest interaction energies of $U \approx h \times 650\,\mathrm{Hz}$ for the dataset with $J = 67\,\mathrm{Hz}$ ($U \approx h \times 400\,\mathrm{Hz}$ for $J = 142\,\mathrm{Hz}$) the overlap decreases to $\approx 92\,\%$ ($\approx 94\,\%$).

Using these two approximations, the spatial wavefunction of a single particle in our double-well system can be described as a superposition of the ground-state wavefunctions of a particle in the left $|L\rangle$ or the right $|R\rangle$ well. This results in a two-level system where the states $|L\rangle$ and $|R\rangle$ are coupled with a tunnel coupling J.

V. CALIBRATION OF THE HUBBARD PARAMETERS

We calibrate the Hubbard parameters of our double well by observing the tunneling dynamics in our system. To determine J and Δ, we study the tunneling of two non-interacting particles between the wells (Sect. V A and Sect. V B). We then determine the on-site interaction energy U for different strengths of the interparticle interaction (Sect. V C).

A. Tunneling oscillations

To prepare the initial state for our tunneling experiments, we start from two non-interacting atoms in the ground state of a single microtrap (see Sec. I). Then we slowly ramp on a second trapping beam (see Sec. II) and thereby change the shape of the potential from a single Gaussian well to a double-well potential. During this ramp, we linearly increase the overall power P_{tot} to keep the depth of the initial well constant. At any time in this process, P_{tot} is large enough to prevent the atoms from tunneling between the wells.

To start the tunneling dynamics, we lower the height of the barrier between the two wells within 2 ms. Since this ramp is fast compared to the time scale of the tunnel coupling we can treat it as a sudden switch-on of the tunneling. Yet, this ramp is slow enough to avoid exciting the atoms into higher bands. We then let the system evolve for different hold times, ramp up the barrier to decouple the wells and finally measure the number of atoms in one of the wells, using the detection scheme described above.

As an example, the tunneling oscillation of two non-interacting atoms in a symmetric double-well at an overall power of $P_{\mathrm{tot}} = 131\,\mu\mathrm{W}$ is shown in Fig. 1. To determine the value of the tunnel coupling J we fit the observed oscillation with a damped sine wave and find $J/h = (142.9 \pm 0.1)\,\mathrm{Hz}$ and a damping time of $(83 \pm 9)\,\mathrm{ms}$. We believe that the main cause for the observed damping is dephasing due to long-term drifts of the tilt of the double-well potential.

To calibrate J for different barrier heights, we perform these measurements for different values of the overall light power P_{tot} (Fig. 2a). For our experiments, we use light powers of $P_{\mathrm{tot}} = 131\,\mu\mathrm{W}$ and $P_{\mathrm{tot}} = 186\,\mu\mathrm{W}$ which result in tunnel couplings of $J/h = (142.0 \pm 0.5)\,\mathrm{Hz}$ and $J/h = (67.3 \pm 0.5)\,\mathrm{Hz}$.

B. Calibration of the tilt

Tunneling between two states that are separated by a potential barrier is only possible if their energy difference Δ is not much larger than their tunnel coupling J. To achieve this for our double-well system, we control the relative depth of the two wells by changing the relative power of the RF signals driving the AOD (see Sec. II).

To calibrate the tilt Δ, we measure the oscillation frequency for various values of the relative RF power (Fig. 2b)[23]. We fit the measured frequencies with the effective coupling $2\,J_{\mathrm{eff}} = 2\sqrt{J^2 + \Delta^2}$ expected for a two-level system. We find good agreement to the data and therefore conclude that our non-interacting system can be described by the two-site Hubbard model (see Sec. IV). Using this fit, we calibrate the tilt Δ in units of the tunnel coupling J and extract the relative RF power where the double well is balanced ($\Delta = 0$).

To observe coherent tunneling in our double-well system, we have to stabilize the relative depth of the two wells with a precision better than J. For our typical trap depth of 30 kHz and tunnel couplings of $J/h \approx 100\,\mathrm{Hz}$ (at an overall light power of $P_{\mathrm{tot}} \approx 200\,\mu\mathrm{W}$), this corresponds to a relative stability of the intensities of the two beams that is on the order of 10^{-4}.

However, switching on the second well leads to heating of the AOD which results in a slow drift of Δ on the order of $h \times 300\,\mathrm{Hz}$ over several seconds. Since these drifts are the same in every experimental cycle, we can compensate them by applying an exponential ramp to the relative RF power. Using this technique, our stability is currently limited by slow drifts of the tilt which are on the order of 10 Hz to 20 Hz per day.

C. Calibration of the on-site interaction

To control the on-site interaction energy U between two particles that occupy the same well, we change the s-wave scattering length a between the atoms with a magnetic Feshbach resonance. To calibrate the interaction energy as a function of the magnetic offset field, we study the tunneling of two interacting particles.

For a system with two particles in one well, the energy is shifted with respect to the non-interacting system by the interaction energy U. If the two particles tunnel together, this interaction energy is conserved and consequently pair tunneling is resonant in a symmetric double well at all interaction strengths. However, if a single particle tunnels to the other well the particles can no longer interact

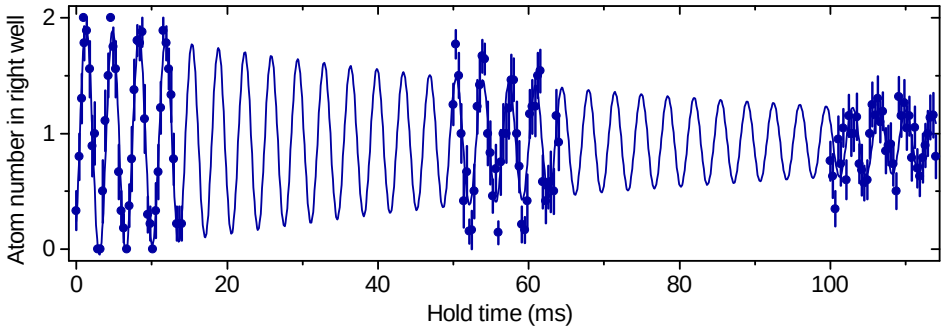

FIG. 1. Tunneling of two non-interacting particles in a symmetric double-well potential. Time evolution of the atom number in the right well for a system with two particles in the left well at $t = 0$. Each data point is the average of 15 measurements. The solid line shows a damped sinusoidal fit to the data from which we determine the tunnel coupling J. The error bars denote the 1σ statistical uncertainties.

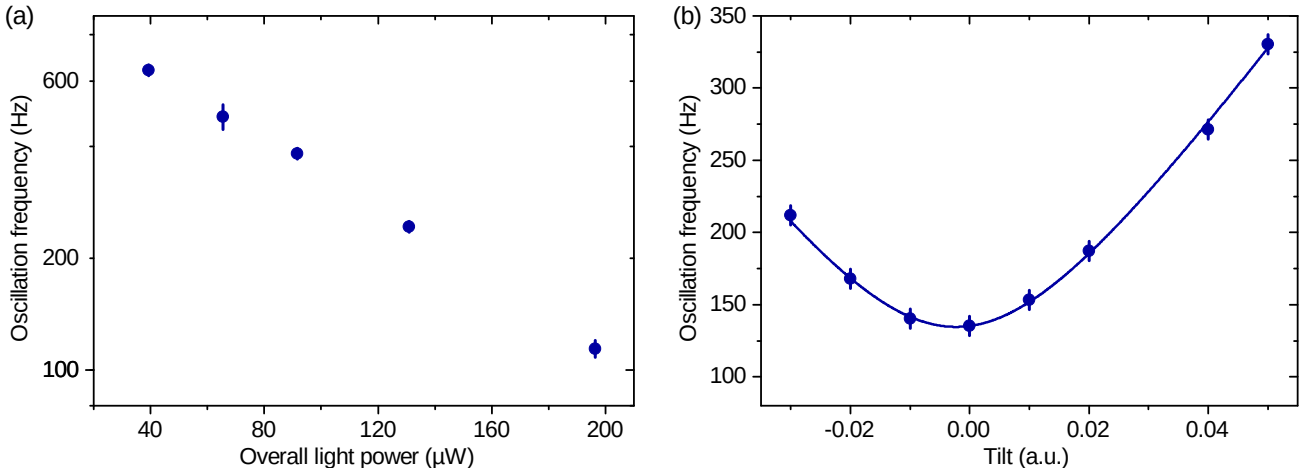

FIG. 2. Oscillation frequencies for different parameters of the double well. (a) Oscillation frequency of two non-interacting particles in a symmetric double well ($\Delta \approx 0$) as a function of the overall light power in the trap beams. A decrease of the total light power lowers the barrier height and thereby leads to a faster tunneling of the atoms between the wells. (b) Oscillation frequency as a function of the relative RF power of the two signals that drive the AOD. The solid line shows a fit with the effective tunnel coupling $2\,J_{\mathrm{eff}} = 2\sqrt{J^2 + \Delta^2}$ expected for a two-level system. From the fit, we extract the relative RF power where the double well is balanced. The error bars denote the 1σ statistical uncertainties.

and hence single-particle tunneling is effectively detuned by the interaction energy U. We can compensate this effective detuning by a tilt of $2\Delta = -U$ between the two wells[11]. This allows us to determine the on-site interaction energy by measuring the value of the tilt at which single-particle tunneling is restored.

To perform this calibration, we measure the amplitudes of single-particle and pair tunneling as a function of tilt. To do this we initialize the system with two interacting atoms in the left well, let them tunnel between the wells for different hold times and measure the number of atoms in the right well. From these measurements, we extract the probabilities of finding 1 or 2 atoms in the right well, average over all hold times and plot them as a function of the tilt (Fig. 2 of main text). We observe that the tilt at which single-particle tunneling is resonant shifts with the interaction strength whereas the pair-tunneling resonance remains at $\Delta = 0$. By fitting Lorentzians to the resonance peaks and measuring their separation, we can therefore determine the value of the on-site interaction U for different magnetic fields (Fig. 3a).

Since the value of the on-site interaction energy depends on the depth of the confining potential, we perform the calibration of U for the two potential depths (see Sec. V C) we use in our experiments. To check whether the measured interaction energies are affected by off-site interactions we compare our results to a calculation of the interaction energy of two particles in a cigar-shaped potential (Fig. 3b)[25, 26]. Within the errors we find good agreement with our data and therefore conclude that the effects of off-site interactions in our experiments are small. The good agreement between the measured and calculated interaction energies allows us to use the results from this calculation as the calibration for U for all our measurements.

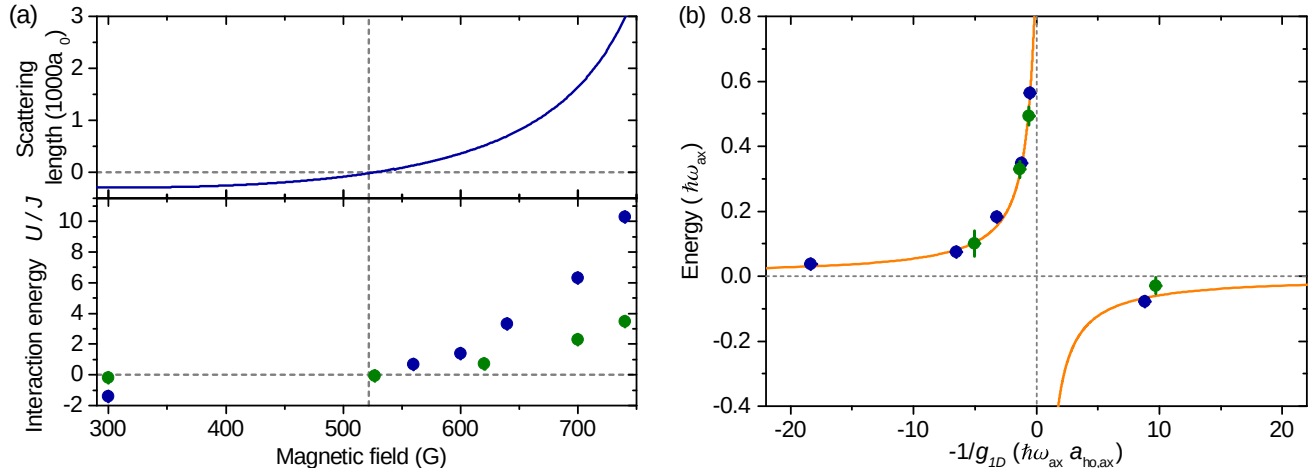

FIG. 3. Measurement of the on-site interaction energy U for two different tunnel couplings. (a) Interaction energy U in units of the tunnel coupling J as a function of the magnetic offset field. The green (blue) dots correspond to a tunnel coupling of $J = h \times (142.0 \pm 0.5)$ Hz ($J = h \times (67.3 \pm 0.5)$ Hz). (b) Interaction energy U in units of the harmonic oscillator energy $\hbar\omega_{\rm ax}$ plotted as a function of the one-dimensional interaction strength $g_{\rm 1D}$ [24] where $a_{\rm ho,ax} = \sqrt{2\hbar/(m\omega_{\rm ax})}$ denotes the harmonic oscillator length in axial direction and m is the mass of a ^{6}Li atom. The data shows good agreement with a calculations of the interaction energy of two particles in a single quasi-1D potential well (solid line)[25]. The error bars denote the 1σ statistical uncertainties.

VI. PREPARATION OF EIGENSTATES OF THE SYMMETRIC DOUBLE WELL

To prepare two atoms in an eigenstate of the symmetric double well, we start with two non-interacting atoms in the ground state of a single well and adiabatically change the shape of the potential to a double well. To prepare the system in the ground state $|a\rangle$, we initialize the system in state $|LL\rangle$, but keep the left well much deeper than the right one. Then, we lower the potential barrier between the wells and thereby set the tunnel coupling J to a value of about $h \times 100$ Hz. By setting a tilt of $|\Delta| \approx \frac{1}{2}\hbar\omega_{ax}$, we make sure that tunneling is far off-resonant ($|\Delta| \gg J$) and the initial state $|LL\rangle$ has almost complete overlap with the ground state of the tilted double well (Fig. 4). By adiabatically reducing the tilt to $\Delta = 0$ within 100 ms we then bring the system into the ground state of the symmetric double well.

Using the same technique, we can also prepare the atoms in the highest energy state $|c\rangle$. To do this, we start again in state $|LL\rangle$, but this time we set the right well to be much deeper than the left one ($\Delta \approx +\frac{1}{2}\hbar\omega_{ax}$). Lowering the barrier then transforms the initial state $|LL\rangle$ into state $|c\rangle$ (Fig. 4).

After preparing the non-interacting eigenstate of the double-well system, we adiabatically introduce interparticle interactions by ramping the magnetic field from the zero-crossing of the scattering length at 527 G to values between 300 G and 740 G over 60 ms. This corresponds to scattering lengths between $-288\,a_0$ and $2974\,a_0$ and interaction energies between $U/h \approx -1.3\,J/h \approx -87$ Hz and $U/h \approx 10.1\,J/h \approx 680$ Hz, where a_0 is the Bohr radius (Fig. 3).

Similar to the experimental sequence presented here, one can also start from an interacting system with large tilt and both particles in the deeper well and then adiabatically go to the ground state of the symmetric double well [27].

To confirm the adiabaticity of the ramps in tilt and in interaction strength, we drive the system from state $|LL\rangle$ to the final configuration, hold the system for different durations and then reverse both ramps. To check for excitations, we measure the mean atom number in the ground state both with and without the ramps. Within the statistical uncertainty of our measurement we could not detect any heating caused by the ramps. From these measurements, we determine a fidelity of $91.6 \pm 0.7\%$ of preparing the system in the ground state of the symmetric double well.

VII. NUMBER STATISTICS AND PREPARATION FIDELITY CORRECTION

To observe the transition from the metallic to the insulating regime, we measure the probability of single and double occupancy in the symmetric double well as a function of interaction strength (Fig. 3 of main text). Hence, we first prepare the system either in state $|a\rangle$ or state $|c\rangle$ at different interaction strengths (see Sec. VI). Then, we quickly ramp up the potential barrier to decouple the wells and measure the atom number in either the left or the right well. We repeat this measurement 300 times for each well and count how often we detect zero atoms (N_0), one atom (N_1), or two atoms (N_2). The probabilities of measuring 0, 1, or 2 atoms follow as: $a'_i = N_i/(N)$, where $i \in 0, 1, 2$ and N is the total number of measurements in

	Δ → − ∞	Δ = 0	Δ → + ∞
|a⟩	|LL⟩	$\frac{1}{2}$(|LL⟩ + |RR⟩ + |LR⟩ + |RL⟩)	|RR⟩
|b⟩	$\frac{1}{\sqrt{2}}$(|RL⟩ + |LR⟩)	$\frac{1}{\sqrt{2}}$(|LL⟩ − |RR⟩)	$\frac{1}{\sqrt{2}}$(|RL⟩ + |LR⟩)
|c⟩	|RR⟩	$\frac{1}{2}$(|LL⟩ + |RR⟩ − |LR⟩ − |RL⟩)	|LL⟩

FIG. 4. Eigenenergies and eigenstates in a tilted double well. Energies of states $|a\rangle$, $|b\rangle$, and $|c\rangle$ in a non-interacting system as a function of the tilt Δ between the wells. Depending on the sign of the initial tilt, state $|LL\rangle$ can be used to prepare either state $|a\rangle$ or state $|c\rangle$.

both wells.

In our measurement, we have finite fidelities both for the preparation of the initial state and the detection of the final atom number. Both the preparation fidelity and the detection fidelity reduce the measured atom numbers as compared to an ideal measurement. In a symmetric double well the influence of these processes on the measured probabilities cannot be distinguished. We therefore combine the preparation and detection fidelity into an overall fidelity p which we define as the mean atom number per well. We determine p by averaging over all individual measurements.

Due to the finite fidelity $p < 1$ of our experiment, the measured probabilities a_0', a_1', and a_2' deviate from the probabilities a_0, a_1, and a_2 of an ideal experiment with $p = 1$:

$$a_2' = a_2 p^2 \tag{2}$$
$$a_1' = a_1 p + 2a_2 p(1-p) \tag{3}$$
$$a_0' = a_0 + a_1(1-p) + a_2(1-p)^2 \tag{4}$$

These three equations can be inverted to calculate the ideal probabilities:

$$a_2 = a_2'/p^2 \tag{5}$$
$$a_1 = a_1'/p - 2(1-p)a_2'/p^2 \tag{6}$$
$$a_0 = a_0' - a_1'(1-p)/p + a_2'(1-p)^2/p^2 \tag{7}$$

Using these corrected probabilities, we define single occupancy as the probability of measuring a single atom ($P_1 = a_1$) and double occupancy as the sum of the probabilities of measuring either zero or two atoms ($P_2 = a_0 + a_2$). For comparison, the results for single occupancy and double occupancy in the ground state $|a\rangle$ using both the corrected and the non-corrected probabilities are shown in Fig. 5. To verify that our measurement of the occupation statistics is insensitive to small drifts of the tilt, we performed the measurement for state $|c\rangle$ at different tilts in a range of ± 30 Hz around $\Delta = 0$. We observe that while the tilt affects the probabilities a_0 and a_2 of finding zero or two particles in the individual wells there is no significant change in the double occupancy $a_0 + a_2$.

VIII. TRAP MODULATION SPECTROSCOPY

To directly observe the effect of the tunnel coupling on the energy of our double-well system, we measure the energy difference $E_{bc} = E_c - E_b$ between state $|c\rangle$ and state $|b\rangle$ by trap modulation spectroscopy. We start by initializing state $|c\rangle$ with a tunnel coupling of $J = h \times 67.3$ Hz and interaction energies between $U = -1.3\,J$ and $U = 10.1\,J$, as described above. Then we perform a sinusoidal modulation of the total trapping power with frequencies between $f = 30$ Hz and $f = 300$ Hz for a

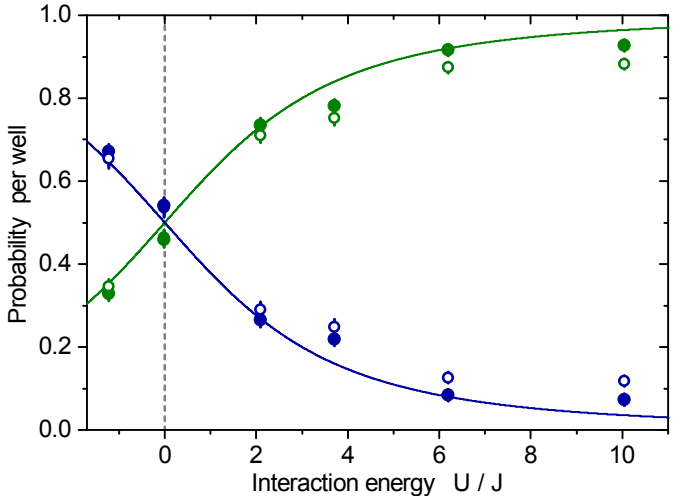

FIG. 5. Corrected and non-corrected occupation statistics. Single occupancy (green) and double occupancy (blue) in state $|a\rangle$ as a function of the on-site interaction energy U at a tunnel coupling of $J/h \simeq 67\,\mathrm{Hz}$. Open symbols correspond to the occupation statistics which were directly calculated from the measured probabilities of finding 0, 1, or 2 atoms in one of the wells. For the filled symbols, these probabilities were corrected for the finite experimental fidelities in the preparation and detection processes before calculating the occupation statistics. The solid lines show the prediction of the Hubbard model. The error bars denote the 1σ statistical uncertainties.

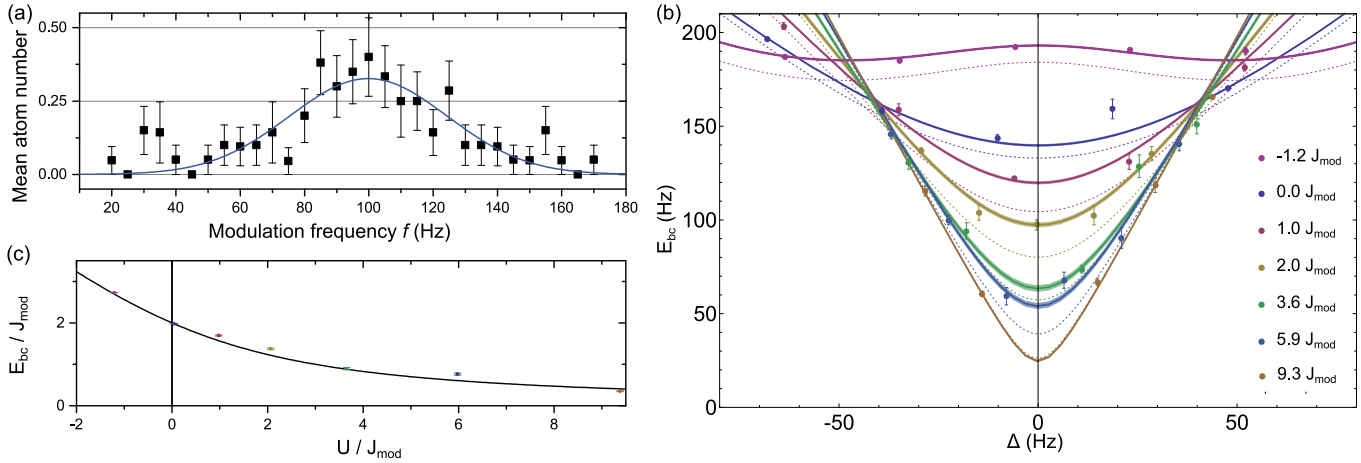

FIG. 6. Energy difference E_{bc} between states $|c\rangle$ and $|b\rangle$. (a) Mean atom number in the right well at different modulation frequencies for $U = 5.9 J_{\mathrm{mod}}$ and $\Delta/h = -22\,\mathrm{Hz}$. The resonance frequency is extracted from a Gaussian fit to the peak (blue curve). (b) Resonance frequency of the transition between states $|c\rangle$ and $|b\rangle$ as a function of the tilt Δ for different interaction energies. The predictions by the Hubbard model without free parameters are shown as dashed lines. The solid curves are fits to the data using the Hubbard model with J as a free parameter, the shaded areas are the respective 1σ confidence bands for the mean predictions. (c) Energy difference E_{bc} of the balanced double well plotted against the interaction energy U. The errors correspond to the width of the respective confidence bands at $\Delta = 0$ in the right panel.

duration of 200 ms. The atoms are transferred resonantly to state $|b\rangle$ if the modulation frequency matches the energy difference E_{bc}. To minimize the distortion of the energy spectrum, we modulate the tunnel coupling only with a small amplitude of $0.11\,J$. To determine whether the atoms have been transferred to state $|b\rangle$, we adiabatically turn off the interactions, ramp to a large tilt $\Delta \gg 0$ and measure the number of atoms in the right well. If the system has remained in state $|c\rangle$ during the modulation, both atoms are then in the left well. However, if the system has been transferred to state $|b\rangle$, there is a large probability to observe a single atom in the right well for $\Delta \gg 0$ (Fig. 4). We plot the mean atom number in the right well as a function of the modulation frequency and extract the resonance frequency with a Gaussian fit (Fig. 6a).

To measure the effects of second-order tunneling, we have to control the tilt better than $4J^2/U$, which is approximately 30 Hz at $U \approx 10J$. This is comparable to the residual drifts in our calibration of the tilt Δ over the

course of several days (see Sec. V B). We solve this problem by measuring the resonance frequency for different tilts around $\Delta = 0$ for each of the interaction energies. We determine the shift $\Delta_0 = \Delta' - \Delta$ between our set value Δ' and the tilt Δ in the experiment for each data set by fitting a Rabi function $f_\mathrm{R} = 2\sqrt{J^2 + (\Delta' - \Delta_0)^2}$ with Δ_0 and J as free parameters. We then center our data by subtracting the respective Δ_0.

For a non-interacting system, the energy difference E_{bc} is given by the transition frequency $f_\mathrm{R}(\Delta = 0)$. For an interacting system, we can still use this fit to center our data, but it does not yield the correct value for E_{bc}. Hence, we compare our measurements to a numeric solution of the Hubbard model with fixed parameters U and J as calibrated from the tunneling measurements (dashed curves in Fig. 6b). We observe resonance frequencies which are systematically higher than predicted. Therefore, we fit the data with a numeric Hubbard model with J' as a free parameter (solid lines). We obtain $E_{bc}(\Delta = 0)$ for the balanced double-well system at different values of U from the fitted curves (Fig. 6c and Fig. 4 of the main text).

One possible cause for the deviation of the fixed-parameter Hubbard model from our data is that the modulation of the trapping potential results in a modified tunnel coupling. Therefore, we scale E_{bc} and U with the modified tunnel coupling $J_\mathrm{mod} = h \times (70.7 \pm 0.3)\,\mathrm{Hz}$ which we obtain from the fit at $U = 0$.
