ABSTRACT Microtubules (MTs) are important cytoskeletal structures engaged in a number of specific cellular activities, including vesicular traffic, cell cyto-architecture and motility, cell division, and information processing within neuronal processes. MTs have also been implicated in higher neuronal functions, including memory and the emergence of ''consciousness''. How MTs handle and process electrical information, however, is heretofore unknown. Here we show new electrodynamic properties of MTs. Isolated, taxol-stabilized MTs behave as biomolecular transistors capable of amplifying electrical information. Electrical amplification by MTs can lead to the enhancement of dynamic information, and processivity in neurons can be conceptualized as an ''ionic-based'' transistor, which may affect, among other known functions, neuronal computational capabilities.

INTRODUCTION

MTs are long hollow cylinders made up of guanosine-triphosphate (GTP)-dependent $\alpha\beta$-tubulin dimer assemblies (1). MTs have outer diameters of ~25 nm and inner diameters of 15 nm, with lengths that reach several micrometers. Recently, it has become apparent that neurons may utilize MTs in cognitive processing. MT-associated proteins, including tau and MAP2, have been implicated in such neuronal processes as learning and memory (2–4). MTs are also linked to the regulation of a number of ion channels, thus contributing to the electrical activity of excitable cells (5). Thus, MTs may play a heretofore unknown role in the processing of electrical signals within the neuron. Morphologically speaking, the elongating processes that sprout from the neuronal soma include a single axon and a variable number of dendrites; both take cable-like properties and contain abundant MTs. Dendrites, in particular, are responsible for both synaptic integration and synaptic plasticity, essential functions of neuronal activity (6,7). It is increasingly clear that cytoskeletal structures play a central role in both the process of ramification and more specialized neuronal functions, including neuronal processivity, long-term potentiation, long-term depression, and memory formation (8,9). Cytoskeletal alterations may reflect changes of neural circuits in response to learning and experience, and they must involve highly dynamic regulatory mechanisms. How this cytoskeletal control of neuronal plasticity takes form remains ill defined. Interestingly, a century ago Cajal proposed that the ''cytoskeleton contain a system for the conduction of the nerve impulse'' (10). To elucidate the electrodynamic properties of MTs and gain insight into the regulatory role that MTs play in dendritic activity, we assessed whether MTs are capable of processing electrical information.

METHODS

Preparation of isolated MTs

Tubulin was polymerized with a combined GTP-taxol ''hybrid'' protocol, following loosely general guidelines as described in Mitchinson Lab's online protocols (http://mitchison.med.harvard.edu/protocols/). Briefly, all reactions were conducted in BRB80 solution, containing 80 mM PIPES (1,4-piperazinediethanesulfonic acid), 1 mM $MgCl_2$, 1 mM EGTA, and pH 6.8 with KOH. In some experiments 10 μl glycerol was added before mixing the tubulin. An aliquot of tubulin in solution (catalog No. T238, Cytoskeleton, Denver, CO) was mixed with 1 mM dithiothreitol (DTT) and 1 mM GTP in an ice bed and incubated for 5 min. Taxol (paclitaxel, Sigma; St. Louis, MO) was then added in steps, first from a 1 μM and then 10 μM solutions. Each stepwise addition of taxol was followed by incubation for 20–30 min in a water bath at 37°C. Taxol was kept in a 10-mM stock in anhydrous dimethylsulfoxide (DMSO). In some instances, the tubulin-containing solution was mixed with BRB80 solution (×2) and added 2 mM DTT, 2 mM GTP, and 20% DMSO, followed by incubation at 37°C for 20–30 min. Polymerized tubulin was centrifuged in a microfuge for 30 min at 14,000 rpm. Two-thirds of the supernatant was discarded, and the remainder constituted the MT sample, which was further stabilized by addition of 1 mM GTP and 1 μM taxol. MTs were visualized under phase contrast microscopy (IMT-2, Olympus, Tokyo, Japan; ×60) to ascertain the lack of nucleated centers induced by higher concentrations of taxol. MTs were stable at room temperature for up to 2 days.

Measurement of electrical signals in isolated MTs

Electrical data were collected with a modified dual ''patch-clamp'' setup as previously reported (11). Briefly, the electrical setup consisted of two independent patch-clamp amplifiers, PC501 and PC501A (Warner Instruments, Hamden, CT), with 1-GΩ and 10-GΩ feedback resistors, respectively, one to stimulate the isolated MT (stimulus, s) and the other to collect current signals (collection, c). Electrical signals were simultaneously collected by respective analog inputs of an analog-to-digital (A/D) converter (TL-1 DMA Interface, Axon Instruments, Foster City, CA). Voltage stimulus protocols were constructed in Clampex 5.5.1 (Axon Instruments) run from a computer. The sampling intervals varied depending on the protocol, such that in most cases a 100-ms signal length contained at least 400 samples. Offset tip potentials within the range of a few millivolts were

compensated immediately before data acquisition. Further zeroing of the offset signal was conducted offline during data processing. Signals were Gaussian filtered at a cutoff frequency of 2.2 kHz. Pipettes were made from borosilicate capillaries (1.2-mm external diameter) and were pulled with tip diameters below 3 μm. The pipettes contained and were immersed in a solution containing in mM: 135 KCl, 5 NaCl, 0.8 $MgCl_2$, 1.2 $CaCl_2$, 10 Hepes. Occasionally, the pipette tip contained a 1:10 dilution of the taxol solution to help attach the MT. The pipettes were connected to the electrodes and head stage of their respective patch-clamp amplifiers. Agar bridges containing 3% agar in 150 mM KCl solution grounded both amplifiers to the chamber. The circuit was closed by two AgCl-plated Ag ground electrodes in solutions far away (1–2 cm) from the pipette tips.

Data analysis

Data were acquired at 2 KHz and further filtered offline for display and analysis when required. Noise analysis was conducted as Lorentzian spectral analysis with a subroutine of Axograph 4.0 (Axon Instruments) from unfiltered files where the variance versus frequency was plotted for paired experiments before and after MT attachment was obtained in the experiment. The method for deriving the amplification is different for the square pulse and for the triangle wave. In the case of the square pulse, we evaluated the average amplitude in solution only and with MT attached for the same conditions. The amplification is simply the ratio. In the case of triangle pulses, a different strategy was used, using the slope of the linear regression of the MT-attached data as a function of the solution-only data at the pulse times. Data are expressed as n = number of files averaged ± SE, where t-test was used to assess statistical significance at $p < 0.05$.

RESULTS

MTs were formed and stabilized as indicated in Methods. Isolated MTs were visualized and identified under phase contrast microscopy and connected to the tips of two patch-clamp amplifiers (Fig. 1 *a*), such that electrical stimulation could be applied to one of them, whereas the elicited signal could be collected with the other one (Fig. 1 *b*). MTs were electrically stimulated by applying 5–10-ms input voltage pulses with amplitudes in the range of ±200 mV. The resulting electrical signals were obtained at the opposite end of an MT, 20–50 μm away with a pipette also connected to a patch amplifier, which was kept ''floating'' at 0 mV. We observed two remarkable findings. First, coupling of the stimulus pipette to an MT increased the overall conductance of the pipette by >300%. The stimulus pipette resistance in KCl saline (135 mM) was 21.6 ± 0.6 MΩ (n = 16). The coupling ratio between pipettes in solution was 41% ± 12% before attachment to an MT. Thus, the collection pipette ''read'' ~40% of the stimulus in solution. The evoked current increased from 1.91 ± 0.13 nA (n = 16) to 2.78 ± 0.17 nA (n = 35) after attachment (Fig. 2 *a*). The signals reaching the collection site were in 30/35 of the cases higher than those obtained in free solution, indicating that the MT amplified both the electrical pulse injected at the stimulus site and the collection site as well (Fig. 2 *a*). Transfer amplification ratios were up to 2.35 with an average of 1.69 ± 0.06 (n = 30, Fig. 2 *c*). Thus, MTs improve electrical connectivity between two locations in saline solution. The currents measured at the collection site were linearly dependent on the stimulus pipette input voltage, indicating a strictly inverse ohmic response, i.e., linear amplification (Fig. 2 *b*). The MT conductances reached up to 9 nS, much higher than that expected from channel conductances (5–200 pS, Fig. 2 *b*, *inset*). The electrical amplifying effect of the MT was observed in either direction (stimulus by either

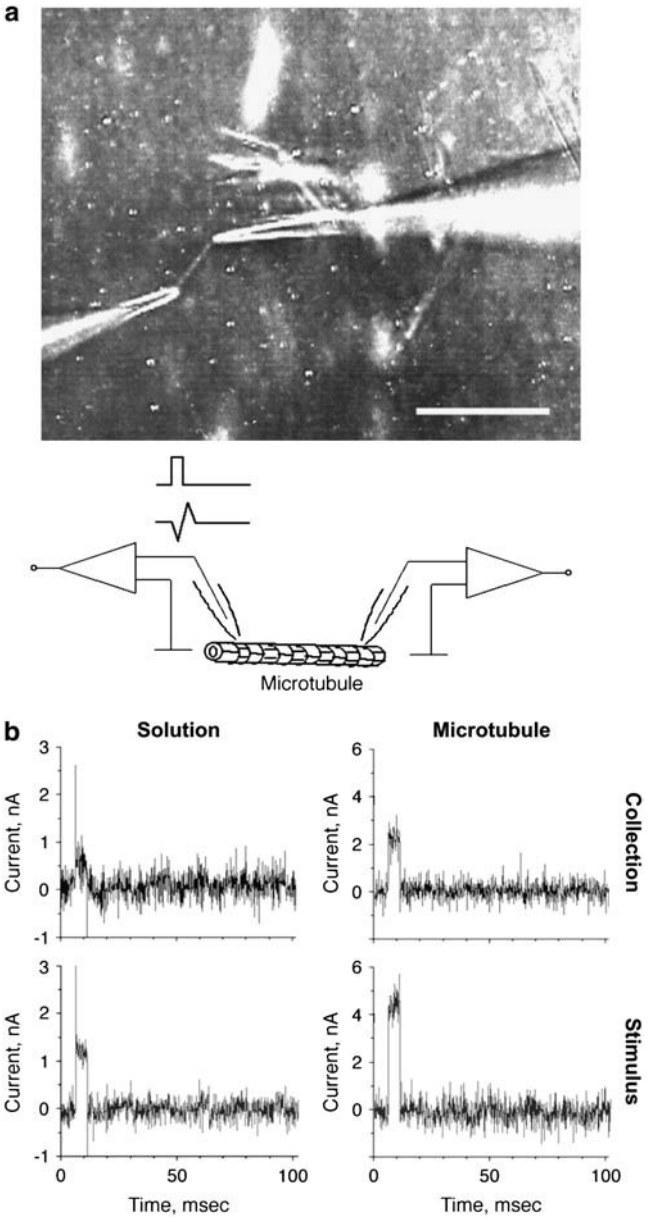

FIGURE 1 Electrical setup. (*a*) (*Top*) A free-floating MT was ''connected'' to two patch pipettes. Horizontal bar is 50 μm. (*Bottom*) Electrical signals were applied to one end and collected from the other end with two patch-clamp amplifiers. (*b*) Voltage pulse (+100 mV) was first applied to the ''stimulus'' pipette in saline solution. The recorded current from stimulus pipette (*left bottom*) and electrical coupling by the ''collection'' pipette (*left top*) were obtained. A similar approach was repeated after MT attachment. Currents were higher after attachment to an MT (*right*), compared to saline solution (*left*). Representative tracings from 16 experiments are shown.

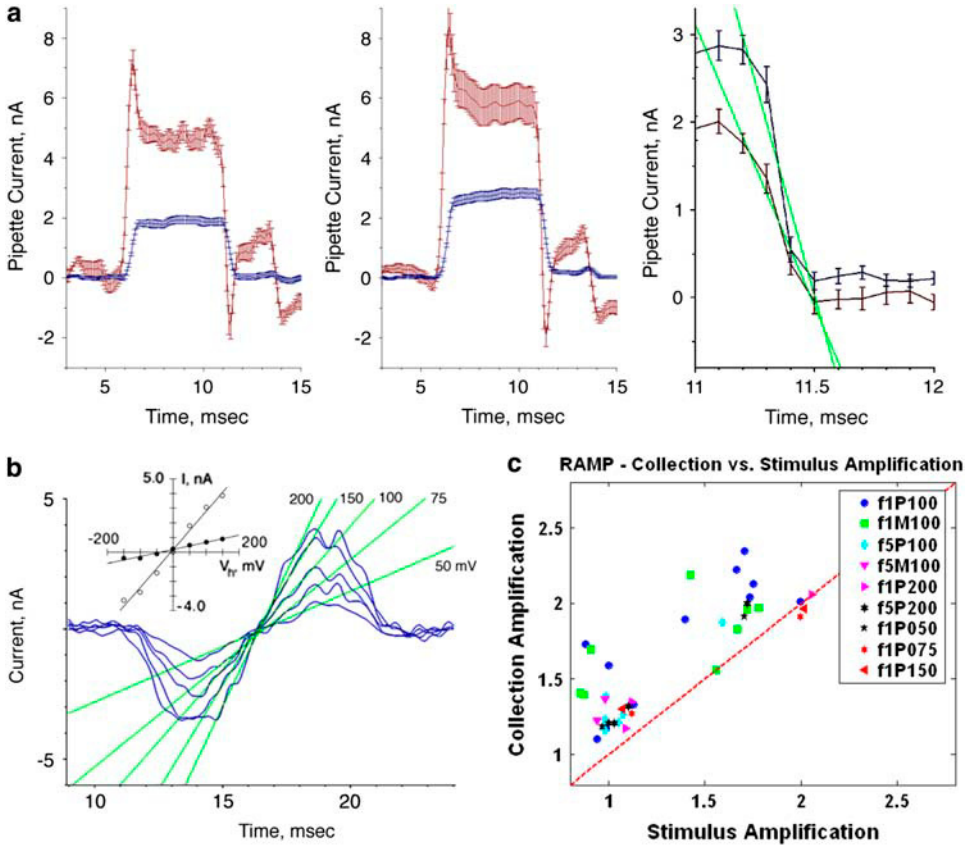

FIGURE 2 Pulse stimulation of isolated MTs. (*a*) Average electric pulses (100 mV, 5 ms) for the ''stimulus'' (*red*) and the ''collection'' (*blue*) sites. Data on the left indicate the signal before attachment. Values are the mean ± SE for five pipettes with similar electrical properties. The decay response of the MT-connected tip at the end of the electrical pulse was ~40 μs faster after connection (*right*). (*b*) MT-attached signals on the collection site for 5-ms ramps at different voltages. Fitted linear slopes (*green*) indicate a linear response. (*Inset*) Current-to-voltage relationship for a connected MT (*open circles*) compared to free solution (*solid circles*). The conductance is linear. The signals increased in average by 1.69 at an average distance of 35 μm. (*c*) Correlation of amplification ratios between the stimulus and collection sites. Identity line (*red*) indicates no amplification by the connected MT. Amplification factors are shown for either 10 ms (f1) or 5 ms (f5) ramps for positive (P) and negative (M) potentials (last three digits).

amplifier). To further prove the linear response in amplification as well as the speed of the electrical amplifying phenomenon, voltage ramps were also applied within the range of ±100 mV at two different rates (100 V/s and 20 V/s, Fig. 2 *b*). The stimulated currents at either rate were again linear, showing a remarkable reproducibility within the range of voltages studied. The amplification ratio remained constant within the range of voltages and rates tested, and the noise in the signal was, as expected, increased as well. The fastest ramps tested showed, however, a 40-μs (or shorter) delay between the stimulus and collection sites, which was consistent with the shift in voltage decay after pulse stimulation (Fig. 2 *a*, *right*). This suggests a lower bound for the transfer rate of the electrical signal of the order of 1.0 m/s. In two out of seven experiments, electrical amplification further increased by addition of GTP (1 mM) to the bath solution (data not shown).

DISCUSSION

Our findings demonstrate that electrical amplification by MTs is equivalent to the polymer's ability to act as a biomolecular transistor at its core. Based on a minimalistic model, both a constant electrical polarization and an active component are required. Despite current interest and extensive literature on the properties and functions of MTs, practically nothing is known about the ionic properties of the MTs intrapolymeric compartment. However, molecular dynamics simulation of tubulin structure (12,13) indicates a strong negative surface charge distribution of the order of $20e^-$ per monomer, distributed more on the outer surface than in the inner core with ratio of ~2:1. Our findings support these theoretical results manifested in the model via a constant (permanent) electric polarization, which follows localized Nernst potentials arising from asymmetries in the ionic distributions between the intra- and extra-MT environments. This polarization is modulated by electrical stimulation such that the forward-reverse biased junctions of an intramolecular transistor (Fig. 3) creates a proper MT-adjacent ionic cloud environment, which allows amplification of axially transferred signals. The proposed model implies that intrinsic semiconductive like properties of the structured tubulin dimers are such that an effective transistor is being formed (14) whose gating ability to modulate localized charges may help amplify axial ionic movements. Recent studies aimed at solving the Poisson-Boltzmann equation for a section of an MT in ionic conditions similar to those reported here (i.e., 150 mM saline) (12) suggest a highly ordered charge distribution. Positive charges are ''sandwiched'' within a two-layered structure of negative charges facing either side of the MT. There also is an asymmetrical distribution of charges on the plus-minus

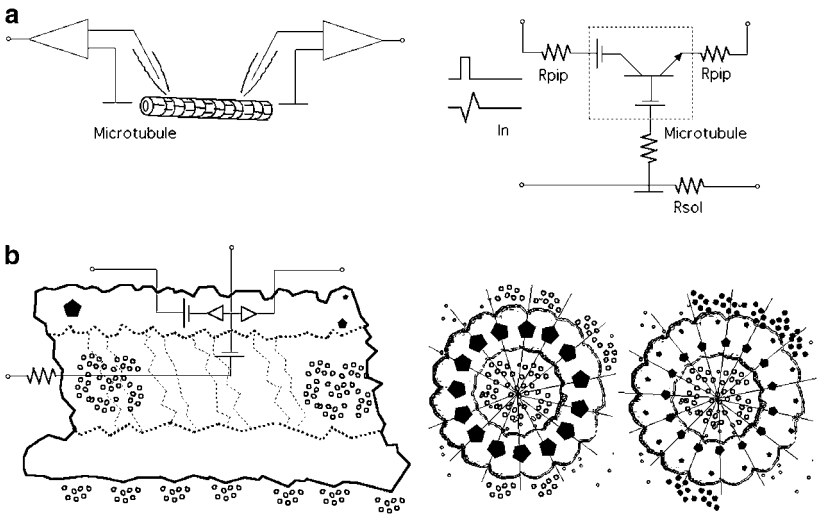

FIGURE 3 Electrical model of the MT. (*a*) Effective electrical model of the MT (*right*) is consistent with an electrical amplifier, including a molecular ''biotransistor'' and energy sources in the form of batteries to polarizing the amplifier. (*b*) Relation of electrical model to the electrostatic properties of an MT for both the plus and minus ends, potential isocontours, reproduced from Baker et al. (11). Electrostatic profile of a cross section of the MT (*right*) shows periodic distribution of positive charges (*black*) on the surface of the electronegative MT. Periodically distributed charges (*large* and *small pentagons*) maintain a ''band junction'' in the surrounding counterions. This is based on an electric potential difference in the MT wall (*open circles* and *solid circles* for cations and anions, respectively).

orientation of the MT. However, to better understand the dynamical properties of the electric field around the MT, it is imperative to apply a method that incorporates the diffusive part of the system. A possible candidate is the Poisson-Nernst-Planck (PNP) theory in which both the electrical potential generated by fixed charges and the flux generated by the moving charges due to potential and concentration gradients are taken into account. This method has been applied successfully to describe ion channels (15), and it would be interesting to test the applicability of this method to a system as large as the MT.

An electrical amplifier by a cytoskeletal biopolymer such as the MT provides a relevant and important key component to an electrodynamic network in conjunction with electrical coupling by current generators (i.e., MT-regulated channels (5)) and MT-coupled intracellular transmission lines (F-actin) (11,16). It is therefore plausible that electrical amplification by MTs may play an important role in processing electrical information in neuronal function. Our data further indicate that this phenomenon is accomplished with speed at least as high as those reported for cable properties in neurites (17).

MT networks (MTNs) play relevant roles in neuron formation and function (18–20). Interconnected bundles of MTs, for example, are present in the axon, the axon hillock, and the dendritic shaft, all regions where ion channels are found. In particular, dendritic MTs are arranged in grid-like networks of mixed polarity interconnected by MAP2s. Thus, we envision a mechanism in which MT-ion channel interactions may regulate synaptic plasticity by the MT's ability to allow spatially oriented intracellular electrical signals in connection with actin filaments also able to transmit electrical information (11,16). According to this hypothesis, postsynaptic electrical signals elicit ion waves along the associated actin filaments at the synaptic spine that propagate to the MTN, where they serve as input signals. The MTN, operating as a large high dimensional ''state machine'', evolves these input states, e.g., by supporting nonlinear wave collisions. The output from the MTN is the state of the system that is being ''read'' (sensed) to propagate and electrically stimulate remote voltage-sensitive ion channels. Thus, our findings provide several advantages in the context of neural function. Cable theory analysis of dendrites (21,22) has challenged the simple integrate and fire models, suggesting that dendrites impose a heavy conductance load on the soma, acting as low-pass filters of postsynaptic potentials, hence changing the response to synaptic activities (22). The dendritic electrical properties are dynamically changed by modulation of voltage-gated ion channels (6,22,23) and by changes in cytoskeletal structures (25–27). Thus, MT electrical amplification may be central to revised models of neuronal adaptability (23,28,29) providing renewed support to nonlinear models of neuronal activity.

A FRÖHLICH INTERACTION OF HUMAN ERYTHROCYTES

S. ROWLANDS, L.S. SEWCHAND, R.E. LOVLIN, J.S. BECK and E.G. ENNS
Faculty of Medicine and Department of Mathematics and Statistics, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Received 4 February 1981

Experiments on human red cells provide evidence for an interaction compatible with the quantum mechanical theory of Fröhlich.

Fröhlich has a theory [1,2] that long-range coherent interactions, known to exist in the solid state, should occur in living cells in a unique form. Necessary conditions of the theory [2] are (a) a cell membrane potential difference, (b) a supply of metabolic energy, and (c) organisation, a type of order which, according to Fröhlich "... exists in a well-working machine in contrast to a broken-down one [2]". In work on human red cell rouleau formation [3–6] we noticed a small attraction between erythrocytes in plasma priorto the actual contact which precedes doublet formation. When we (a) reduce the membrane potential near to zero or (b) deplete the cells of ATP or (c) derange the cellular organisation with glutaraldehyde, the attraction can no longer be detected.

Membrane potentials act across very short distances (≈ 10 nm) which implies that the membrane is strongly polarised electrically. Vibrations of membrane molecules will be dipolar, representing an electric wave of half wavelength equal to the thickness of the membrane [2]. If the velocity of mechanical membrane waves is assumed to be 10^3 ms^{-1}, the frequency of such oscillations will be of the order of 10^{11} Hz. There is evidence for such oscillations in microorganisms [2].

Fröhlich considers two basic collective excitations. The first, quasi-static, is of metastable states of very high electric polarisation. He then introduces metabolic energy which can excite coherent vibrations. If the supply of energy to the modes of a band of electric polarisation waves exceeds a minimum value, the energy may be channelled into a single mode, giving rise to a strong coherent oscillation extending throughout the cell. Collective vibrations are quantised (phonons) and obey Bose–Einstein statistics. Fröhlich likens the excitation of a single mode to the Einstein condensation of a Bose gas [7], a condensation in momentum space, not in coordinate space as in liquefaction. In the quasi-static case interactions between highly polarised cell constituents will be repulsive and of short range. Fröhlich posits quite a different situation at $\approx 10^{11}$ Hz when ionic screening is only significant at distances of micrometres. Moreover interactions may be attractive or repulsive as conditions change. Cooper [8] has applied the theory to the movement of macromolecules in the complex processes of cell mitosis.

In our experiments, heparinised blood at a haematocrit of $\approx 0.5\%$ in a haemacytometer chamber is photographed every 15 s with a time-lapse 16 mm ciné-microscope for 3 h. About 200 erythrocytes are in view. In an early frame of the developed film, pairs of cells less than a cell diameter apart (<8 μm) are identified and their subsequent motion is followed until a doublet forms or until the end of the film. Isolated cells execute brownian movement. If the motion of pairs is also random, simple geometry predicts a maximum probability of the pair making contact of 0.5 if the initial separation is zero, to 0.15 at an initial separation of 8 μm. The average probability is about 0.3. It will be seen from table 1 that in six experiments on four subjects and involving 212 pairs, the fraction of pairs which collided was 0.85 ± 0.06.

The pH of the plasma was reduced with 0.14 M HCl

in 0.14 M NaCl and restored to normal with 0.14 M NaOH. At pH = 6.3 the membrane potential is close to zero [9,10]. Pair collision is reduced to the random value but is restored to a non-random value on returning the same cells to pH = 7.6 (table 2). Ionophore A23187 induces rapid entry of Mg^{++} and depolarisation of membrane potential [11]. Cells were washed in standard phosphate-buffered saline (PBS) containing 10 μM A23187 and then suspended in plasma to which had been added 10 mM $MgCl_2$, 10 μM EGTA and 10 μM A23187 [11]. Pair collision is reduced to just within the random range by this procedure (table 2). Cells were metabolically depleted by washing in PBS followed by incubation in PBS for 22 h at 37°C [12,13]. Such cells also give a result in the random range and the same cells are restored nearly to the mean fraction for normal cells by incubation for a further 3 h in 30 mM adenosine (table 2). Glutaraldehyde crosslinks protein and so "disorganises" the cell [14]. Cells were washed twice in PBS containing 0.04% glutaraldehyde, resuspended in the same solution and shaken gently for 24 h at 22.0°C. The mean fraction is well within the theoretical random range (table 2) but it is likely that in these embalmed cells the membrane potential and metabolic mechanisms were abolished. Latex microspheres suspended in plasma were used as controls (table 2).

Brownian motion is monitored in each experiment by measuring the X coordinate against time of ten or more cells which remain isolated (>8 μm) throughout 3 h. From theory [15]

$$\langle X^2 \rangle = 2kTt\mu^{-1},$$

where μ is the drag coefficient. Correlation coefficients averaged 0.94 ± 0.03 (for microspheres r = 0.96) but μ (including that for microspheres) was consistently higher than the value calculated from Stoke's law or from the rate of free fall of erythrocytes [16]. So cells, normal and experimentally modified, and artificial particles when resting on a surface, experience a drag greater than that of the suspending medium.

By simple experiments we have demonstrated a hitherto unknown interaction of human erythrocytes and tested it against the Fröhlich theory. The most satisfactory of our tests is the reversible disappearance of the interaction by abolition of the membrane potential. Metabolic depletion does more than cut off the supply of energy. Although reversible it modifies structure [17] and results in ion shifts [18]. The zeta potential, however, is unchanged [12]. We measured intra- and extra-cellular chloride before and after metabolic depletion and, from the Nernst equation [10], calculated the membrane potential. It dropped from 15.0 mV to 7.1 mV and so might have fallen beneath some threshold for the Fröhlich effect. Glutaraldehyde

has a rather drastic effect on structure although some enzyme activity remains [14]. The theory regards organisation, membrane potential and energy supply as separate but the three entities are likely to be functionally interwoven and may prove difficult to isolate. Fröhlich forces will be universal in living systems. We offer our preliminary findings to enable other workers to check and extend them.

Had it not been for Dr. H.A. Buckmaster of the Department of Physics we might not have found the Fröhlich theory. We thank Dr. A.D. Dickson for the laon of the camera, Dr. R.D. Laurenson for the loan of the haemacytometer and Ms. Donna Foggo for technical assistance. We are supported by the Medical Research Council of Canada.

ORIGINAL PAPER

A nonlinear model of ionic wave propagation along microtubules

Abstract Microtubules (MTs) are important cytoskeletal polymers engaged in a number of specific cellular activities including the traffic of organelles using motor proteins, cellular architecture and motility, cell division and a possible participation in information processing within neuronal functioning. How MTs operate and process electrical information is still largely unknown. In this paper we investigate the conditions enabling MTs to act as electrical transmission lines for ion flows along their lengths. We introduce a model in which each tubulin dimer is viewed as an electric element with a capacitive, inductive and resistive characteristics arising due to polyelectrolyte nature of MTs. Based on Kirchhoff's laws taken in the continuum limit, a nonlinear partial differential equation is derived and analyzed. We demonstrate that it can be used to describe the electrostatic potential coupled to the propagating localized ionic waves.

Introduction

The cytoskeleton is a major component of all living cells. It is made up of three different types of filamentous structures, including actin-based filaments, intermediate filaments (e.g. keratin) and tubulin based microtubules (MTs). All of them are organized into networks, which are interconnected through numerous proteins, with specific roles to play in the functioning of the cell. MTs are hollow cylinders with outer diameter of approximately 25 nm. Their lengths vary but commonly reach 5–10 μm. They are comprised of exclusively 13 parallel protofilaments in vivo. These protofilaments are strongly bound internally and are connected via weaker lateral bonds to form a sheet that is wrapped up into a tube following the nucleation process (Chrétien et al. 1995) (see Fig. 1).

Each tubulin monomer of the MT lattice has a short C-terminal helix H12 followed by a highly acidic amino acid sequence projecting out of the MT outer surface called a tubulin tail (TT). The TTs are short polypeptide sequences of 4–5 nm length when completely outstretched, protruding from the MT surface into the solution. They are essential for MT interactions with MT associated proteins and motor proteins.

Jimenez et al. (1999) determined the helicity of α (404–451) and β (394–445) tubulin C-terminal recombinant peptides with the use of NMR spectroscopy. The α-tubulin TT amino acid sequence is EEVGADSVEGEGEEEGEEY. The α-TT is 19 amino acids long and possesses ten negatively charged residues. The situation in the β-tubulin C-terminal domain is even more interesting. Jimenez et al. found a helix there, which is nine amino acids longer than in α-tubulin. This suggests an extension into the protein, supporting the possibility of a functional coil-to-helix transition at the TT zone. The β-tubulin TT helix H12 is formed by

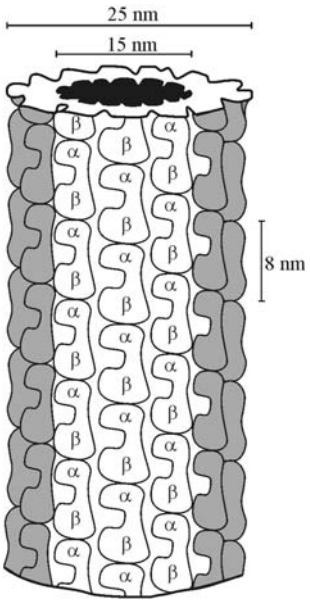

Fig. 1 Sketch of a MT cylinder with characteristic dimensions and α–β dimers clearly discerned

amino acid residues (408–431) but it seems that the reversible transition between coil and the helix comprising the last nine amino acid residues (423–431) from β-TT helix (with sequence QQYQDATAD) could either increase or decrease the length of H12, at the same time changing the β-TT length, as has been recently demonstrated using molecular dynamics simulations on human beta tubulin C-termini by Luchko et al. (2008). The corresponding residues (432–445) contain the 14 amino acids EQGEFEEEEGE DEA with nine negatively charged residues (E, A). At neutral pH the negative charge on a TT causes it to remain extended due to electrostatic repulsion within the tail (Tuszynski et al. 2005). Under more acidic conditions the negative charge of TTs is partially neutralized by associated counter-ions condensed on them. The effect is to allow the β-TTs to acquire a more compact form by folding (see Fig. 3). This is probably the largest structural effect in MTs which occurs due to change in the cell's pH. This fact will be of great importance in our model, with respect to the variable effective electrical capacitance of MTs.

The detailed charge distribution on the tubulin surface was calculated by Tuszynski et al. (2005), leading to the determination of an electrostatic potential around tubulin within a MT. It exhibits non-uniformity along the MT radius with a peak and a trough corresponding to every protofilament and the area between them, respectively. This fact plays a crucial role in our modeling of MTs as a "cable" conducting 13 parallel currents comprised of ionic flows. Keeping in mind that MTs are mostly negatively charged, especially on their outer surface, they can be referred to as polyelectrolyte polymers. This is based on the fact that numerous amino acids forming tubulin have many negatively charged residues under physiological conditions, especially those located on TTs. Since a sufficiently high surface charge density is present on the MT surface, Manning's theory (1969) can be applied to determine the conditions for the solution's positive counter-ions to "condense" on the surface of a MT. Thus, every MT should attract positive counter-ions near its surface, while negative ions of the cytosol are repelled such that a cylindrical depletion area around a MT is created. The thickness of this depleted area is defined by the so-called Bjerrum length, which is the distance from the MT surface at which the Coulomb energy of the screened surface charges equals the thermal energy:

$$\frac{e^2}{4\pi\varepsilon_0\varepsilon\ell_B} = k_B T. \tag{1.1}$$

Here, e is the charge of an electron, ε_0 the permittivity of vacuum, ε the relative permittivity of cytosol, and k_B is Boltzmann's constant. At a physiological temperature of 310 K and taking $\varepsilon = 80$, it is easy to find from Eq. 1.1 that:

$$\ell_B = 6.7 \times 10^{-10}\,\text{m}. \tag{1.2}$$

Counter-ion condensation along MTs occurs when the average distance between the intrinsic negative surface charges is smaller than ℓ_B.

The idea to examine MTs in the context of polyelectrolyte features was inspired by the experimental and theoretical results obtained earlier for actin filaments (Lin and Cantiello 1993; Tuszynski et al. 2004). From Figs. 2 and 3 it is clear that the surface of a MT filament is very rough due to the presence of TTs. We assume that the flow

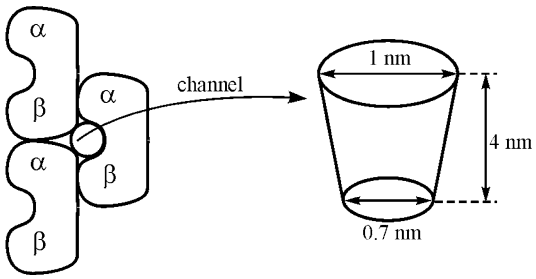

Fig. 4 Sketch of the channel connecting inner and outer surfaces of a MT

of ions along MTs, caused by the concentration gradient and by intrinsic electric fields created by the protein's charge distribution, should be mostly channeled through potential valleys (troughs) running parallel to each of the 13 protofilaments. The walls of valleys include TTs whose flexibility could significantly affect ionic current flows. In addition to the presence of TTs, it is important to note that the globular shape of tubulin dimers results in the creation of small pores representing channels that connect the inner and the outer surface of a MT (see Fig. 4).

These channels could be thought of as candidates for additional leakage of ions which would then be able to rectify currents along the depleted (Bjerrum) cylindrical layer around a MT. Recent experimental evidence (Priel et al. 2006) indicates that MTs could act as biopolymer transistors clearly amplifying input electrical signals. It is our objective in this paper to propose a model which provides an explanation of these peculiar properties of MTs and their possible role in information processing. We will follow the same theoretical approach first outlined in Tuszynski et al. (2004) for actin filaments, but it will be applied to MTs with special attention placed on their specific structural features.

The paper is organized in the following way: in Sect. "The model of MT as a nonlinear electric transmission line" we introduce the model of a MT as a nonlinear electric transmission line segmenting it into elementary rings. In Sect. "Modeling MT as nonlinear RLC transmission line" we derive and analyze a nonlinear differential equation for the local electrostatic potential coupled to the ionic wave propagating along a MT. Section "The impact of the cell's intrinsic electric fields on the dynamics of AKs in MTs" demonstrates the possible role of cell's intrinsic electric fields in the dynamics of localized ionic waves propagating along MTs. Section "Conclusion and discussion" presents a discussion and conclusions regarding this important physical mechanism in terms of the cell's electrical activity brought about by the presence of MTs and their effects on ions.

The model of MT as a nonlinear electric transmission line

We start from the fact that a MT with condensed counter-ions is separated from the rest of the ions in the bulk solution by a depleted layer which plays the role of a dielectric medium located between MTs and the bulk solution. This depleted layer provides both a resistive and capacitive component for the electrical characteristics of protofilaments that make up the MT. The injected ions are expected to flow at a radial distance from the surface of the MT with the thickness of ℓ_B. We will also estimate the inductive component of ionic waves due to 13 parallel currents and show it to be negligible compared to the other impedance components.

The estimation of elementary capacitance of a MT ring

In a continuum model we treat the MT as a polyelectrolyte represented by a volume which is bounded by a charged cylindrical surface in contact with an electrolyte (cytosol) whose dielectric constant is assumed to be time-invariant and uniform. In this case Poisson's equation is an appropriate physical description and it has the form:

$$\nabla^2 V = -\frac{\rho}{\varepsilon_0 \varepsilon}, \tag{2.1}$$

where ρ is the volume charge density at any point in the cytosol and ε is its relative dielectric constant. The charge density ρ results from the presence of counter-ions and co-ions. These are assumed to satisfy a Boltzmann distribution function. This means that in a solution containing n_s dissociated molecules of salt (for example NaCl) the number n_1 of counter-ions (Na^+) with charge $z_1 = e$ at a distance r from the MT cylinder axis is given by the expression:

$$n_1(r) = n_s \exp\left(\frac{eV}{k_B T}\right), \tag{2.2}$$

since z_1 and V have opposite signs. The number of negative (Cl^-) ions is:

$$n_2(r) = n_s \exp\left(-\frac{eV}{k_B T}\right). \tag{2.3}$$

This implies the total charge density given by:

$$\begin{aligned}\rho(r) &= n_s e\left[-\exp\left(\frac{eV}{k_B T}\right) + \exp\left(-\frac{eV}{k_B T}\right)\right] \\ &= -2n_s e \sinh\left(\frac{eV}{k_B T}\right).\end{aligned} \tag{2.4}$$

Using this result in Eq. 2.1 yields the Poisson–Boltzmann equation (PBE):

$$\nabla^2 V = \frac{2n_s e}{\varepsilon_0 \varepsilon} \sinh\left(\frac{eV}{k_B T}\right). \tag{2.5}$$

This nonlinear differential equation can be brought into a more compact form by introducing two dimensionless variables:

$$\psi = \frac{eV}{k_B T} \quad \text{and} \quad x = \frac{r}{\mathcal{D}}, \tag{2.6}$$

where the Debye length $\mathcal{D}$ is defined as:

$$\mathcal{D} = \sqrt{\frac{\varepsilon_0 \varepsilon k_B T}{2n_s e^2}}. \tag{2.7}$$

It gives:

$$\nabla^2 \psi(x) = \sinh[\psi(x)]. \tag{2.8}$$

In the Debye–Hückel approximation it is assumed that $eV \ll k_B T$ or $\psi \ll 1$, so that Eq. 2.8 can be linearized by the approximation $\sinh[\psi(x)] \approx \psi(x)$. Thus PBE in cylindrical coordinates now reads:

$$\frac{1}{x}\frac{\mathrm{d}}{\mathrm{d}x}\left(x\frac{\mathrm{d}\psi}{\mathrm{d}x}\right) = \psi \quad \text{or} \quad \frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} + \frac{1}{x}\frac{\mathrm{d}\psi}{\mathrm{d}x} - \psi = 0. \tag{2.9}$$

On the surface of the MT cylinder we have: $x_0 = R/\mathcal{D}$ and $\psi_0 = eV_0/k_B T$, where R = 12.5 nm. The solution of PBE, Eq. 2.9 is a modified Bessel function of zero order denoted by $K_0(x)$, so we have:

$$\psi(x) = cK_0(x) \tag{2.10}$$

where c is the constant of integration. The above Bessel function does not oscillate and behaves asymptotically like $\exp[-x]$ as $x \to \infty$. From Eq. 2.10 one has:

$$\frac{\mathrm{d}\psi}{\mathrm{d}x} = -cK_1(x), \tag{2.11}$$

where $K_1(x)$ is the modified Bessel function of the first order. Using the relationship for the electric field:

$$E = -\frac{k_B T \mathrm{d}V}{e\mathcal{D}\ \mathrm{d}x}$$

we have:

$$-x_0\left(\frac{\mathrm{d}\psi}{\mathrm{d}x}\right)_{x=x_0} = \frac{e^2}{4\pi\varepsilon_0 \varepsilon k_B T g} = \xi; \quad g = \frac{\mathcal{L}}{N} \tag{2.12}$$

where ξ represents a scaled charge parameter of a MT, $\mathcal{L}$ is the length of a MT and Ne is the total surface charge of the same MT, Fig. 5.

Returning to the variable r, the above equations yield:

$$\psi(r) = \frac{2\xi\mathcal{D}K_0\left(\frac{r}{\mathcal{D}}\right)}{RK_1\left(\frac{r}{\mathcal{D}}\right)}. \tag{2.13}$$

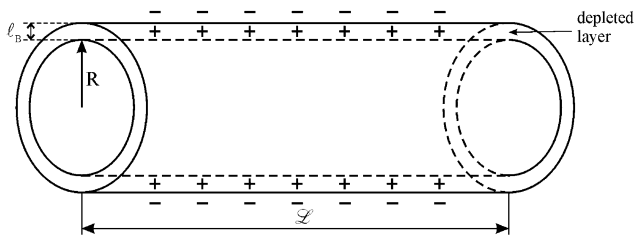

Fig. 5 MT cylinder with a depleted layer with the thickness equal to Bjerrum length ℓ_B

This equation in the case of low ionic strengths $(r/\mathcal{D} \to 0)$ behaves like $-\ln\left(\frac{r}{\mathcal{D}}\right)$, and hence we obtain the solution of PBE as:

$$V(r) = -\frac{eN}{2\pi\varepsilon_0\varepsilon\mathcal{L}}(\ln r - \ln \mathcal{D}) = -\frac{Q}{2\pi\varepsilon_0\varepsilon\mathcal{L}}\ln\left(\frac{r}{\mathcal{D}}\right). \quad (2.14)$$

The first term corresponds to the potential due to the surface charge of a MT and the second term $(\ln \mathcal{D})$ to the potential due to the counter-ions. The potential difference between the MT surface cylinder and the outer cylinder of the depleted zone at a distance ℓ_B is therefore given by:

$$\Delta V = -\frac{Q}{2\pi\varepsilon_0\varepsilon\mathcal{L}}\ln\left(1+\frac{\ell_B}{R}\right). \quad (2.15)$$

The capacitance of a MT is defined by $C = \frac{Q}{|\Delta V|}$, giving the total value for a MT:

$$C = \frac{2\pi\varepsilon_0\varepsilon\mathcal{L}}{\ln\left(1+\frac{\ell_B}{R}\right)} \quad (2.16)$$

Taking as an elementary capacitor C_0 a ring of 13 tubulin dimers with the length $\ell = 8 \times 10^{-9}$ m, and using $\varepsilon_0 = 8.85 \times 10^{-12}$ F/m, and $\varepsilon = 80$, with the above values for ℓ_B and R, we find the first part of the ring's capacitance from Eq. 2.16:

$$C_0^{(1)} = 6.8 \times 10^{-16}\,\mathrm{F} = 0.68\,\mathrm{fF}.$$

In the same way, considering an extended TT as a cylinder with length $\ell_C = 4.5$ nm and radius $R_C = 0.5$ nm we calculate an additional capacity $C_0^{(2)}$ for $n = 13 \times 2 = 26$ TTs contained in the same elementary ring composed of 13 dimers as above (see Fig. 6).

Using the same formula, Eq. 2.16, we obtain:

$$C_0^{(2)} = \frac{26 \times 3.14 \times 80 \times 8.85 \times 10^{-12} \times 4.5 \times 10^{-9}}{\ln\left(1+\frac{0.67}{0.5}\right)}\,\mathrm{F}$$
$$= 0.64 \times 10^{-15}\,\mathrm{F} = 0.64\,\mathrm{fF}.$$

Thus, treating the two contributing capacitances to be connected in parallel, the total maximal capacity of the elementary ring is found to be:

$$C_0 = C_0^{(1)} + C_0^{(2)} = 1.32 \times 10^{-15}\,\mathrm{F}. \quad (2.17)$$

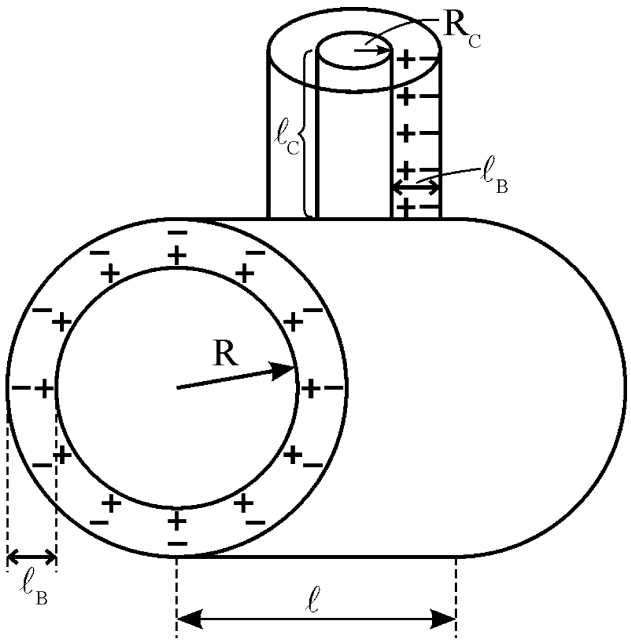

Fig. 6 Elementary ring of a MT with characteristic cylindrical capacitors and corresponding dimensions

We have already stressed that the increase of negative voltage should increase the concentration of positive counter-ions. These ions additionally condense on the surface of a MT and on TTs. This causes β-TTs to shrink diminishing their effective length ℓ_C and thus the capacity $C_0^{(2)}$. We may initially at least assume that this effect is linear with respect to the applied voltage. This observation is of crucial importance to the development of an appropriate model of MTs as nonlinear transmission lines for ionic currents.

The estimation of effective inductance of a MT ring

We start from the assumption that a current I along the MT can be conceived as a sum of 13 thin parallel wires along every protofilament (see Fig. 7).

If we calculate the resulting magnetic field in the location $R < r < R + \ell_B$, we have to add the 13 components together. Due to the radial symmetry present, we found that the total flux of the magnetic field through area $A = \ell \cdot \ell_B$ is given as follows:

$$\Phi = \frac{\mu_0 \ell I_0}{\pi}\left[\frac{3\ell_B}{R} + \frac{1}{2}\ln\left(1+\frac{\ell_B}{R_d}\right)\right],$$

where I_0 stands for the ionic current along a single protofilament and R_d is the radius of a protofilament (tubulin dimer). Using Faraday's law, we readily find the induced voltage as:

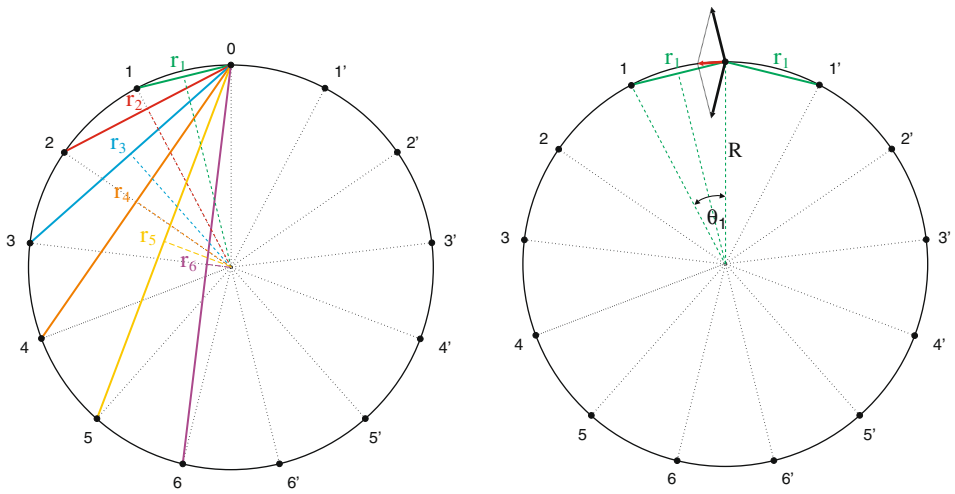

Fig. 7 The diagram for estimation of flux of magnetic field around a MT brought about by 13 currents I_0 along protofilaments

H/m=henry/meter= magnetic permeability

$$\mathcal{E} = -\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -L\frac{\mathrm{d}I_0}{\mathrm{d}t} = -\frac{\mu_0 \ell}{\pi}\left[\frac{3\ell_\mathrm{B}}{R} + \frac{1}{2}\ln\left(1 + \frac{\ell_\mathrm{B}}{R_\mathrm{d}}\right)\right]\frac{\mathrm{d}I_0}{\mathrm{d}t},$$

which brings about the inductance of a MT ring:

$$L = \frac{\mu_0 \ell}{\pi}\left[\frac{3\ell_\mathrm{B}}{R} + \frac{1}{2}\ln\left(1 + \frac{\ell_\mathrm{B}}{R_\mathrm{d}}\right)\right]. \tag{2.18}$$

Inserting the set of parameters: $\ell = 8$ nm, $R = 12.5$ nm, $R_\mathrm{d} = 4$ nm, $\ell_\mathrm{B} = 0.67$ nm, $\mu_0 = 4\pi \times 10^{-7}$ H/m, we obtain:

$$L = 8 \times 10^{-16}\,\mathrm{H} = 0.8\,\mathrm{fH}. \tag{2.19}$$

Modeling the longitudinal and transverse resistance components

Recently published accurate measurements of individual MTs using the electro-orientational method performed in vitro by Minoura and Muto (2006) produced the value of MT conductivity:

$$\sigma = (0.15 \pm 0.01)\,\mathrm{S/m}. \tag{2.20}$$

If we now take that the resistivity within the depleted cylindrical shell around a MT with thickness ℓ_B is homogeneous, the longitudinal resistance of the elementary ring with length $\ell = 8 \times 10^{-9}$ m and area $A_1 = 2\pi R\,\ell_\mathrm{B}$ (see Fig. 8) is expected to be:

$$R_1 = \frac{1}{\sigma}\frac{\ell}{2\pi R \ell_\mathrm{B}} = \frac{8 \times 10^{-9}}{0.15 \times 2\pi \times 12.5 \times 10^{-9} \times 0.67 \times 10^{-9}}\,\Omega = 10^9\,\Omega. \tag{2.21}$$

The transversal resistance of the same ring R_2 is calculated by the same formula, but the length of each resistor is now ℓ_B and the area $A_2 = 2\pi R\,\ell$, giving:

$$R_2 = 7 \times 10^6\,\Omega. \tag{2.22}$$

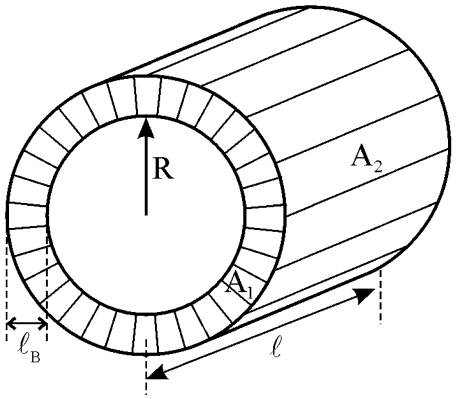

Fig. 8 Elementary ring of a MT with characteristic areas A_1 and A_2 pertaining to resistivities R_1 and R_2

Modeling MT as nonlinear RLC transmission line

On the basis of the above estimates for the resistive components of the elementary ring of a MT we are now able to develop and analyze an electrical model by applying Kirchhoff's laws to the series of elementary rings envisaged to represent coupled electrical circuits. We expect a potential difference between the MT charged surface with condensed counter-ions and ions located along the coaxial cylinder at a distance of one Bjerrum length away. These "Bjerrum ions" are responsible for the creation of 13 time-dependent currents which generate the inductance L, Eq. 2.19. In series with L one should insert a resistive component R_1, Eq. 2.21 (see Fig. 9).

In addition to the above components there is also a cylindrical capacitance C_0, Eq. 2.17 connected in series with transversal resistivity R_2, Eq. 2.22, acting between the "Bjerrum ions" and the surface of a MT. We have already

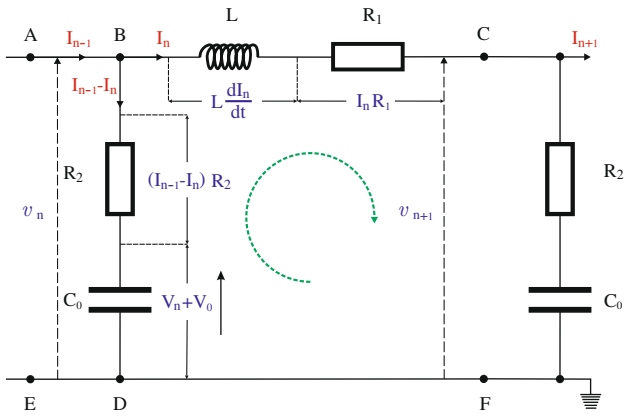

Fig. 9 An effective circuit diagram for the nth elementary ring between the doted lines

pointed out that the capacitance C_0 should change with an increasing concentration of counter-ions due to the flexibility of β-TTs. It implies that the charge on this elementary capacitor varies in a nonlinear way with voltage, much like the charge-voltage relation for a reverse-biased diode junction (Wang et al. 1999). Thus we take for the nth MT ring:

$$Q_n = C_0\left(V_n - bV_n^2\right), \tag{3.1}$$

where b is expected to be small ($bV_n \ll 1$) since the change of the area of β-TT is small compared with the outer surface of the corresponding dimer. From Kirchhoff's laws, on the basis of Fig. 9, if I_n is the current through the inductance L and the resistor R_1, and I_{n-1} is the other current flowing along AB, the current through line DB should be $I_n - I_{n-1}$. Thus for the section BC of the nth MT ring we obtain:

$$v_n - v_{n+1} = L\frac{\mathrm{d}I_n}{\mathrm{d}t} + I_nR_1, \tag{3.2}$$

where v_n and v_{n+1} are the voltages across AE and CF, respectively. Similarly, if the voltage across the variable capacitor $C_0\left(V_n - bV_n^2\right)$ is $V_n + V_0$, where V_0 is the bias voltage of the capacitor, we have:

$$v_n = R_2(I_{n-1} - I_n) + V_0 + V_n. \tag{3.3}$$

Moreover, the current through the section BD should be found as the rate of change of Q_n:

$$I_{n-1} - I_n = \frac{\mathrm{d}Q_n}{\mathrm{d}t}. \tag{3.4}$$

From Eq. 3.2 we have

$$L\frac{\mathrm{d}I_{n-1}}{\mathrm{d}t} = v_{n-1} - v_n - I_{n-1}R_1 \quad \text{and}$$
$$L\frac{\mathrm{d}I_n}{\mathrm{d}t} = v_n - v_{n+1} - I_nR_1$$

and including it in Eq. 3.4 we find

$$L\frac{\mathrm{d}^2Q_n}{\mathrm{d}t^2} = v_{n+1} + v_{n-1} - 2v_n + R_1(I_n - I_{n-1}). \tag{3.5}$$

Substituting v_{n+1}, v_n and v_{n-1} from Eqs. 3.3 to 3.5 one obtains

$$\begin{aligned} L\frac{\mathrm{d}^2}{\mathrm{d}t^2}\left[C_0\left(V_n - bV_n^2\right)\right] &= V_{n+1} + V_{n-1} - 2V_n \\ &- R_1C_0\frac{\mathrm{d}}{\mathrm{d}t}\left(V_n - bV_n^2\right) \\ &- R_2C_0\left\{2\frac{\mathrm{d}}{\mathrm{d}t}\left(V_n - bV_n^2\right) - \frac{\mathrm{d}}{\mathrm{d}t}\left(V_{n+1} - bV_{n+1}^2\right)\right. \\ &\left. - \frac{\mathrm{d}}{\mathrm{d}t}\left(V_{n-1} - bV_{n-1}^2\right)\right\}. \end{aligned} \tag{3.6}$$

Bearing in mind that voltage V_n changes gradually from ring n to its neighbors, we can safely expand V_n in a continuum approximation using a Taylor expansion in terms of a small spatial parameter ℓ (the length of a dimer):

$$\begin{aligned} V_{n\pm1} = V &\pm \ell\left(\frac{\partial V}{\partial x}\right) + \frac{\ell^2}{2!}\left(\frac{\partial^2 V}{\partial x^2}\right) \\ &\pm \frac{\ell^3}{3!}\left(\frac{\partial^3 V}{\partial x^3}\right) + \frac{\ell^4}{4!}\left(\frac{\partial^4 V}{\partial x^4}\right) \pm \cdots. \end{aligned} \tag{3.7}$$

We discarded terms on the order of ℓ^5 and ℓ^6 since $\ell^5 \sim 0.33 \times 10^{-40}$ m^5 is a very small value. The above expansion leads to the following relation:

$$V_{n+1} - 2V_n + V_{n-1} = \ell^2\left(\frac{\partial^2 V}{\partial x^2}\right) + \frac{\ell^4}{12}\left(\frac{\partial^4 V}{\partial x^4}\right). \tag{3.8}$$

Inserting Eqs. 3.7 and 3.8 into Eq. 3.6 yields:

$$\begin{aligned} LC_0\frac{\partial^2}{\partial t^2}\left(V - bV^2\right) &= \ell^2\left(\frac{\partial^2 V}{\partial x^2}\right) + \frac{\ell^4}{12}\left(\frac{\partial^4 V}{\partial x^4}\right) \\ &- R_1C_0\frac{\partial}{\partial t}\left(V - bV^2\right) + R_2C_0\frac{\partial}{\partial t}\left[\ell^2\left(\frac{\partial^2 V}{\partial x^2}\right) + \frac{\ell^4}{12}\left(\frac{\partial^4 V}{\partial x^4}\right)\right] \\ &- R_2C_0b\frac{\partial}{\partial t}\left[2\ell^2\left(\frac{\partial^2 V}{\partial x^2}\right) + 2\ell^2\left(\frac{\partial V}{\partial x}\right)^2 + \frac{\ell^4}{6}V\left(\frac{\partial^4 V}{\partial x^4}\right)\right. \\ &\left. + \frac{2}{3}\ell^4\left(\frac{\partial V}{\partial x}\right)\left(\frac{\partial^3 V}{\partial x^3}\right) + \frac{\ell^4}{2}\left(\frac{\partial^2 V}{\partial x^2}\right)^4\right]. \end{aligned} \tag{3.9}$$

The above derivation closely parallels an analogous derivation for actin filaments whose details can be found in Tuszynski et al. (2004).

Considering that the time variations of the local voltage V are small compared to the constant background voltage V_0, we can safely assume that the time derivative is of the order of the small parameter ε as well as the nonlinear

Capital V is voltage and small v is velocity

voltage terms bV^2 are of the order ε^2. Thus Eq. 3.9 can be vastly reduced by collecting only the leading terms:

$$LC_0\frac{\partial^2 V}{\partial t^2} = \ell^2\left(\frac{\partial^2 V}{\partial x^2}\right) + R_2C_0\frac{\partial}{\partial t}\left[\ell^2\left(\frac{\partial^2 V}{\partial x^2}\right)\right] - R_1C_0\frac{\partial V}{\partial t} + R_1C_0 2bV\frac{\partial V}{\partial t}. \tag{3.10}$$

Taking into account the values of L and C_0, Eqs. 2.19 and 2.17, it is clear that the factor $LC_0 \sim 10^{-30}$ s is exceedingly small and hence the second derivative term can be safely ignored. Moreover, since $R_1 \gg R_2$, the term proportional to the factor $R_2\ C_0$ can also be discarded bringing Eq. 3.10 into its final form:

$$\ell^2\frac{\partial^2 V}{\partial x^2} - R_1C_0\frac{\partial V}{\partial t} + R_1C_0 2bV\frac{\partial V}{\partial t} = 0. \tag{3.11}$$

As a first step we can linearize this equation taking $b \to 0$, which yields $b \to 0$, thus getting

$$\frac{\ell^2}{R_1C_0}\frac{\partial^2 V}{\partial x^2} = \frac{\partial V}{\partial t}. \tag{3.12}$$

This simply represents Fick's law of diffusion with a coefficient of diffusion

$$D = \frac{\ell^2}{R_1C_0} = 0.8\times 10^{-10}\,\mathrm{m^2/s},$$

a value that, for example, falls within the experimentally observed range (Albriton et al. 1992) for calcium waves in intracellular calcium dynamics from endoplasmic reticulum.

The spatio-temporal voltage function in Eq. 3.12 follows the diffusion of ions along the MT. The solution of this equation is a well-known Gaussian wave packet that spreads with time according to:

$$V(x,t) = V_0\left(\frac{R_1C_0}{\pi\ell^2 t}\right)^{\frac{1}{2}}\exp\left\{-\left[\frac{x}{2\left(\frac{\ell^2 t}{R_1C_0}\right)^{\frac{1}{2}}}\right]^2\right\}. \tag{3.13}$$

We now analyze Eq. 3.10 by introducing a set of dimensionless variables as follows:

$$\left.\begin{aligned} &\frac{x}{\ell} = \eta; \quad \frac{t}{R_1C_0} = \tau; \quad \xi = \eta - v_0\tau \\ &V_0 = \frac{v}{v_0}; \quad v_0 = \frac{\ell}{R_1C_0}; \quad W = \frac{V}{V_0} \end{aligned}\right\} \tag{3.14}$$

Here, v is the actual propagation velocity of ionic waves while v_0 is the maximum value of the propagation velocity in a given medium.

The characteristic velocity of ionic waves is found to be

$$v_0 = \frac{8\times 10^{-9}}{10^9\times 1.32\times 10^{-15}}\,(\mathrm{m/s}) = 6\,(\mathrm{mm/s}), \tag{3.15}$$

and is two orders of magnitude greater than the velocity of calcium waves in bulk cytoplasm (Wang et al. 2004). However, since $v < v_0$ ($V_0 < 1$) this appears to be a reasonably accurate estimate which is likely to correspond to the velocity of MT-guided ionic waves in vivo. In terms of the new variables in Eq. 3.14, the nonlinear partial differential equation of (3.11) now becomes an ordinary differential equation which reads:

$$\frac{\mathrm{d}^2 W}{\mathrm{d}\xi^2} + v_0\frac{\mathrm{d}W}{\mathrm{d}\xi} - 2v_0V_0bW\frac{\mathrm{d}W}{\mathrm{d}\xi} = 0. \tag{3.16}$$

Integrating it once we easily find that:

$$\frac{\mathrm{d}W}{\mathrm{d}\xi} + v_0W - v_0V_0bW^2 = c_1. \tag{3.17}$$

Interestingly, the same form of a differential equation can be found to describe the thermophoresis of biopolymers in solution (Braun and Libchaber 2004) where temperature changes linearly with distance ($T = T_0 + \alpha x$)

$$j = -D\frac{\mathrm{d}c}{\mathrm{d}x} - D_{\mathrm{T}}c(1-c)\frac{\mathrm{d}T}{\mathrm{d}x} = \mathrm{const}, \tag{3.18}$$

where $c(x)$ is the polymer concentration function, D is the diffusion coefficient, D_{T} is the thermal diffusion coefficient, and j is the steady-state current density of the polymer. This is the basis for a thermal force scenario proposing that life might have originated in pores, driven by gradients of temperature and electrical potential at hydrothermal mounds developed over submarine seepages. Moreover, if $c_1 = 0$ in Eq. 3.17, it reduces to the same mathematical form describing the logistic equation of population growth (Strogatz 1994).

In order to determine c_1 in Eq. 3.17 we impose the natural initial condition of the type

$$\frac{\mathrm{d}W}{\mathrm{d}\xi} = -A < 0, \quad \text{for} \quad W = 0.$$

Separating variables in Eq. 3.17 and factorizing it, we have

$$\int\frac{\mathrm{d}W}{W - W_1} - \int\frac{\mathrm{d}W}{W - W_2} = \alpha\xi + \ln c_2, \tag{3.19}$$

where

$$W_{1,2} = \frac{1}{2bV_0}\left[1 \pm \left(1 + 4\frac{AV_0b}{v_0}\right)^{\frac{1}{2}}\right] \quad \text{and} \quad \alpha = (W_1 - W_2)V_0v_0b > 0. \tag{3.20}$$

The integration of Eq. 3.19 with the initial conditions: $\xi = 0 \Rightarrow W = 0$, yields:

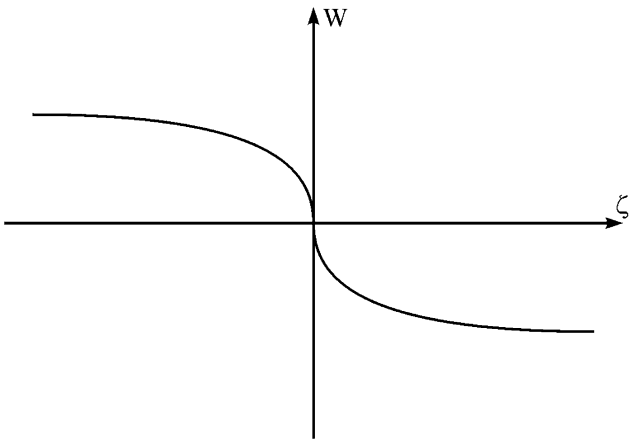

Fig. 10 The anti-kink profile of ionic potential propagating with small velocity along MT

$$W(\xi) = W_1\left[\frac{1-\exp(\alpha\xi)}{1-\frac{W_1}{W_2}\exp(\alpha\xi)}\right]. \tag{3.21}$$

Let us consider the interesting case of slow waves with velocities v_0 obeying the inequality

$$\frac{4AV_0b}{v_0} \gg 1, \tag{3.22}$$

which implies that Eq. 3.21 becomes

$$W_0(\xi) = -\left(\frac{A}{bV_0v_0}\right)^{\frac{1}{2}}\tanh(\alpha\xi), \quad \alpha = 2(AbV_0v_0)^{\frac{1}{2}}. \tag{3.23}$$

This is a symmetric anti-kink (AK) represented graphically in Fig. 10.

In order to examine Eq. 3.17 with respect to its stability we start from a slightly distorted trial solution of the form

$$W = W_0 + \delta; \quad \delta \ll W_0.$$

Inserting this trial solution into Eq. 3.17 we readily obtain

$$\frac{d^2\delta}{d\xi^2} + v_0(1-bV_0)\frac{d\delta}{d\xi} - \left(\frac{dW_0}{d\xi}\right)bV_0\delta = 0. \tag{3.24}$$

Since the inequalities

$$bV_0 \ll 1; \quad \frac{dW_0}{d\xi} < 0$$

always hold, this clearly indicates that the AK of Eq. 3.23 represents a robust stable front of propagating ionic wave as shown in Fig. 10.

The impact of the cell's intrinsic electric fields on the dynamics of AKs in MTs

Satarić et al. (1993, 2007) and Satarić and Tuszynski (2003, 2005) developed the ferroelectric model of MTs with oppositely charged ends as giant dipoles arising as a consequence of the fact that every tubulin dimer possesses an intrinsic electric dipole (see Fig. 11) that becomes compensated by the dipoles of its neighbors only partially.

These ferroelectric features of MTs lead to the conclusion that every MT has an intrinsic, almost constant, electric field E whose magnitude depends on the environmental pH conditions and the MT length. This field gives rise to an additional potential V_{int}. In this context the dimensionless Eq. 3.16 cab be analyzed numerically by taking into account V_{int}.

If we judiciously choose the set of parameters:

$$v_0 = 0.1, \quad v_0bV_0 = 0.05, \quad \frac{V_{int}}{V_0} = 0.4,$$

we have the resultant equation in the form

$$\frac{d^2W}{d\xi^2} + 0.1\frac{dW}{d\xi} - 0.05W\frac{dW}{d\xi} + 0.1 = 0. \tag{4.1}$$

Taking the initial conditions as

$$\frac{dW}{d\xi}(0) = -0.5, \quad W(0) = 0$$

we calculate the trajectory for the center of the AK as a function of the dimensionless time represented graphically in Fig. 12.

This figure shows that the AK is initially driven by acceleration and after $\tau = 50 (t \sim 0.5\,\mu s)$ it attains a constant terminal velocity $V_0 = 0.1$ ($v = 0.1 \cdot v_0 \approx 600$ μm/s) which is reasonably close to the experimentally determined values for waves of Ca^{2+} ions.

We further assume that certain intrinsic alternating electric fields (IAEF) can be elicited in the cell's compartments. It was already suggested earlier that such fields can originate from the oriented (vicinal) water molecules which form an electric dipole field occurring on either side

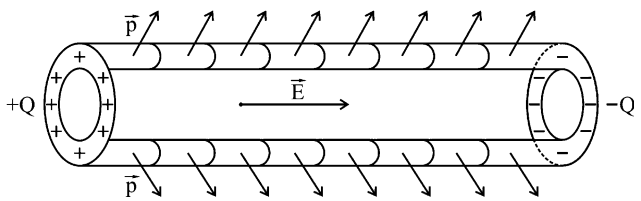

Fig. 11 Ferroelectric features of a MT. The charged tips bring about a constant intrinsic electric field E

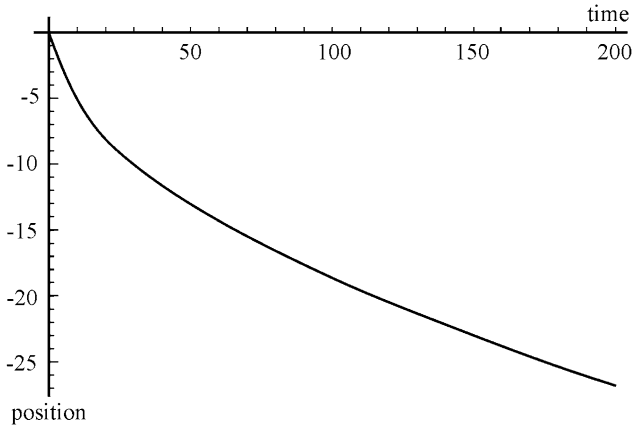

Fig. 12 The trajectory of the center of AK under the action of constant intrinsic electric field, Eq. 4.1

of the cell membrane. Del Giudice et al. (1988) have proposed that electromagnetic fields arising from the coherent oscillations of the above-mentioned water molecules represent signals comparable in size with the dimensions of the cell's MTs. It is potentially of major significance that MTs themselves may be a source of oscillating electric fields in living cells as discussed by Pokorny et al. (2005). We can safely assume that the associated dimensionless driving force has a wavelength greater than the average MT length and it harmonically depends on the dimensionless time τ as follows

$$V_{\mathrm{WF}}(\tau) = A_0 \cos(\Omega\tau + \varphi_0), \tag{4.2}$$

where A_0 is the amplitude, Ω is the frequency and φ_0 is the initial phase of the potential of the water field (WF). Using the same parameters for the homogeneous part of Eq. 4.1 as those used before, and taking $A_0 = 0.5$, $\Omega = 0.5$ and $\varphi_0 = 0$, we have

$$\frac{\mathrm{d}^2 W}{\mathrm{d}\xi^2} + 0.1\frac{\mathrm{d}W}{\mathrm{d}\xi} - 0.05W\frac{\mathrm{d}W}{\mathrm{d}\xi} + 0.1 = 0.5\cos(0.5\tau). \tag{4.3}$$

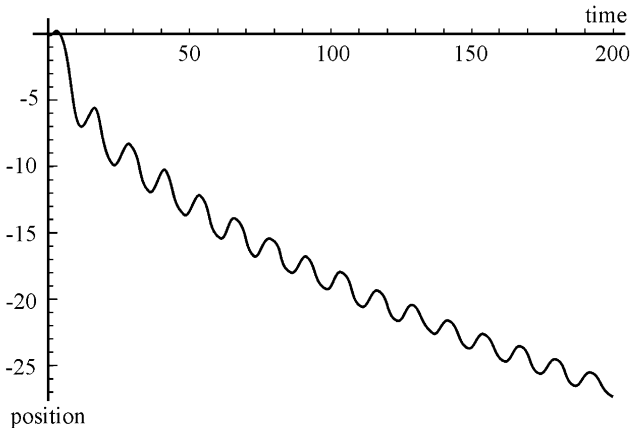

Fig. 13 The trajectory of the center of AK subjected to constant and harmonically changeable intrinsic electric fields, Eq. 4.3

A numerical solution of the above equation produces a trajectory of the corresponding AK as shown in Fig. 13.

We have again found similar characteristics of the unidirectional AK motion with the same average velocity but now superimposed with harmonic oscillations around the center of the AK.

Conclusion and discussion

A new model for ionic currents along MTs has been presented in this paper with a strong emphasis on the concept of a MT as a polyelectrolyte. The background for the model is the molecular structure and geometry of a MT and its interaction with solvent ions. In this context the MT cylinder with brush-like TTs surrounded by ions from cytosol is represented as an electrical transmission line with R, C and L elements whose values have been estimated using the available experimental data and known geometry. The important feature of the nonlinearity of MT capacitance has arisen naturally from the structure of β-TTs. As a result, the nonlinear second order differential equation for the electric potential propagating along the MT was evaluated. The traveling wave solution of this equation, Eq. 3.16, is a localized front profile of the AK type. This front resembles a so-called "nano-tsunami" and it propagates with a velocity which has been estimated to be reasonably close to the experimental findings, for example for waves of Ca^{2+} ions elicited by endosome reticulum compartments. These AKs appear to be stable and robust against perturbations. The remaining part of the paper has been dedicated to the possible impact of the cell's endogenous (intrinsic) electric fields on the dynamics of ionic AKs. It appears that the velocity and direction of propagation of an AK could be tuned by changing the parameters of the above-mentioned fields (i.e. their amplitude, frequency and phase). It is our hope that the model developed here will provide a better insight into the still unknown roles of MTs in the cell's information processing capabilities.

ROWLANDS, S., L. S. SEWCHAND, and E. G. ENNS. 1982. A quantum mechanical interaction of human erythrocytes. Can. J. Physiol. Pharmacol. **60**: 52–59.

Theory predicts that the membrane potential will polarize membrane molecules and cause them to vibrate coherently at a frequency of $\sim 10^{11}$ Hz. If the supply of metabolic energy exceeds a minimum value, membrane phonons may condense their momentum into a single "giant" vibrational mode. At 10^{11} Hz ionic screening is small up to distances of approximately a micrometre, so forces of a range several orders of magnitude longer than chemical forces can arise. These forces may be attractive or repulsive depending on frequency. They should occur in every metabolically active membrane and may control macromolecular transport and enzyme–substrate interactions. We find that normal human erythrocytes in plasma form rouleaux faster than Brownian motion predicts. When cells are fixed in glutaraldehyde or are metabolically depleted, or if the membrane potential is brought to zero, the rate of aggregation agrees with Brownian theory. When the metabolically depleted cells are revived or if the membrane potential is restored, then the interaction returns.

ROWLANDS, S., L. S. SEWCHAND et E. G. ENNS. 1982. A quantum mechanical interaction of human erythrocytes. Can. J. Physiol. Pharmacol. **60**: 52–59.

La théorie veut que le potentiel de membrane polarise les molécules membraneuses et les fait vibrer cohéremment à une fréquence d'environ 10^{11} Hz. Si l'apport d'énergie métabolique dépasse une valeur minimale, les phonons membraneux peuvent concentrer leur momentum en un seul mode de vibration. A 10^{11} Hz, l'interaction ionique est faible jusqu'à des distances de quelques micromètres, de sorte que des forces de plusieurs ordres de grandeur plus élevées que les forces chimiques peuvent se développer. Ces forces peuvent être attractives ou répulsives suivant la fréquence. Elles devraient apparaître dans chaque membrane métaboliquement active et peuvent contrôler le transport macromoléculaire et les interactions enzyme–substrat. Nous constatons que les érythrocytes humains normaux contenus dans le plasma forment des rouleaux plus rapidement que ne le prévoit le mouvement brownien. Quand les cellules sont fixées dans le glutaraldéhyde ou appauvries métaboliquement ou encore si le potentiel de membrane est placé à zéro, le taux d'aggrégation concorde avec la théorie brownienne. Quand les cellules appauvries métaboliquement sont revivifiées ou lorsque le potentiel de membrane est rétabli, alors l'interaction se normalise.

Introduction

For over a decade Fröhlich (1968) has been developing the concept of a unique collective interaction of the molecules comprising cell membranes. Collective interactions are well known in the physics of the condensed state of matter and are responsible for such subtleties as super-conductivity and the bizarre behaviour of liquid helium II. The manifestations of Fröhlich's theory should arise at normal temperatures and should occur in all living systems. In particular the theory predicts the existence of very long-range forces (~ 1 μm) which are highly specific in that an organelle or a cell could recognize another at a distance and be attracted or repelled. Fröhlich (1980) recently reviewed the theory and the evidence in its support.

Since the membrane potential acts across a membrane thickness of the order of 10 nm, the electric field is very great ($\sim 10^7$ V·m^{-1}), and membrane molecules will be strongly polarized in this field. Thermal vibration of the dipoles in the membrane correspond to a polarization wave of half wavelength roughly equal to the membrane thickness. If the velocity of mechanical waves in the membrane has the reasonable value of 10^3 m·s^{-1}, the vibrations will have a frequency of $\sim 10^{11}$ Hz. Resonant absorption in tissue cultures and in microorganisms in the neighbourhood of this frequency comprises the main evidence for the theory (Fröhlich 1980). Since polar molecules interact electrically, the vibrations of the membrane constituents will be col-

lective and the quantum-mechanical properties of these collective interactions will be apparent and important at 10^{11} Hz. The name phonon is given to this aspect of the vibration by analogy with the photon, the corresponding "quasi-particle" of the electromagnetic waves. In a strong electric field, conformational change in macromolecules and the readjustment of counter ions can result in minima appearing in the relationshp between polarization and electric field. If these minima are above the energy of the ground state, they will correspond with metastable polar states; if lower than the ground state, the system will be ferroelectric. Even if the metastable states have a short life their occupancy may remain high by the exchange of thermal phonons with the surroundings, which is a heat bath in the thermodynamic sense. If energy, say from cell metabolism, is now supplied to the modes of such a system of collective polar excitations, a new process arises with the exchange of the difference in energy of two quanta with the heat bath. If this process dominates single-phonon exchange, the supply of energy will become concentrated into the mode of highest wave number and constitute a giant vibration. Phonons have zero spin and obey Bose–Einstein statistics. The mathematical formulation of the accumulation of energy into a single zero wave-number mode is similar to that of the Einstein condensation of a Bose gas (London 1950; Kittel 1958), a condensation in momentum space, not in coordinate space which is the case for the condensation of a common gas. Liquid helium II is presumed to result from such a quantum condensation (London 1950).

Fröhlich's theory as it stands is quite general and makes no predictions about specific cell systems. The important conclusion is that forces, of a range several orders of magnitude longer than London–van der Waals' forces should exist between macromolecular systems within the cell and between cells, perhaps over distances of micrometres. The forces may be attractive or replusive depending on the natural frequencies of the interacting systems and the dispersion of the dielectric constant, as a function of frequency, of the medium in which the systems are suspended. The necessary features of an entity which might be expected to manifest a Fröhlich effect are (*a*) an organization of molecules into some system, (*b*) a membrane potential to polarize the array of molecules in the system, and (*c*) a supply of metabolic energy. In the course of experimentation on red-cell rouleau formation (Rowlands and Skibo 1972; Sewchand and Canham 1979) we noticed a small attraction and a "jiggling" of the membranes just prior to the contact which precedes doublet formation. When we upset the organization of the membrane or remove the supply of energy or alter the membrane potential, this attraction is affected. An account of our early results has been published (Rowlands et al. 1981).

Methods

Venous blood was drawn on the morning of an experiment and immediately mixed with heparin (14 USP units/mL of blood). The plasma was separated by centrifugation and filtered through a 0.3-μm Millipore filter. Red cells, normal or experimentally modified, were added to the plasma at a concentration (v/v) of 0.5%. The low haematocrit blood was stirred rapidly with a magnetic stirrer to break up rouleaux and quickly transferred to a siliconized (Dow Corning, Midland, MI, Sylgard 184 or R4-3117) haemacytometer chamber (Spencer Bright-Line, American Optical Corporation, Buffalo, NY) using a 30-gauge needle to ensure high shear rate and so minimize prior rouleau formation. The chamber was sealed with silicone grease to prevent evaporation and photographed with a time-lapse cinécamera on an Ortholux microscope (Wild-Leitz, Rockleigh, NJ) at about 60× magnification. An exposure was taken every 15 s for 3 h. About 150–200 cells were in view.

Glutaraldehyde-fixed cells

Red cells were washed twice in phosphate-buffered saline (PBS) containing 0.04% glutaraldehyde (PBS composition: 150 m*M* NaCl, 7.3 m*M* Na_2HPO_4, 2.8 m*M* NaH_2PO_4, 2.2 m*M* $CaCl_2$, 4.6 m*M* $MgCl_2$, 310 mosmol, pH 7.4 at 22°C), suspended in the same solution, and shaken gently for 24 h at 22°C. They were stored at 4°C until use. Cells so treated retain normal shape, area, and volume (R. E. Lovlin, unpublished observations).

Microspheres

Latex microspheres 3.4 μm in diameter (Coulter Electronics, Hialeah, FL) were added to plasma at a concentration (v/v) of about 0.2%, shaken, and used immediately. Polystyrene DVB microspheres 5.9 and 8.0 μm in diameter (Duke Scientific, Palo Alto, CA) stuck to the floor of the haemacytometer chamber when in plasma. They were therefore suspended in soapy water at a similar concentration.

Variation of membrane potential

The pH of the cell suspension was measured (PHM 64 Radiometer, Copenhagen, electrode GK2421C) and then lowered by adding 0.14 *M* HCl in 0.14 *M* NaCl (so keeping $[Na^+]$ constant) or increased by adding 0.14 *M* NaOH (Funder and Wieth 1966; Lassen et al. 1980). The membrane potential was calculated from $[Cl_i^-]/[Cl_o^-]$ using the Nernst equation. $[Cl^-]$ was measured with a Corning chloride meter (model 920 M, Corning, Medfield, MA).

Abolition of membrane potential by ionophore A23187

Flatman and Lew (1980) used this ionophore to study magnesium buffering in the human red cell and showed that entry of magnesium depolarized the membrane. We used their method to achieve an approximately zero potential in the following way. The cells were washed twice in PBS containing 10 μ*M* A23187 and then were suspended in plasma to which had been added 10 m*M* $MgCl_2$, 10 μ*M* EGTA, and 10 μ*M* A23187. The pretreatment of the cells with the ionophore was necessary because it is readily adsorbed by albumin (Sarkadi et al. 1976).

Metabolic depletion and repletion

Cells were washed in PBS, resuspended in PBS, and incu-

Can. J. Physiol. Pharmacol. Downloaded from www.nrcresearchpress.com by EAST CAROLINA UNIVERSITY on 05/25/14
For personal use only.

bated at 37°C for 22 h. They were repleted by adding 30 m*M* adenosine to the suspending medium and incubating for a further 3 h (Weed et al. 1969; Meiselman and Baker 1977).

Viscosity

The viscosity of plasma ($\eta \sim 1.7 \times 10^{-3}$ Pa·s) for each subject and of the soapy water ($\eta = 1.06 \times 10^{-3}$ Pa·s) for the microspheres was measured with a cone and plate viscometer (Synchro-Lectric, Brookfield, Stoughton, MA).

Analysis of results

The phenomenon is a coagulation of particles undergoing Brownian movement on which is superimposed a specific interaction at a distance. Smoluchowski (1917) developed a theory for the coagulation of the particles of colloidal suspensions. The theory is reviewed in a shortened form by Chandrasekhar (1943) and experimental tests are described by Swift and Friedlander (1964). It is assumed that the diffusion coefficient of the individual particles is given by the Stokes–Einstein relation

$$[1] \quad D = \frac{kT}{6\pi\eta r}$$

where k is Boltzmann's constant, T absolute temperature, η the viscosity of the suspending medium, and r the particle radius. In the theory, Smoluchowski incorporates the possibility of a zone of attraction, radius $Z > r$, around each particle, which ceases to exist if $Z = r$, and if $Z < r$ a repulsive force is implied. Chandrasekhar (1943, equation 461) gives an expression for the variation in the total number of particles as a function of time. We also adopt Swift and Friedlander's (1964) simplifying assumption that all particles have the same radius (and the implication that all zones of attraction have the same radius $Z \neq r$). If, then, N is the total number of particles (single and multiple) the kinetics of coagulation is given by

$$[2] \quad \frac{1}{N_t} - \frac{1}{N_0} = \frac{4kTZ}{3\eta r} t$$

Equation 2 is for a three-dimensional process and would apply if the cells had the same density as plasma and so were distributed randomly in depth as well as in the other two dimensions of the chamber. Cells sediment, however, so the process is compressed into two dimensions and the rate constant will be higher by a factor of 1.5. Equation 2 becomes

$$[3] \quad \frac{1}{N_t} - \frac{1}{N_0} = \frac{2kTZ}{\eta r} t$$

which predicts a linear relation between N_t^{-1} and t.

The developed cinéfilm was projected with a photo-optical data analyser (model 224A, L-W International, Woodland Hills, CA), and in the earliest frame at which the cells had settled, the total number of cells and rouleaux (N_0) was counted in an area defined by the haemacytometer grid. The count was repeated every fifth frame (75 s) initially, and at increasing intervals up to 20 frames (300 s). The regression of N^{-1} on t was computed.

Einstein's (1926) theory of Brownian motion gives the mean square deviation in two dimensions as a function of time

$$[4] \quad \langle U^2 \rangle = 4kTt\mu^{-1}$$

where μ is Stokes' drag coefficient for spheres

$$[5] \quad \mu = 6\pi\eta r$$

which is also the denominator in [1]. To check that isolated cells were executing Brownian motion, U was measured against t for each of 30 cells which did not come within 6 μm of another during the first 15 min of each experiment. Beyond 15 min fewer than 30 cells fulfilled this criterion. The correlation of $\langle U^2 \rangle$ with t and the value of μ were calculated.

Results

Drag coefficients

The interaction occurs against a background of Brownian movement and, in differentiating between the two, the observations on the drag coefficient are pivotal. If the measured value of plasma viscosity is inserted into Stokes' Eq. 5, the drag coefficient for spheres of the same diameter as cells is 1.28×10^{-7} N·s·m^{-1}. Canham et al. (1971) observed the free fall of erythrocytes in Ringer's solution. Allowing for the different viscosity of plasma, we calculate from their published data $\mu = 1.49 \times 10^{-7}$ N·s·m^{-1}. The cells were tumbling as they fell so Perrin's correction to Stokes' formula for oblate spheroids (Tanford 1961) is appropriate, bringing the theoretical value up to $\mu = 1.54 \times 10^{-7}$ N·s·m^{-1}. Deformability of cells could well account for the difference in the last two figures. These two values are substantially less than the experimental values (Table 1). The results for microspheres give an explanation. For the small microspheres the drag coefficient by Stokes' Eq. 5 is 0.57×10^{-7} N·s·m^{-1} and the measured value 0.62×10^{-7} N·s·m^{-1}, 1.1 times higher. On the cinéfilm these particles are seen to be going in and out of focus, rising and falling continually and so spending a negligible fraction of time in contact with the floor of the chamber. The larger spheres have a specific gravity of $\rho = 1.05$ and are suspended in soapy water ($\rho = 1$). They remain in focus and are therefore close to the surface. For 5.9-μm spheres, the Stokes' $\mu = 0.59 \times 10^{-7}$ N·s·m^{-1} ($\eta = 1.06 \times 10^{-3}$ Pa·s) whereas the experimental value is 1.8 times higher at 1.06×10^{-7} N·s·m^{-1}. Similarly for 8.0-μm spheres the factor is 2.1. If we compare the mean μ for cells (Table 1) with the Stokes' μ for oblate spheroids of the same major diameter the factor is 1.78. We infer that the juxtaposition of either cells or large microspheres with the floor of the chamber introduces an additional hydrodynamic drag.

Since [2] and thus [3] are derived from [1] in which the denominator is the Stokes' coefficient, the rate constant in [3] has to be divided by the ratio of the experimentally determined to the theoretical drag coefficient (Table 1). In this way, for each experiment, a

TABLE 1. Drag coefficients

	$\mu \times 10^7$ N·s·m^{-1}	Experimental value/ Stokes' value for oblate spheroids
Normal cells	2.80±0.66[a]	1.82±0.43[a]
Cells fixed in glutaraldehyde	2.96±0.68	1.92±0.44
Cells at pH 6.3	2.78±0.76	1.80±0.50
Cells restored to pH ~7.6	2.57±0.83	1.67±0.54
Ionophore-treated cells	3.39±0.14	2.21±0.09
Metabolically depleted cells	2.18±0.34	1.42±0.23

[a]Standard deviation.
[b]Standard error of the mean.
[c]The larger microspheres in plasma stick to the floor of the chamber. These experiments were done in soapy water ($\eta = 1.06 \times 10^{-3}$ Pa·s).
[d]The Stokes' drag coefficient for spheres was used in this calculation.

"Brownian motion rate constant" (no interaction; $Z = r$) is calculated. The values are in the neighbourhood of 2.6×10^{-18} m^3·s^{-1}. For convenience we use an "interaction coefficient" Ξ which has a magnitude of unity when representing the "Brownian motion rate constant". Slopes of the graph N_t^{-1} against t are reported in terms of Ξ and from [3]

$$[6] \quad \Xi = Z/r$$

To get a measurement of the accuracy of the determination of the drag coefficient, U ([4]) was measured in seven experiments on the same blood. The standard error of the mean value of $\langle U^2 \rangle$ was 19% which sets a lower limit to the accuracy of the experiments as presently performed. Correlation coefficients for the regression of $\langle U^2 \rangle$ on t averaged 0.94 and for N_t^{-1} on t averaged 0.98.

Normal cells, glutaraldehyde-fixed cells, and microspheres

In Table 2 the present results and those derived by an earlier method (Rowlands et al. 1981) are displayed together. The simple geometrical analysis, which we used previously, predicted that if there was no interaction the mean probability that pairs of cells, initially less than 8 μm apart, would collide in 3 h was 0.3. The theory used in analyzing the present results has ample experimental support (Swift and Friedlander 1964) from the coagulation of hydrosols. This theory predicts an attractive interaction if $\Xi > 1$. The figures in column two, by having the same trend as those in column one, confirm our previous conclusions though the mathematical relationship between the two sets of figures is nonlinear, as might be expected.

The interaction coefficient Ξ for normal cells is three times greater than the theoretical value for neutral particles. The experimental value of $\Xi = 2.9$ taken together with a probability by the earlier method of 0.85 (value for no interaction ~0.3) is our evidence for an attraction at a distance between normal erythrocytes. Cells fixed in glutaraldehyde and the microspheres have significantly lower values for Ξ close to unity. Glutaraldehyde-fixed cells have a negative surface charge which is at least as large as that of normal cells (Vassar et al. 1972) but it will be neutralized by counter ions up to very short distances of approach (~1 nm) so an electrostatic repulsion is unlikely to be detected in the present experiments.

Variation in pH of the suspending medium

At pH 6.3 the membrane potential is close to zero (Funder and Wieth 1966), there should be no Fröhlich-type interaction, and Ξ should be equal to unity, which it is. At pH 6.3 the membrane potential calculated from the chloride ratio was 1.5 mV as against that in normal cells of 16 mV. Restoring pH to 7.6 raises Ξ significantly above unity and the membrane potential to 12 mV.

Ionophore-treated cells

Reducing the membrane potential by the procedure

[c]Standard deviation: $p < 0.001$ normal versus glutaraldehyde cells; normal versus pH 6.3 cells; pH 6.3 versus pH 7.6 cells; normal versus metabolically depleted cells; $p < 0.003$ normal versus ionophore-treated cells.

of Flatman and Lew (1980) also reduced Ξ significantly. There were only two experiments so further work is needed to discover if the difference between the two methods of changing membrane potential is real. There are some difficulties common to both the ionophore and the metabolic depletion experiments which will be explained in the Discussion.

Metabolic depletion and repletion

Depleting the cells of ATP caused the largest decrease in Ξ into a range suggestive of a repulsion. Repletion with adenosine reversed the alteration completely. Metabolic depletion reduced the calculated membrane potential from 15.0 to 7.1 mV so the marked change might be the result of a combination of two effects which may be difficult to separate (see Discussion).

Range of the attraction

From [3] and the definition of Ξ, it follows that the range of attraction $Z = \Xi r$ where r is the radius of the cell. For normal cells $\Xi = 3$ and therefore $Z = 12$ μm. The implication is that cells separated beyond this zone execute Brownian movement. On closer approach, pairs of cells are, on the average, committed to make contact and to form a rouleau. Energetic fluctuations of Brownian movement can of course drive some "committed" pairs apart.

Discussion

Substantial experimental support for Fröhlich's theory would impose radical changes on physiological thought. The evidence which Fröhlich recently reviewed (Fröhlich 1980) has made little impact. The frequency of the predicted oscillations poses technically difficult problems and the results, while indicative of vibrational modes, offer no evidence for the broader implication of the theory. The experiments reported in this paper were designed to test three major aspects of the theory, all of which are necessary features (see Introduction).

The membrane potential

When the pH of the suspending medium is reduced to 6.3 and the chloride determinations indicate that the membrane potential is close to zero, the interaction coefficient is that of a random interaction between cells. In normal cells the interaction coefficient is three times greater and if the pH is restored from 6.3 to 7.6, the interaction returns. In addition to having a membrane potential, erythrocytes have a negative surface charge which keeps cells apart when they are suspended in artificial media devoid of macromolecules. This charge varies with pH and the isoelectric point is in the neighbourhood of pH 2 (Ponder 1948; Bateman and Zellner 1956; Heard and Seaman 1960). The effect, if any, of a reduction to pH 6.3 will therefore be to reduce the surface charge and so act in the opposite direction to the change we have observed. For reasons already given (see Results) an electrostatic repulsion would have a very short range. There was no change in plasma viscosity with change in pH.

Metabolic depletion

Whereas, in the pH experiments, cells which touch proceed to rouleau formation and so make the analysis unequivocal, crenation and sphering of metabolically depleted cells introduce a technical difficulty. Such

Can. J. Physiol. Pharmacol. Downloaded from www.nrcresearchpress.com by EAST CAROLINA UNIVERSITY on 05/25/14
For personal use only.

cells adhere but they do not form rouleaux and it is a matter of judgement to decide, at the low magnification and resolution perforce used, the instant of contact. When the cellular concentration of ATP falls to about half the normal value, crenation occurs quite abruptly (Nakao 1974) but it is difficult to predict just how long the incubation should last to avoid this transition. In one of our experiments, however, less than 10% of the cells were crenated and the rest were forming rouleaux. The interaction coefficient was close to that in the other three experiments. This obviates the objection that it might be crenation *per se* which led to the low value of Ξ in metabolic depletion.

Nevertheless, the technique may have significant effects in addition to that of cutting off the supply of metabolic energy and so account for the value of $\Xi < 1$ which implies a repulsion, small enough to be overcome by Brownian motion. We know that the membrane potential is halved to 7 mV. There are also ion shifts (Clemens et al. 1980) but the zeta potential and thus the surface charge is unaffected (Weed et al. 1969). Once again there was no change in plasma viscosity.

Metabolic depletion modifies membrane structure in other ways than crenation (Lutz 1978). Indeed, Glansdorff and Prigogine (1971) assert that a supply of metabolic energy is a fundamental thermodynamic necessity, not only for the function of a cellular membrane but also for its stability and for the assembly of its structure.

Glutaraldehyde-fixed cells

Fröhlich's last major requirement is for molecular organization. A great deal is known about the structure of the cellular membrane (Marchesi et al. 1976), the functions of receptors (Edelman 1976), the assembly of proteins (Wickner 1980), and the transport of various substances (Lassen et al. 1980). But of a membrane regarded by Fröhlich as an intricate machine, needing a power supply and undoubtedly subject to control of its function as an entity, we know as yet nothing that enables us to interfere other than destructively. Almost certainly glutaraldehyde, which cross-links proteins and aminophospholipids (Carvalho et al. 1980), wreaks havoc. Some enzyme and receptor activity remains and our method preserves the shape, volume, and area of the cells, but undoubtedly the supply of energy and the membrane potential are lost. So at present we regard this type of experiment as a control along with experiments using microspheres.

Ionophore-treated cells

The treatment of erythrocytes with ionophore A23187 in the manner described caused morphological changes, largely sphering, in a minority of the cells. This led to difficulties similar to those described for crenated cells after metabolic depletion. Nevertheless, reduction in the membrane potential by this method reduced the interaction substantially and so confirms the necessity of a membrane potential to the interaction.

General discussion

All the described experiments were done in plasma and there is no detectable attraction between cells suspended in artificial media devoid of macromolecules. Preliminary experiments using PBS containing polyvinylpyrrolidone or Dextran 70, both rouleau-inducing agents (Sewchand and Canham 1979; Sewchand and Bruckschwaiger 1980), suggest that these macromolecules can transmit the interaction. Experiments are in progress to dissect plasma to discover which component is the transmitting medium, but we are as yet unable to suggest what is being transmitted, be they phonons, some other quasiparticle for which there are many candidates, or quantized polar waves. Exchange of phonons between superconducting electrons overcomes electrical repulsion with an attractive force (Fröhlich 1950 cited by Rose-Innes and Rhoderick 1978) so perhaps an analogous process is more than abolishing the Coulomb repulsion between erythrocytes.

The Fröhlich theory predicts that polarized cell membranes may be triggered into coherent, cooperative oscillations if supplied with energy above a minimum rate. The laser is the best known example of such a process but the phonon-maser (Chiao et al. 1964) is the closest comparison we know. The work presented in this paper demonstrates a hitherto unknown interaction of human erythrocytes and we have tested it against Fröhlich's theory. The theory demands a strong transmembrane electric field. When it is abolished experimentally, the interaction disappears, only to reappear when the field is restored. Cutting off ATP also abolishes the interaction but we are in doubt about the integrity of the subtleties of membrane structure as a result, and certainly the electric field is halved. The theory deals with organization, electric field, and energy supply as separate entities but the three are likely to be functionally inseparable. It is an obvious suggestion that the electric field not only polarizes membrane molecules but also is the ultimate supply of energy to the vibrations. The mechanism is there in the work of Mitchell (1976). He uses the term "proticity" to refer to the flow of protons, as electricity refers to the flow of electrons, and describes a number of proticity generators in biological cells. "A generator of proticity plugged through the membrane at any point can act as a source of protonic power than can be drawn upon by a suitable consumer unit plugged through the membrane at any other point, even when the producer and consumer units are quite far apart on a molecular scale . . .

Can. J. Physiol. Pharmacol. Downloaded from www.nrcresearchpress.com by EAST CAROLINA UNIVERSITY on 05/25/14
For personal use only.

the use of proticity for power transmission in biology is unique in its ubiquitous occurrence and wide range of application." It may therefore be impossible to dissociate, unequivocally, membrane potential difference from the supply of energy.

This interaction of human erythrocytes has features in common with Fröhlich's theoretical predictions. One prediction which is not tested in the present work is that of specificity. The interaction should be attractive, repulsive, or null depending on the relative frequencies or phases of the vibrations of the neighbouring membranes. Evidence of specificity can be deduced from the experiments of Sewchand and Canham (1976) on rouleau formation in mixtures of erythrocytes from different mammalian species. In such interspecies rouleaux, the cells can be recognized by differences in size and they are seen not to be distributed at random within a rouleau. Overbeek (1952) reviewed theoretical and experimental work on the aggregation of polydispersed colloids and showed that the *least* likely collision in Brownian movement is between particles of the *same* size. Yet, in the interspecies experiments, cells of the same size and so of the same species show a preference to adhere to each other. In 10 pairings of species, the only exception was the rat–mouse combination, though the difference in cell size is larger than in some pairs which did show a species preference. As they belong to the same biological family, perhaps all murine erythrocytes are indistinguishable in respect to a Fröhlich interaction. Whether the interspecies interaction is a repulsion, a null interaction, or a smaller attraction than that between cells of the same species cannot be deduced from Sewchand and Canham's (1976) results, but further experiments using methods similar to those described in this paper should answer that question.

It is interesting to note that the history of this line of thought goes back at least 30 years. Fritz London (1950) asking if the study of liquid helium II was of any practical use, wrote "... certain actions between macromolecules in biochemistry could not be understood unless they could be conceived as conditioned by some quantum mechanism involving the system as a whole ...". More recently Glansdorff and Prigogine (1971) wrote "... [There] exist new dynamic states of matter induced by a flow of free energy far from equilibrium ... governed by a new physical chemistry on a supermolecular level, while all the laws referring to the molecular level remain essentially unchanged ...".

Acknowledgments

A Review of the Applications of Solid State Physics Concepts to Biological Systems*†

Freeman W. Cope

Biochemistry Laboratory
U. S. Naval Air Development Center
Warminster, Pa. 18974 USA

ABSTRACT. The evidence for solid state physical processes in diverse biological systems is reviewed. Semiconduction of electrons across the enzyme particles as the rate-limiting process in cytochrome oxidase is evidenced by the peculiar kinetic patterns of this enzyme and by microwave Hall effect measurements. PN junction conduction of electrons is suggested by kinetics of photobiological free radicals in eye and photosynthesis. Superconduction at physiological temperatures may be involved in growth and nerve. Phonons and polarons seem likely to be involved in mitochondrial phosphorylation. Piezoelectricity and pyroelectricity may be involved in growth and nerve. Infrared electromagnetic waves may transmit energy in lipid bilayers of nerve and mitochondria. Complexed sodium and potassium ions in structured cell water may be analogous to valence band electrons in a semiconductor, and the free cations may be considered analogous to conduction band electrons. Ionic processes in cell water therefore resemble electronic conduction processes in solid semiconductors, which leads to kinetic predictions in agreement with experiment. The future of solid state biology depends on the development of new experimental methods able to measure solid state physical properties in biological materials which are non-crystalline, impure, particulate, and wet.

I. Introduction

The physics and chemistry of the *liquid* state has been widely applied to biological systems. However in addition to liquids, cells contain *solids* (particles and membranes), so that it is reasonable to expect that events of biological importance might occur in the solid parts of cells, and that these events should be governed by the physics of solids. Only recently, and only in a few laboratories, has serious attention been given to this possibility.

Szent-Györgyi[1] in 1941 suggested a role for semiconduction in biology, but the high activation energies of semiconduction in many biological solids measured during subsequent years made this suggestion seem unlikely. However, a particular protein (cytochrome oxidase), which gives kinetic evidence of semiconduction, was measured to have a much lower semiconduction activation energy, approximately equal to the activation energy of the enzymatic reaction catalyzed by this protein, which supports the concept of a semiconductive mechanism. Evidence for other sorts of solid state physical processes in cells (P-N junction conduction, superconduction, piezoelectricity, infrared electromagnetic wave transmission) has also been developed in recent years.

The only previous comprehensive reviews of solid state biology were those of Rosenberg and Postow[2] in 1969 and Cope[3] in 1970. Much has been done since then. The present review will update the 1970 review of Cope.[3] We shall describe in considerable detail work appearing since 1970, but earlier work will be described less completely, and the previous review[3] should be consulted if more details are needed regarding earlier studies. For general background in theory and experiment of organic semiconduction, the books by Gutman and Lyons[4] and Boguslavskii and Vannekov[5] may be consulted.

Solid state biology has been approached in two different ways from two opposite ends of the problem. The two approaches are described in partial separation in the next two sections of this review.

First, purified organic solids, extracted from living animals or plants, have been tested for various solid state physical properties such as semiconduction, superconduction and piezoelectricity. These and other solid state physical phenomena have indeed been observed in purified biological solids. One does not immediately know, however, whether the solid state physical properties of isolated, purified biological solids necessarily play any role in the function of living systems. They might not.

Second, solid state biology has been approached from the other end. Some observed properties of *organized living systems* are not easy to explain in terms of chemical processes in aqueous solutions, but may be derived readily from hypotheses of solid state physical processes in cells. One may then use the observed characteristics of organized living systems to deduce the quantitative properties of solid state physical phenomena which may cause them. One may then compare these deductions with the observed solid state physical properties of purified components of these complex organized living systems.

II. Solid State Physical Phenomena in Components of Living Cells

A. Semiconduction. In 1941, Szent-Györgyi[1] hypothesized that semiconduction of electrons in solid proteins or DNA might play a role in biological function. This idea led many investigators to measure the temperature dependence of electron conductivity for dried, compressed pellets of many components and extracts of biological systems, such as proteins or cell fragments. In general, the data did indeed conform to the semiconduction equation

$$\sigma = \sigma_0 \exp(-E_a/kT) \tag{1}$$

where σ = measured conductivity, E_a is activation energy of semiconduction, k is Boltzmann constant, T is absolute temperature and σ_0 is a constant. However, the value of E_a was usually in the region of 1.0 ev, so that conductivity at physiological temperature was very low, perhaps too low to

serve any useful biological function, and the 1.0 ev was much higher than the observed activation energies of most biological processes.[6] For these reasons, by the middle 1950's, most investigators concluded that semiconduction probably played no role in biology.

Several important points had however been overlooked.

First, the possible influence of water was overlooked. Measurements of semiconduction had been made only in *dried* systems. Living systems function only when wet (80 percent water). Water as an impurity at the surface of tiny biological particles or membranes might change electron conductivity by many orders of magnitude, as impurities adsorbed on thin film inorganic semiconductors are often observed to do. This effect of water adsorbed on a thin film semiconductor is used for humidity measurement in a commercially available humidity meter. The experiments of Rosenberg[7,8] suggest that the presence of water may indeed cause significant changes in conductivity and activation energy of semiconduction of proteins. A pulsed electron beam method with wet protein films in Russia seems to show the same result.[5,9]

Second, it was overlooked that a few proteins might exist which had unusual structures, specially adapted for high electron conductivities and low semiconduction activation energies. Cope[10] showed that the enzyme cytochrome oxidase had kinetic properties which suggested that it was rate-limited by solid state conduction in this particular protein (which has a specific and complicated structure quite different from most proteins). Then Straub[11,12] measured semiconduction activation energy in this particular protein, cytochrome oxidase, and found it to be approximately 0.3 ev (3 times lower than with most proteins, the high values of which were confirmed by Straub). It therefore seems that although most proteins do indeed have very high values of semiconduction activation energy which make them poorly suited to perform biological functions by semiconduction, there is at least one specialized protein with a low activation energy well suited to the biochemical role which it seems to play.

Third, it was overlooked that electron conduction *within* individual solid particles might be quite different from conduction across interfaces from particle to particle, which may be what one measures when one puts electrodes across a compressed mass of thousands of microscopic particles. To measure electron conductivity *within* individual tiny biological particles, a microwave Hall effect technique was developed by Trukhan[13,14] in Russia, and applied to various biological particles by various investigators.[14-22] The results seem to show that electron conductivities within individual biological particles may be much higher than previously deduced from conductivities of compressed masses of particles, and that cytochrome oxidase activity is positively correlated with microwave Hall effect mobility of electrons.[19,20]

It therefore seems likely that semiconduction within solid biological particles may indeed play a role in biological function in at least a few important biological systems, especially in the enzyme cytochrome oxidase. For more details and references to the earlier work, the previous review[3] may be consulted.*

B. PN Junction or Activation Energy Barrier Conduction. Conduction across an activation energy barrier, such as at a PN solid-state junction or liquid-solid junction of an electrode in an aqueous solution commonly shows a exponential or logarithmic voltage-current equation.

In exponential form

$$I = I_0 \exp(V/kT) \tag{2}$$

is known as the diode equation. In logarithmic form

$$V = a + b \log(I) \tag{3}$$

is known as the Tafel equation of electrodes, where V is voltage, I is current, k is the Boltzmann constant, T is absolute temperature and a and b are constants.

Liquid-solid, and solid-solid interfaces are common in biological systems. Therefore, this type of conduction might be expected in biological systems. Its existence has been deduced from behavior of organized systems as described in Section III of this review.

C. Phonons and Polarons. It has been proposed by Straub[11,23,24] that phonons (packets of lattice vibrational energy) may be involved in transmission of energy from oxidative reactions to phosphorylative reactions in solid protein systems such as membranes of mitochondria. Destruction of the phonons in the solid protein by thermalization may be prevented by the hydrophobic bonding of a layer of lipid separating the protein from the surrounding water.[24] The mitochondrial processes of respiratory control, reversed electron flow, uncoupling, and utilization of two electron transfer to accomplish one bond formation seem to be compatable with the phonon hypothesis.[11,23-26]

Phonon coupling between a pair of electrons to form a superconductive Cooper pair may also occur in biological systems at physiological temperatures. Biological superconduction will be discussed in the next section of this review.

A problem with the concept of phonons in mitochondria is probable lack of mobility, because these phonons would need to have an energy of approximately 0.39 ev (9.0 kcal/mole) which is the energy required for phosphorylation of ADP (the chief phosphorylation reaction carried out by mitochondria). Phonons of this energy are *optical* phonons (wavelength

*Good experimental evidence for electronic conduction in lipid membranes[167-169] and across the shells of crabs[170-172] is also available.

3.24 microns in the infrared band). Optical phonons are generally immobile, so that transport of energy by phonons from sites of oxidation to sites of phosphorylation might be expected to be slow.[25] However, the structure and geometry of the lipid bilayer of mitochondria seems well adapted to carry infrared electromagnetic waves (photons), which could serve as a rapid and efficient method to carry the energy of the phonons throughout the mitochondrion.[25] This mechanism is discussed in Section IIIC of this review.

That polarons rather than phonons may be the vibrational packets in mitochondria is suggested by the reversal at low temperatures of the enzyme activity vs (1/T) curve of cytochrome oxidase measured by DeVault and Chance[27] as analyzed by Cope and Straub.[12] Such a reversal is predicted from the concept that the charge carriers in solid cytochrome oxidase are polarons, according to the theory of Holstein.[28,29] A polaron is an electron or hole tied to a phonon. The probability of polaron conduction in organic semiconductors has been discussed by Siebrand[30] and by Gutman and Lyons.[4]

It has been suggested by Kemeny and Rosenberg[159] that polarons may be the charge carriers in proteins and other organic semiconductors, and may be responsible for the observed compensation law in these substances.

Volkenstein[160] has proposed a state in a protein which he calls a conformon, which he claims should be different from a polaron because of the non-regularity of the atomic lattice, resulting in lack of mobility and short lifetime. This has been studied further by others.[165-166]

It has been proposed on theoretical grounds that melanin (the black pigment found in skin, eye, and in parts of the brain and ear) may be a particularly efficient converter of photons to phonons and of the reverse process.[161-162] Evidence suggesting the phonon to photon conversion by melanin was the observation that ultrasound (10^4 Hz) was more damaging to cells containing melanin than to similar cells without melanin, correlated with previous observations that photons of high intensity light are more damaging to cells if melanin is present.[163-164] At lower intensities, however, melanin protects cells against damage by light.[162]

D. **Superconduction.** Superconduction is the conduction of electrons without the generation of heat, and hence with an electrical resistance equal to zero. Until recently, superconduction had been observed only in certain metals and only at a temperature colder than approximately 20° Kelvin. Theorists have long predicted that superconduction might occur at room temperature in organic solids. The development of new techniques of very high sensitivity has now led to the experimental detection of superconductive transitions in organic solids (various cholates) at temperatures as high as

277°K. Indirect evidence suggests that superconduction plays a controlling role in various functions of living systems at physiological temperatures.

A comprehensive mathematical theory (the BCS theory) of superconduction has been developed which explains and predicts many (but not all) of the experimentally observed electrical and magnetic properties of superconductors[31] and properties of electron tunneling across junctions between superconductors.[32,33] An extension of the BCS theory by Little[34,35] predicted that superconduction should occur in certain types of organic polymers *at room temperatures and above.* There is much controversy among theoretical physicists regarding the validity of this prediction.[36] All attempts to synthesize Little's superconductive polymers have so far failed, which may be due to inadequacies of the attempts.

Pauling[37] and London[38] claim that electron currents around benzene rings in aromatic compounds are analogous to superconductive currents in metals. This claim is disputed by Musher.[39,40] However, much quantitive data on magnitudes of chemical shifts of observed nuclear magnetic resonance spectra of compounds containing benzene rings is explainable in terms of superconductive ring currents.[41-45]

High temperature superconduction has also been predicted in a thin metal film adjacent to a dielectric layer, where the interaction between the two electrons of the pair occurs through the dielectric instead of within the conductor.[36,46-48] All attempts to manufacture such superconductive bilayers or sandwiches have failed, perhaps because the correct method was not tried.

Experimental evidence of superconduction in organic solids at high temperatures has been obtained very recently by Halpern and Wolf.[49-51] These findings required the use of new instrumental methods for the measurement of extremely small changes in magnetic susceptibility.[49-51,177] Transitions (abrupt changes) in susceptibility as a function of temperature and of applied magnetic field were observed in various cholates (4 rings with various side chains).[49-51] The rise of susceptibility is predicated on the concept that transition from normal to superconducting regions would initiate the Meissner effect which would cause internal magnetic field changes to be less than those imposed externally. X-ray diffraction patterns were observed to be unchanged at temperatures across the transition temperature, which showed that no change occured in the in the structure of the atomic lattice.[52] Therefore, the transition must be due to *electronic* rearrangements. A change between superconducting and normal conducting state was the most obvious possibility, and was consistent with the experimental data.[49-51,177] Transition temperatures observed for the cholates were as high as 277°K. Other types of organic compounds studied did not show evidence of superconductivity.[50,51] Cholates showed superconductive phenomena only when crystallized in

certain ways.[50-51,177] The heights of the observed transitions were small, which indicated that only a small fraction of cholate molecules were in the superconducting state at any given time.

Extrapolation[52] of the experimental data on cholates[49-51,177] suggests that cholesterol (a major constituent of nerve and of other tissues) may superconduct at physiological temperatures and above, so that cholesterol might be a site of superconduction in living systems.

Another experimental observation of probable high temperature organic superconduction is the recent data of Antonowicz.[54] He observed fluctuations in current through thin carbon films at room temperature as a function of magnetic field at very low fields (0.5 to 2.0 Gauss), with a pattern like that seen with the Josephson effect for two-electron tunneling at superconducting junctions. No other known physical phenomenon seems adequate to explain this experimental finding.

There is evidence suggesting that high electric fields may promote superconduction in organic fields at high temperatures, and that this might play a role in nerve conduction.[53] The room temperature Josephson effect of Antonowicz[54] in carbon films required a 2 volt electric potential across a carbon film that was presumably only a few molecules thick, so that the electric field would be very high. Magnetic fields of 2000-3000 Gauss cause changes in photocurrent in organic solids (anthracene and tetracene) at room temperature but only if the voltage is sufficiently high to be above the ohmic conduction region and into the square law conduction region.[55] This probably implies charge injection into the organic crystal.[53,55] The magnetic effects in both the above sets of experiments, as well as the square law conduction, may be understood from the hypothesis that high voltage electron injection into organic solids may produce superconductive Cooper pair charge carriers.[53] It is reasonable to consider that this superconductive process might occur in the thin lipid layers of nerve in response to the high electric fields which occur there,[53] especially since extrapolation of the data on cholates suggests that cholesterol (which occurs in large quantities in nerve) should superconduct at physiological temperatures.[52]

The evidence for high temperature superconduction in organic solids raises the possibility that superconduction in solid portions of cells might play a role in living systems. Three lines of indirect evidence suggest that this is so.

First, that bulk superconduction may play a biological role is suggested by the abrupt changes in rates of metabolism of growing tissues induced by magnetic fields of 50 to 150 Gauss,[56-58] although lower fields produced no effect, the higher fields produced no additional effect. A superconductive transition is the most obvious possible cause of a discontinuous effect produced by a magnetic field.[56]

Second, a role in biology for *two*-electron superconductive tunneling (Josephson effect) is suggested by the demonstration tnat numorous living systems (birds, insects, snails, and possibly man) can detect very low magnetic fields (0.5 to 1.0 Gauss).[59,60] No physical phenomenon other than the Josephson effect seems to have sufficiently high magnetic sensitivity to provide the physical basis for this observed biological magneto-detection.[59,60] In addition, the rates of some biological processes are observed to show *negative* temperature coefficients, which cannot be explained by ordinary chemical and physical rate processes, which all show *positive* temperature coefficients. However, Josephson superconductive tunneling has a *negative* temperature coefficient and hence could provide a physical basis for these observed biological phenomena.[56]

Third, a controlling role for *single*-electron superconductive tunneling in living systems is suggested by the temperature dependences of the rates of certain nerve and growth processes.[56] For the rates of most biological processes, like most chemical processes, the temperature dependence is given by linear plots of log of rate vs 1/T (a linear Arrhenius plot). However, a few biological processes show curved Arrhenius plots, and some of these are described by the equation

$$E_a^2 = aT + b \tag{4}$$

where E_a is the activation energy, measured from the slope of the Arrhenius plot, T is temperature in degrees Kelvin and a and b are constants. This type of temperature dependence is predicted for and observed in *single*-electron superconductive tunneling.[56] Therefore, one may surmise that these biological processes (all involving either nerve or growth) are rate-limited by single-electron superconductive tunneling.[56]

piezoelectricity in microtubules

E. **Piezoelectricity and Pyroelectricity.** A piezoelectric solid is usually defined as one which generates a voltage proportional to an applied mechanical force, due to mechanical distortion or displacement of electric dipoles in the lattice.[61] Piezoelectricity has been observed directly in bone[62,63] and wood[64] by measuring electrical potentials induced by bending or compression.

Biological materials which are available only in powdered form cannot be tested for piezoelectricity by the *direct* method used for bone and wood. However, an *indirect* method capable of measuring weak piezoelectricity in powders is available and has been applied to dry biological powders. This method was developed by Giebe and Sheibe[65] and has been improved by others.[66-70] It uses the principle of the vacuum tube crystal oscillator, which has for many years been used as a source of frequency-stable radio-frequency voltage. In this circuit, a piezoelectric quartz crystal, cut to a size and shape to allow mechanical vibration resonance at the desired radiofrequency, is placed between metal electrodes, which are connected

to a vacuum tube feedback circuit. The entire electro-mechanical system then goes into oscillation, which generates a sinusoidal voltage whose frequency is determined by the mechanical properties of the piezoelectric crystal.

Because electrical oscillation in this type of circuit depends on the piezoelectricity of the crystal, the electrical oscillations can be used to detect piezoelectricity in the crystal. The same may be done if a compacted powder is used instead of a single crystal.

To obtain highest sensitivity of detection of weak piezoelectricity in powdered materials, special superregenerative oscillator circuits have been developed in which the amplitude of oscillation is decreased at frequencies at which piezoelectric resonance occurs in the powder.[65-70] These circuits have been used to measure the piezoelectric spectrum of biological materials as a function of frequency and temperature by Duchesne and Monfils[69,71-73] and others.[70,74-77]

Duchesne and Monfils[69,71-73] observed that the positions of the peaks in the piezoelectric spectrum showed a temperature dependence which could be described by the equation

$$\Delta = \frac{-1}{f}\frac{df}{dT} \tag{4A}$$

where df/dT is the observed change in the frequency (f) of the piezoelectric absorption peak per unit change in temperature (T), f is the approximate frequency of the peak, and the calculated constant (Δ) turns out to have approximately the same value for all peaks at all frequencies for any particular type of powdered sample. Δ is therefore a measurable piezoelectric constant characteristic of each organic or biological powder. Duchesne *et al*[69,71-73] believe that the constant Δ is related to other physical parameters of the solid by equation

$$\Delta = \alpha\gamma \tag{4B}$$

where α is the thermal expansion coefficient of the solid sample, and γ is the Grüneisen constant,[78,79] which is a dimensionless measure of the change in entropy with volume of the crystal.

Measured values of Δ for various biological and non-biological powders are given in Table 1.

We should like to know whether the observed piezoelectric properties of these biological materials play any role in function of living systems. They might or might not.

The characteristics of several biological processes suggest that piezoelectric phenomena do indeed perform biological functions.

First, it is observed that the architecture of bone continuously adapts itself to the mechanical loads placed upon it.[80] Growth of bone is

TABLE 1

Piezoelectric Temperature Coefficient of Various Substances

Sample	Δ ($\times 10^{-6}$) $(°C)^{-1}$	Reference
Quartz	6	77
Zinc sulfide	46	77
Potassium sodium tartrate	400	77
1-Chloramphenicol	100	71
DNA (thymus)	50	73
DNA (sperm)	56	73
DNA (yeast)	18	77
RNA (yeast)	6	77
Myosin	85	73
Actomyosin	100	73
Collagen	47	73

The constant Δ is characteristic of the material and is calculated by equation 4A from measurements of the frequency shifts of piezoelectric resonance absorption peaks as a function of temperature, which are measured as described in the text.

experimentally observed to be controllable by applied electric potentials.[81,83-88] Piezoelectric potentials of bone, generated in response to mechanical stress on the bone, may then serve to control the growth of bone to adapt it to the stresses placed upon it.[82]

Second, growth of tissue is stimulated by implantation of piezoelectric dusts.[89-91]

Third, the temperature dependence of the resting potential of nerve is observed to conform to the temperature dependence of piezoelectric resonance.[92] Petrov[93] has theorized that a membrane potential may be dependent on piezoelectric (flexoelectric) properties of liquid crystalline lipids. Piezoelectric properties of liquid crystals have been studied theoretically[94-97] and experimentally.[98,99] Therefore, piezoelectricity may be involved in nerve function.

Fourth, some of the observed properties of muscle stretch receptors may be derived from the hypothesis that piezoelectric elastic polymers are involved in detection of muscle stretch.[100]

Piezoelectric materials are usually also pyroelectric, which means that an electric potential is generated by the application of heat or cold. Pyroelectricity has been measured directly in tendon and bone,[149-155] meninges,[156] spinal cord,[149] and nerves.[156] Also, it is observed that the electrical responses of temperature sense organs of living systems show behavior which is typical of pyroelectric materials.[100] Application of a square pulse of increased temperature causes transient nerve responses of opposite sign at the two ends of the temperature pulse[100] (Fig. 1). This suggests that pyroelectricity does indeed play a role in biological temperature detection.

F. Amorphous Semiconductor Switching. McGinness *et al*[157] have shown that melanins (from melanoma tumors or synthetic melanins) switch from low current to high current when voltage is increased past a certain threshold voltage, which resembles the switching behavior of inorganic amorphous semiconductors (Ovshinsky effect). The increase from low to high current is 10 to 1000 times.

The mechanism of this effect in inorganic materials is in dispute, so that extrapolations of mechanism from inorganics to melanin have not been made. Some information regarding the mechanism of switching in melanin has been deduced from the experiments of McGinness *et al.*[157]

First, the current in the on-state is mostly electronic rather than ionic, because weight loss of sample which would occur if water were lost by electrolysis is negligible.[157]

Second, even though conduction is electronic, water is necessary for switching, because thoroughly dried melanin does not switch, but switching ability is recovered when the melanin is slightly hydrated.[157] Perhaps, water alters electronic conductivity of the melanin by lowering the activation energy for conduction of electrons between sites, analogous to the mechanism proposed by Rosenberg[8] for proteins. This requirement for water for switching to the high conductivity state may be related to the requirement for water for reversibility of electron transfer measured by generation and decay of photogenerated free radicals in eye melanin.[158]

The voltage threshold for switching for hydrated melanin is approximately 500 volts/cm which is much lower than the 5×10^5 volts/cm observed for cytochrome C, which is comparable to the values of voltage threshold observed for inorganics.[157] Various other organic materials of biological origin were tested and found not to show switching behavior.[157]

It would be interesting to know whether switching behavior in melanin plays any role in biological switching processes in regions where melanin occurs, such as skin, retina, brain, or ear.

III. Solid State Processes in Integrated Biological Systems

A. Growth. It is experimentally observable that a living bone grows continuously in a way that adapts it to withstand the stresses to which it is subjected.[80] The boney struts on the inside of a long bone (e.g. the leg bone) are located along the lines of stress. During life, a bone may change its structure to increase or decrease its strength to adapt to the loads habitually placed upon it. For example, a longshoreman's bones

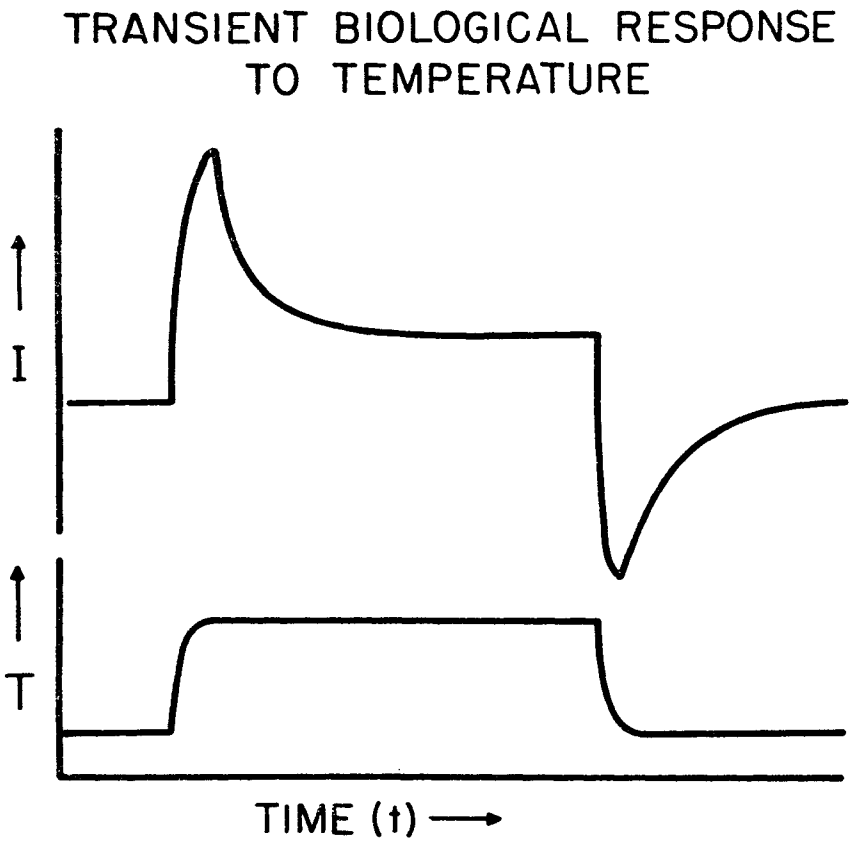

Fig. 1. Transient Biological Response to Temperature Pulse. Lower curve shows a pulse of temperature (T) applied to biological system during the passage of time (t). Upper curve sketches the form of a typical pattern of biological response (I), with transients of opposite sign at the start and end of the temperature pulse, and a steady state response after the initial transient has faded away.[100]

will become much stronger than average, while a person who remains in bed for some months will develop lighter bones. There must therefore exist some sort of system which controls the growth of bones in response to applied stress. It has been observed that application of a D.C. electric potential to the end of a broken bone causes growth.[81,83-88] It has also been observed that bones are piezoelectric, i.e. bending a bone generates an electrical potential.[62,63] It was therefore suggested by Becker, Bassett and Bachman[82] that these two phenomena working together might serve as a closed-loop feedback system by which the body controls the growth of bones in response to the applied stresses.

An additional indication of a relation of piezoelectricity to growth is the observation that implantation of peisoelectric dusts stimulates tissue growth.[89-91]

That superconductivity participates in cell growth is suggested by two lines of evidence. First, various growth processes show a temperature dependence described by a linear relationship between temperature and the square of the activation energy.[56] Such behavior is predicted and observed for single electron superconductive tunneling.[56] Second, the incidence of cancer throughout the world is a periodic function of earth's magnetic field for very low fields.[101] Such behavior is characteristic of two electron Josephson superconductive tunneling.[101]

B. Photobiological Systems (Eye and Photosynthesis). When light falls on a biological system, it may kick an electron up out of its resting position into some other state. One may know that this has happened by the observation by electron spin resonance spectroscopy of generation of free radicals (unpaired electrons) when the biological system is illuminated. This can be observed with illuminated particles (melanin granules) from the eye[102] and with photosynthetic particles (chromatophores) from bacteria.[103] Because decay of the free radical concentration after the end of illumination is slow (several seconds), there must be a barrier of some kind between the illuminated and resting positions of electrons.

Because these biological systems are solid particles floating in watery solution, it is reasonable to suppose that the laws of solid state physics apply within the particle, and that the particle surface acts as a solid-liquid interface, to which electrode physics should apply.

A simple hypothesis for such a system as to why return of illuminated electrons to equilibrium might be slow is that light has kicked the electrons across an activation energy barrier at the particle surface. Activation energy barriers at liquid-solid interfaces are commonly observed[105-107] in electrode physics, and give rise to a voltage-current relation across the interface of the form

$$V = b - \frac{RT}{Fa} \log_e(-i) \tag{5}$$

where V is voltage across the interface, i is current across the interface, T is absolute temperature, R is the gas constant, and a and b are constants. In electrode physics, this relationship is known as the Tafel equation,[104,105] but the same relation (written in exponential form) is seen in solid state physics at solid-solid interfaces, at which it is known as the diode equation. The use of equation 5 for electron conduction across interfaces is well justified on the basis of experimental observation. It also has a theoretical

basis, because it may be derived from the concept of electron conduction across an activation energy barrier at an interface by charge carriers having a Boltzmann distribution of energies and constant charge carrier concentration.[3,105]

We might like to test the hypothesis of an interfacial activation energy barrier in a particulate photobiological system by testing for conformity to equation 5. Unfortunately, a *direct* test is impossible because the eye melanin particles and photosynthetic particle are so small that one cannot make electrical contacts to the two sides of the interface in order to measure the voltage-current curve. An indirect test however, is possible because equation 5 leads to a prediction regarding the shape of the decay of concentration of unpaired electrons vs time after the end of illumination, which can be measured by electron spin resonance.

We may derive the concentration vs time curve as follows:

Let us consider a liquid-solid interface at a particle surface, across which electron current flow is described by equation 5. In the solution outside the particle, let there be an ion (a small molecular weight substance) which can exist in either the oxidized or reduced state, depending on whether it has gained or lost an electron from the nearby solid surface. This reaction may be written

$$x_{ox} + \epsilon^- \rightleftharpoons x_r$$

where x_{ox} and x_r are the oxidized and reduced forms of substrate molecule X respectively, and ϵ^- represents an electron, which may be rapidly and reversibly exchanged between the molecule X and the solid surface of the biological particle. According to theory and experiment of electrode physics, the particle surface then experiences an electrical potential *(V)* given by the familiar electrode equation

$$V = V_0 + (RT/F) \log_e (x_{ox}/x_r) \tag{6}$$

where x_{ox} and x_r are concentrations of oxidized and reduced forms respectively of substate molecule X, V_0 is a constant, and the other symbols are constants as previously defined. Because the sum of oxidized plus reduced forms of X-substrate is always constant $(= C_x)$, we may write

$$x_{ox} + x_r = C_x \tag{7}$$

Combining equations 6 and 7, we obtain

$$V = V_0 - (RT/F) \log_e \left[x_r/(C_x - x_r) \right] \tag{8}$$

If as assumed, light kicks electrons across the particle surface, it disturbs the equilibrium between the two sides of the surface and sets up an electrical potential difference across the surface. Decay of photogenerated unpaired electrons then consists of conduction of electrons back across the

surface in accord with the conduction equation (equation 5), driven by the potential difference of equation 8 for the potential on the liquid side of the surface minus a constant potential which we shall assume for simplicity on the solid side of the surface (this merely assumes an electron concentration in the solid that is large compared to the number of electrons transferred). *The surface reaction described above is equivalent to an electric circuit consisting of a diode connected across a battery.*

We may then equate the driving potential across the interface (given by equation 8 minus a constant) to the voltage drop across the interface given by equation 5 to yield

$$-\frac{RT}{F}\log\left[x_r/(C_x - x_r)\right] = \frac{RT}{Fa}\log(-i) + B \tag{9}$$

where B is a new constant. Because the conduction of one mole of electrons across the particle surface reduces (or oxidized) one mole of substrate molecules, we may write

$$i = F\,dx_r/dt \tag{10}$$

where t is time. Substituting equation 10 in equation 9, we obtain

$$-\frac{RT}{F}\log\left[x_r/(C_x - x_r)\right] = \frac{RT}{Fa}\log\left[-F\frac{dx_r}{dt}\right] + B \tag{11}$$

which is easily converted to

$$-\frac{dx}{dt} = \frac{1}{Fg}\left[\frac{x}{C_x - x_r}\right]^a \tag{12}$$

where g is a new constant. If a = 1, as is theoretically the case for an ideal electrode surface,[108] and if reaction velocity (v) is defined as $v = dx/dt$, then equation 12 may be written in the form

$$\frac{1}{v} = \frac{Fg}{1}\left[\frac{C_x}{x_r} - 1\right] \tag{13}$$

which may be compared with the classical rate equation of Michaelis-Menten for enzyme kinetics

$$\frac{1}{v} = \frac{1}{V}\left[\frac{K_s}{s} + 1\right] \tag{14}$$

where s is substrate concentration and V and K_s are constants.

The rate equation of classical enzyme kinetics (equation 14) is derived from the hypothesis of reactants in free solution obeying the mass action principle, while equation 13 was derived from solid state and electrode physics concepts. Equation 13 and 14 both predict linearity of a double

reciprocal plot of reaction velocity vs substrate concentration, but differ in that they predict opposite signs for the intercepts on the 1/v − axis.

The relevance of the solid state activation energy barrier equation (equation 13) to biology is supported by the fact that decay of photo-generated free radicals in eye melanin particles (Fig. 2) conforms to equation 13 and so does the decay of photoconductivity (Fig. 3) in invertebrate nerve.

Equation 12 for activation barrier kinetics may be put into another form, which is sometimes more convenient for application to experimental data, and which shows an important correlation with experimental solid state physics. This is true because the function log $[x_r/(C_x - x_r)]$ may be adequately approximated by a linear function of x_r which may be shown in the following way: Let us define a new variable λ equal to that fraction of total substrate concentration which is present in the reduced form. Hence, λ is defined by

$$\lambda = x_r/C_x \tag{15}$$

A graph of (Fig. 4) of the function $log_{10}[\lambda/(1-\lambda)]$ *vs* λ shows that $log_{10}[\lambda/(1-\lambda)]$ can be expressed fairly accurately as a linear function of λ for values of λ between approximately 0.15 and 0.85. By measuring the slope and intercept of the straight line approximation, we may write the approximate equation

$$log_{10}\left[\frac{\lambda}{1-\lambda}\right] = 2\lambda - 1 \tag{16}$$

The right hand side of equation 16 is actually the first two terms of the Taylor series expansion of the left hand side. Substitution of equation 15 in equation 16 and conversion to *log* to the base *e* gives

$$log_e\left[\frac{x_r}{C_x - x_r}\right] = \frac{4.6x_r}{C_x} - 2.3 \tag{17}$$

Equation 17 may be written in the form

$$\left[\frac{x_r}{C_x - x_r}\right] = exp\left[2.3\left(\frac{2x_r}{C_x} - 1\right)\right] \tag{18}$$

Equation 18 may be substituted in equation 12 to give

$$-\frac{dx_r}{dt} = me^{nx_r} \tag{19}$$

where m and n are new constants defined by

$$m = \frac{A'}{Fg}\ exp(2.3a) \tag{20}$$

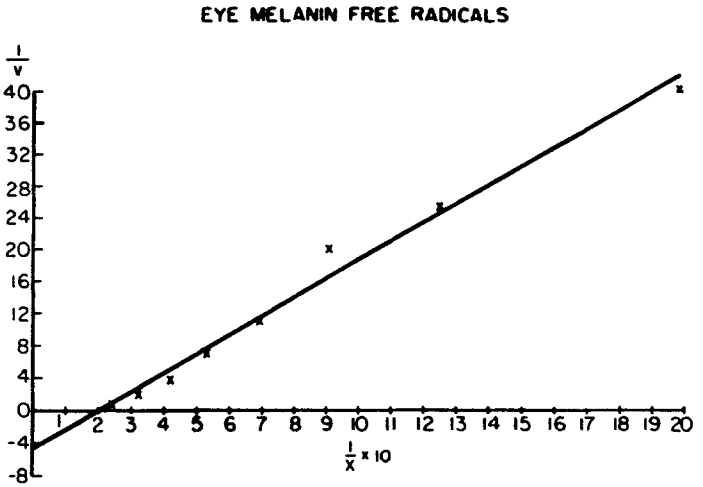

Fig. 2. Double Reciprocal Plot for Decay of Eye Melanin Free Radicals. x = substrate (free radical) concentration. v = reaction velocity = $-dx/dt$. This graph shows a *negative* intercept on the 1/v-axis, which may be contrasted with the *positive* intercept seen in the usual Lineweaver-Burk plot of data from an enzyme reaction conforming to Michaelis-Menten kinetics. Experimental data was obtained from electron spin resonance analysis of eye melanin particles in aqueous suspension at end of illumination with visible light.[109]

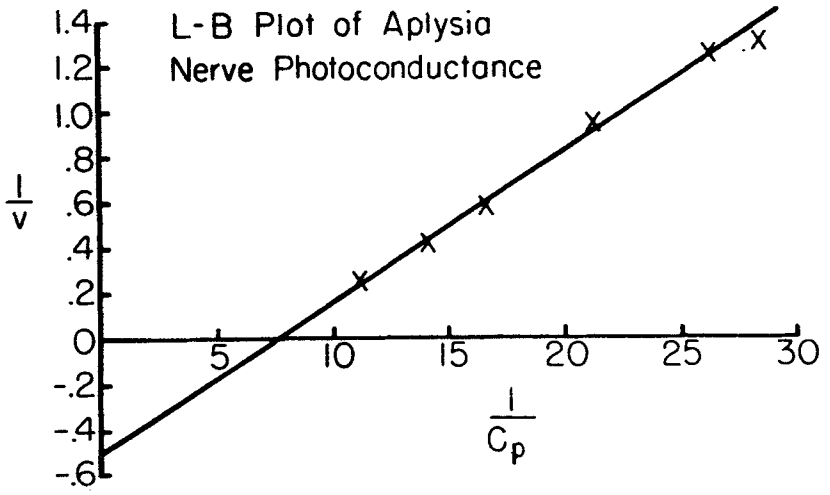

Fig. 3. Double Reciprocal Plot for Decay of Photoconductivity in Nerve. C_p = photoconductance in $(M\ \Omega)^{-1}$ of membrane of *Aplysia* neuron; $v = dC_p/dt$, where t is time. Experimental data were taken from figure 9 of Chalazonitis,[118] in which the data points represent microelectrode measurements of electrical resistance across the membrane of the photo-active neuron of *Aplysia* at various times after the end of exposure to 18 seconds of light with a wavelength of 470-510 $m\mu$. Calculations are taken from Cope.[119]

and

$$n = \frac{4.6a}{C_x} \tag{21}$$

Equation 19 is called the Roginsky-Zeldovich equation or the Elovich equation.[109] It is named after its discoverers who observed that it described data on oxygen absorption and charge decay at surfaces of inorganic semiconductors. The applicability of the Elovich equation to experimental data of surface physics of semiconductors, such as Ge and Si, has been confirmed repeatedly.[109] The frequency of experimental observation of this equation suggested that it was a manifestation of fundamental physico-chemical principles of surfaces, probably connected with electron transport processes. A variety of derivations of the Elovich equation have been

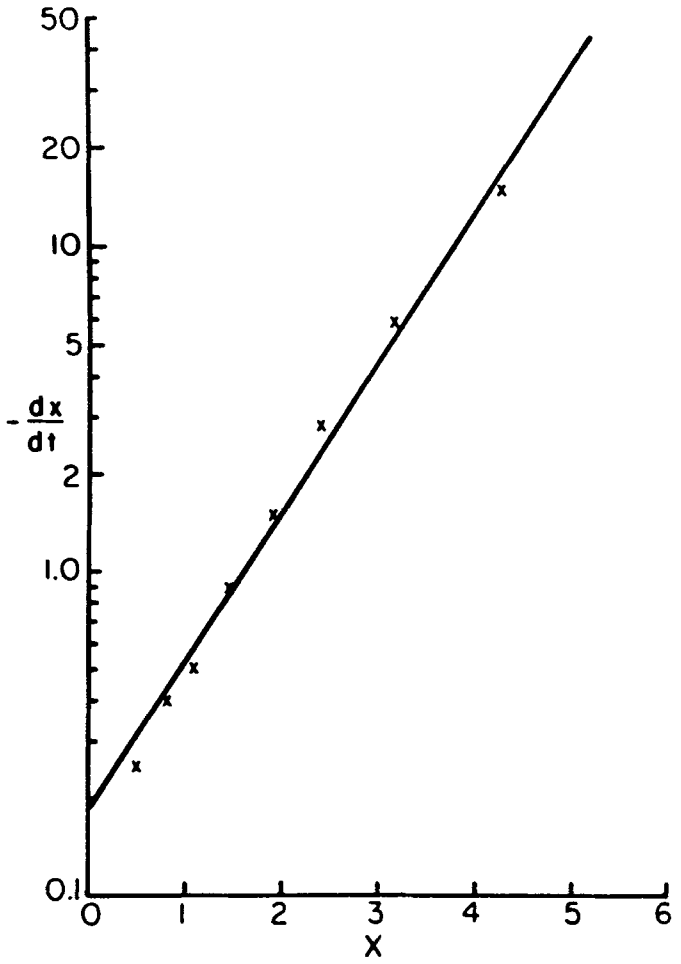

Fig. 5. Test of Eye Melanin Free Radical Decay Data for Conformity to Elovich Equation. Graph of log of reaction rate (−dx/dt) vs free radical concentration (x) for the experimental data of Fig. 2. Linearity of this graph indicates conformity of this data to the Elovich equation (equation 19).

proposed, but all seem to be based on postulates of doubtful validity.[109] The derivation presented here represents a new approach, which is based on postulates that have a good basis in experiment and theory.[109]

After the Elovich equation had been derived by Cope[109] from solid state activation barrier theory, its relevance to biology was confirmed by showing that it described considerable biological data. The Elovich equation describes well the decay of free radicals in eye melanin particles (Fig. 5) and the decay of photoconductivity in nerve (Fig. 6). It also described the decay of free radicals in photosynthetic particles,[110] and the decay of molecules responsible for delayed emission of light from green leaves.[111] All of these biological systems contain particles or membranes

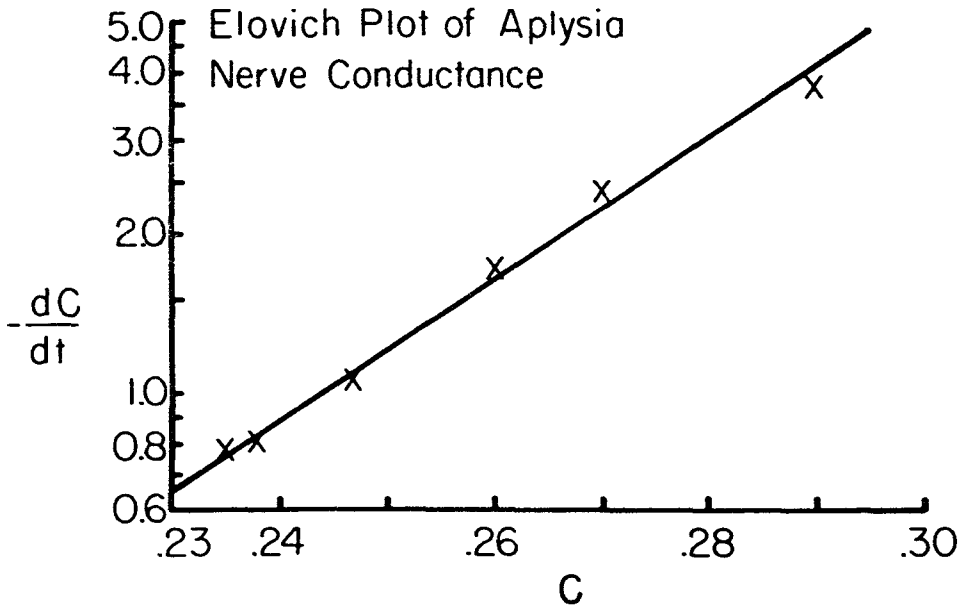

Fig. 6. Test of Nerve Photoconductivitv Decay Data for Conformity to the Elovich Equation. Graph of log of rate of change of nerve membrane conductivity (−dC/dt) vs conductivity (C) for the experimental data of Fig. 3 on *Aplysia* nerve membrane, using the data of Chalazonitis[118] as calculated by Cope.[119] Linearity of this graph indicates conformity of this data to the Elovich equation (equation 19).

as required by the activation overvoltage derivation of the Elovich equation. Support for the concept that solid state electron conduction may be involved in the eye melanin reaction derives from the measurement of relatively high electron mobilities in eye melanin by the new experimental technique of microwave Hall effect.[15]

In addition, the temperature dependence of the Elovich equation has been derived from activation overvoltage theory, and has been found to agree well with experiment, both for inorganic solid systems and for biological systems.[112]

C. Enzymes (Cytochrome Oxidase). Enzymes are the catalysts in cells with cause the chemical reactions necessary for life to procede at rapid rates. Without enzymes these chemical reactions would occur too slowly to support life. Because of their importance to life, the structure of enzymes, and the kinetics and mechanisms of chemical reactions catalyzed by enzymes, have been studied extensively by biochemists and physical chemists for many years.

The classical approach to chemical kinetics is the mass action theory. This is based on the hypothesis that all reacting molecules float free in solution, which implies that the rate of reaction is proportional to the rate of collision between reactants, which is proportional to concentrations of reactants. Most kinetic theories of enzyme action are merely elaborations of this simple idea. The Michaelis-Menten theory of enzyme kinetics is a well known form of the mass action treatment of enzyme kinetics, which has been found to describe much experimental data on many enzymes. For many of these cases, the enzymes and their substrates probably do float free in solution in cell water, so that the basic hypothesis of the mass action theory is in accord with reality.

Some enzymes are bound in or on particles or membranes in the cell. Despite this violation of the mass action hypothesis, biochemists have nevertheless attempted to use mass action theory to analyze such enzymes. One such enzyme is cytochrome oxidase, which in the cell exists as a part of the mitochondrial membrane, which can by appropriate treatment be cracked up into fragments of molecular weight 500,000 or more which retain the ability to catalyze the reduction of O_2 by the reduced form of the protein cytochrome c. The membrane fragment called cytochrome oxidase contains protein, unsaturated lipids, at least two types of haeme-iron groups, and copper. Purifications which remove any of these substances cause loss of catalytic activity of the enzyme.

Despite the fact that cytochrome oxidase is part of a membrane and hence violates the free solution hypothesis of mass action theory, biochemists have nevertheless tried to analyze its kinetics on the basis of mass action theory. The results have been poor. Cytochrome oxidase does *not* conform to the Michaelis-Menten pattern. Instead, it shows first order kinetics, with the peculiar feature that larger initial amounts of reduced cytochrome c substrate decrease the first order rate constant in a hyperbolic pattern. Such a result is difficult to derive from mass action theory. It can be done by assuming a four step reaction, *if the rate constants of the first and last step are assumed to be equal.*[113] The latter is possible, but seems rather unlikely.

Persistence by biochemists in attempts to apply mass action theory to membrane-bound enzymes which violate its postulates is psychologically understandable because of the great success of mass action theory in dealing with soluble enzymes. Reason dictates, however, that when reality conflicts with the postulates of theory and when predictions of theory are difficult to reconcile with experiment, then a different theoretical approach should be sought. This has been done by Cope[10,12,114] in order to deal with the kinetics of redox reactions in biological particles and membranes using realistic postulates. No longer does one impose the restrictive hypothesis of mass action theory that all processes must occur

in free solution. One concedes that the catalytic system contains solid particles and membranes, and that therefore catalysis may involve electron conduction through these solids in accord with the laws of solid state physics, and may involve electron conduction across the liquid-solid interfaces in accord with the behavior of electrodes. This approach leads in a direct manner to kinetic predictions that describe accurately and in considerable detail the kinetic experimental behavior of various particulate and membranous biological processes, including that of cytochrome oxidase.

The purpose of a kinetic theory of enzymes is to predict correctly the substrate concentration vs time curve for the chemical reaction when catalyzed by the enzyme (concentration vs time is the most easily measured characteristic of an enzymatic process). The derivation should be based on physical and chemical principles appropriate to the enzyme structure and conditions.

We shall now derive the substrate concentration vs time curve for a redox reaction catalyzed by an enzyme which is assumed to be a solid particle across which electrons can be conducted in response to a potential difference generated by electrode redox potentials of substrates on the opposite ends of the conductive particle (Fig. 7).* An equivalent electrical circuit would be a resistor connected across a battery. This model seems appropriate for an enzyme such as cytochrome oxidase which when studied in the test tube is a high-molecular weight fragment of a membrane. In life, cytochrome oxidase exists as part of the membrane of the mitochondrion. When in this larger and more complex solid system, some additional solid state processes may influence the cytochrome oxidase reaction, as will be discussed later in this section. The derivation, which will now be presented in simplified form, can be found in complete detail elsewhere.[10,12,114]

Let us postulate an enzymatic particle (or membrane fragment) as shown in Fig. 7. Let there be two sites on the particle at which small molecular weight substrate molecules can exchange electrons with the particle. The two substrates (X and Y) can each exist in an oxidased or reduced form. We assume enzymatic specificity of site for substrate: in other words, the X-site on the particle can exchange electrons only with X-substrate, and the Y-site can exchange electrons only with the Y-site.

Let us now consider the system shown in Fig. 7 from the point of view of solid state theory. The X-site and Y-site may be considered as two electrodes immersed in two solutions with different equilibrium electrode potentials. When the two electrode sites are connected by a wire, or by the internal resistance of the enzyme particle, a current of electrons will flow, which will be limited by the electrical resistance across the particle. This solid state model of an enzyme is electrically equivalent to a resistor

*Digby[170] independently proposed that this same mechanism operates across the shells of crabs and shrimps. The same mechanism had been proposed earlier by Lund[173-175] and by Jahn.[176]

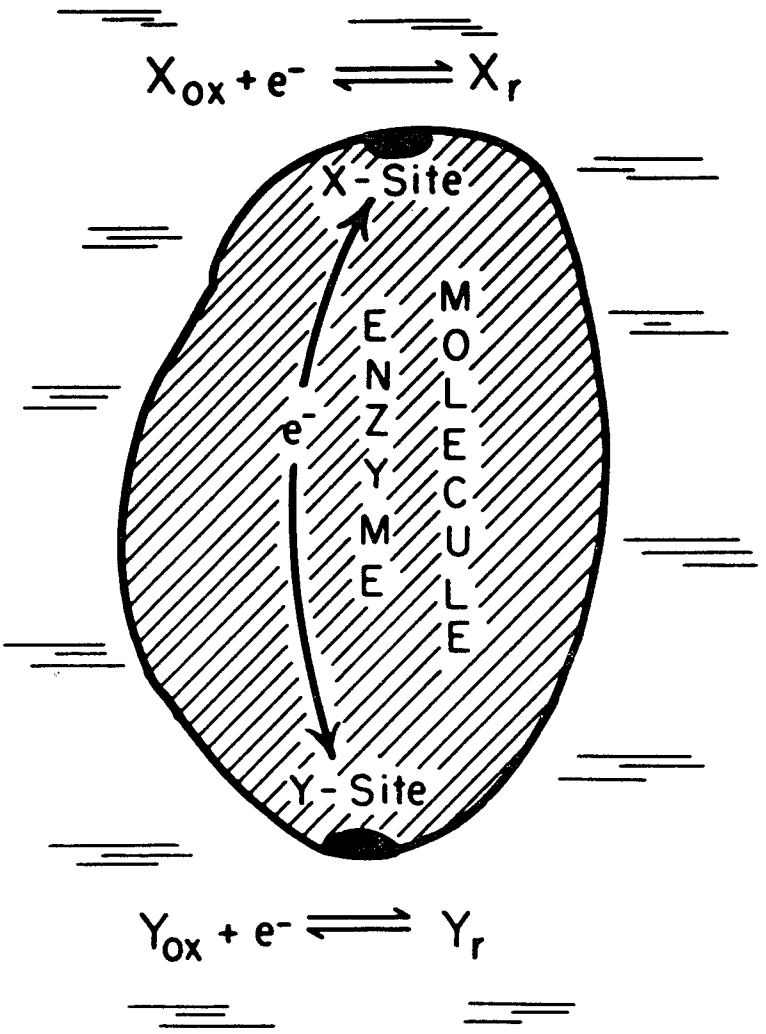

Fig. 7. Solid State and Electrode Model of the Cytochrome Oxidase Enzyme Particle. X-site on the particle acts like an electrode immersed in a solution of redox substrate X, so that the X-site develops on equilibrium electrode potential governed by the percent reduction of substrate X. The X-site is assumed to have enzymatic specificity for reaction with X-substrate. In other words, X-site can exchange electrons freely with X-substrate but will not react with Y-substrate. The Y-site, at the other end of the enzyme particle acts like a second electrode immersed in a solution of a second redox substrate Y, and develops an equilibrium electrode potential governed by percent reduction of Y. The direct reaction of X- and Y-substrates in solution is assumed to be insignificantly slow. The difference in electrode potentials at the X- and Y-sites causes a current of electrons to flow through the conductive solid enzyme particle. The rate of current flow, and hence the rate of oxidation of X-substrate by Y-substrate, is governed by the over-voltage phenomena at the X- and Y-sites, and by the electrical resistance across the solid enzyme particle.

connected across a tiny battery. To develop the theory of this behavior, we shall express the site (or electrode) potentials and the voltage-current equation in terms of substrate concentrations and time.

First, let us calculate the potential difference across the particle (Fig. 7), which we shall call the cell potential (V_{cell}). This is merely the difference in equilibrium electrode potentials experienced by the two sites at the two ends of the particle. Hence:

$$V_{cell} = V_x - V_y \tag{22}$$

where V_x and V_y are the electrode potentials at the X- and Y-sites respectively. Equation 22 may be put in terms of substrate concentration by the use of the familiar electrode equation

$$V_x = V_x^0 + (RT/F) \log_e (x_{ox}/x_r) \tag{23}$$

where x_{ox} and x_r are the concentrations of the oxidized and reduced forms of X-substrate, R is the gas constant, T is absolute temperature, F is the Faraday and V_x is a constant. Because the sum of oxidized plus reduced forms of X-substrate is always constant $(= C_x)$, we may write

$$x_{ox} + x_r = C_x \tag{24}$$

We shall assume for simplicity that Y-substrate is present in excess, so that the redox potential at the Y-site on the particle is constant $(= Y)$. We may then combine equations 22, 23, and 24 to obtain the potential difference across the particle (V_{cell}) (Fig. 7) in terms of concentration of reduced substrate as follows:

$$V_{cell} = V_0 - (RT/F) \log \left[x_r/(C_x - x_r) \right] \tag{25}$$

where V_0 is a new constant $(= V_x^0 - Y)$.

The potential difference across the enzyme particle causes a flow of electron current across the particle, like that which would occur through a resistor connected across a pair of electrodes in a battery. If we assume that current flow *(i)* across the enzyme particle is governed by Ohm's law, as is true for most organic semiconductors, we may write

$$V_{cell} = ir \tag{26}$$

where r is the electrical resistance across the enzyme particle.

Because the conduction of one mole of electrons across the enzyme particle reduces (or oxidizes) one mole of substrate, we may write

$$i = F\, dx_r/dt \tag{27}$$

We may now derive the differential equation for substrate reduction by substituting equations 25 and 27 in equation 26 to obtain an equation of the form

$$-\frac{dx_r}{dt} = A \log \left[\frac{x_r}{C_x - x_r}\right] - B \tag{28}$$

where x_r is concentration of the reduced form of X-substrate, t is time, C_x is total concentration of oxidized plus reduced forms of X-substrate, and A and B are constants.

Equation 28 is the basic differential rate equation describing the kinetics of a particulate enzyme that is rate-limited by ohmic conduction of electrons across the particle. Unfortunately, because of the log term, equation 28 cannot be integrated by any exact method. We may, however, test experimental data for ohmic conduction kinetics by plotting a graph of (dx_r/dt) vs log $[x_r/(C_x - x_r)]$, although this is rather inconvenient. Linearity of such a plot would indicate conformity of the data to equation 28.

Fortunately, equation 28 may be converted to an approximate form of reasonable accuracy, which is easy to integrate and easy to use for the analysis of experimental data. We may substitute the approximate equation 17 in equation 28 to give a new differential rate equation for a particulate electron conduction equation having the simple form

$$-\frac{dx_r}{dt} = \left[\frac{\alpha}{C_x}\right] x_r + \delta \tag{29}$$

where α and δ are constants. This approximation[10] is moderately accurate from 15 percent to 85 percent reduction of substrate (Fig. 4).

Equation 29 was derived on the assumption that ir is the only voltage drop in the equivalent circuit of Fig. 7. If we make our picture more realistic by assuming that a diffusion overvoltage at the X-site also exists due to slow diffusion of large substrate molecules and that Y-substrate is also significantly reduced during the course of the reaction, then the differential equation of reaction kinetics remains of the same general form as equation 29, but with some extra constants and becomes

$$-\frac{dx_r}{dt} = \left[\frac{\alpha}{C_x + \beta} + \gamma\right] x_r + \epsilon \tag{30}$$

where β is a positive constant that is a function of the diffusion constant of substrate x_r, γ is a positive constant and ϵ is a constant. Hence, like equation 29 for the simpler model, the improved theory predicts a hyperbolic relationship between the first order rate constant (k') and C_x, but of a more complicated form as follows:

$$k' = \frac{\alpha}{C_x + \beta} + \gamma \tag{31}$$

or

$$(k' - \gamma)\cdot(C_x + \beta) = \alpha \qquad (32)$$

Equations 29 and 30 predict the kinetics of substrate reduction to be expected from an enzyme particle which is rate limited by ohmic conduction of electrons across the solid particle without or with a diffusion overvoltage at the particle surface. The kinetics are predicted to be of first order with respect to the concentration of reduced substrate (x_r). The important and unusual special feature of the prediction is that the first order rate constant (k′) should decrease if larger *total* (oxidized plus reduced) concentrations (C_x) of substrate are used, and the relationship is predicted to be hyperbolic of the form given by equation 32.

A kinetic pattern of exactly this form has been observed experimentally with the enzyme cytochrome oxidase when catalyzing the oxidation of reduced cytochrome c by O_2 and has also been observed for the enzymes cytochrome peroxidase[10] and pyruvate carboxylase.[114] To account for this unusual behavior in terms of classical mass action mechanisms, one would have to postulate some sort of substrate inhibition, or a complicated sequence of reactions.[113]

In addition to predicting the kinetic pattern of the cytochrome oxidase reaction, the solid state theory predicts the experimentally observed temperature dependence of this enzyme.[12] The theory given here predicts that the activation energy of the functioning cytochrome oxidase enzyme should equal the semiconduction activation energy for the solid protein of the enzyme particle.[12] Solid state physical measurements made recently on purified dried cytochrome oxidase do indeed agree with this prediction, and show that cytochrome oxidase is unique among proteins thus far studied, in that it has a semiconduction activation energy three times lower than other proteins.[11,12] Additional support for the concept that cytochrome oxidase activity involves solid state electron conduction is provided by measurements of relatively high electron mobilities in mitochondria by two new experimental techniques (pulsed electron beam[5,9] and microwave Hall effect[13-22]).

When the cytochrome oxidase reaction is studied at low oxygen concentrations, the rate equation of the reaction is observed to change from first to second order, the oxygen concentration shows an inhibitory effect on the second order rate constant of hyperbolic form.[115] These experimental findings are quantitatively understandable from the same concept of a solid state electron conduction enzyme, with the additional features of space change injection of electrons (yielding square law instead of ohmic conduction) and trapping.[116]

According to intuition, and also according to detailed theory,[12] if cytochrome oxidase functions by a solid state mechanism, then the

activation energy of the cytochrome oxidase reaction should approximately equal the activation energy for semiconduction in dried cytochrome oxidase, as measured by solid state physical techniques. For various simple proteins, semiconduction activation energies as measured by numerous investigators had always been found to be in the region of 1.0 eV. Since the cytochrome oxidase enzymatic reaction had been observed to have an activation energy of 0.3 eV or lower, a semiconductive mechanism for enzyme action had been thought unlikely. The possibility was overlooked that cytochrome oxidase protein might have a different activation energy of semiconduction from most other proteins. When at long last it was measured,[11,12] the semiconduction activation energy of dried cytochrome oxidase was found to be approximately 0.3 eV, which supports the solid state physical concept of the cytochrome oxidase mechanism.

Direct experimental measurements of electron conductivity under physiological conditions in cytochrome oxidase and in other systems that show solid state kinetics would be desirable to test theoretical deductions. Such measurements present great technical difficulties. The conductivity and electron mobility techniques generally used in inorganic solid state physics require samples that are single crystals yet are big enough to allow the attachment of electrodes, purity to parts per million, absence of water, and ohmic contacts between electrode and sample. Biological samples usually satisfy none of these criteria. Therefore, conventional solid state physical techniques have proved useful only to a limited extent. New techniques to avoid the problems inherent in biological samples are under development and have yielded some interesting preliminary data.

The only study by conventional solid-state techniques that has proved illuminating is the measurement by Straub[11,12] of the activation energy of semiconduction of purified, dried cytochrome oxidase. This showed that cytochrome oxidase was unique among the proteins thus far studied in having an activation energy threefold lower than others, in agreement with the predictions of solid state kinetic theory. With regard to new techniques, preliminary results are available from a pulsed electron beam method developed in Russia,[5,9] which showed relatively high electron mobilities in mitochondria. This result, which agrees with theoretical expectations, has been confirmed in preliminary measurements with a new microwave Hall-effect technique by Eley and Pethig.[18] The method was invented in Russia by Trukhan[13,14] and improved in England by Eley and Pethig.[16,22] More recently, Eley *et al*[19,20] showed that cytochrome oxidase activity is positively correlated with microwave Hall mobility of electrons, which strongly supports the concept that cytochrome oxidase enzyme activity is rate-limited by solid state electron conduction.

In conclusion, the evidence in support of a solid state mechanism for cytochrome oxidase now seems fairly strong.

The theory just presented describes well the experimental behavior of cytochrome oxidase in reactions in the test tube. In life, however, cytochrome oxidase exists as a part of a much larger solid membrane system, which performs at least one important biochemical function in addition to what is done by purified cytochrome oxidase in the test tube. In life, cytochrome oxidase exists as part of the membrane of mitochondria (small granules present in every cell which are barely visible under the light microscope). Cytochrome oxidase participates in the oxidative or electron transport process of the mitochondria. In mitochondria which are undamaged, the energy from oxidation is converted into high energy phosphate bond energy by phosphorylation of adenosine dephosphate (ADP) to adenosine triphosphate (ATP) which is the immediate source of energy for most body functions (muscle contraction, nerve firing, secretion of acid in the stomach, etc.).

The mechanism of coupling between oxidation and phosphorylation in mitochondria is not understood by biochemists. Various biochemists present various explanations with an air of confidence, but the various explanations are different, so that at least some of them must be wrong.

If one concedes that the *oxidative* part of the oxidative phosphorylation of cytochrome oxidase might occur in a solid, then one may ask whether *phosphorylation* and the coupling process might also occur by solid state mechanisms. Preliminary theoretical considerations suggest that this is indeed possible. No experimental tests of this hypothesis have yet been made.

It was suggested by Straub[11,23,24] that phonons (packets of lattice vibrational energy) might be the immediate source of energy for the phosphorylation in the mitochondrial solid. It was then suggested by Cope and Straub[12] that the coupling process was a polaron (a combination of a phonon and an electron), which could be conducted across the mitochondrial solid and would give up its phonon for a phosphorylation. The evidence that suggested polaron conduction was derived from an analysis in terms of solid state kinetic theory of the temperature dependence of the cytochrome oxidase reaction as measured by deVault and Chance.[27]

If the carrier of the energy for phosphorylation is the phonon, we may inquire about the mobility of this carrier for transport of the energy through the mitochondrial solid. We must first note that the free energy of hydrolysis of adenosine triphosphate is 9.0 kcal/M or 0.39 eV, which must be the energy of phosphorylation of ADP. Hence, the phosphorylation phonon must carry at least this much energy, which is equivalent to a photon of light of 3.24μ wavelength, which is in the infrared (IR) range. Phonons of this energy range are localized vibrations (optical phonons) and do not significantly propagate through the solid, in contrast to lower energy

phonons (acoustic phonons) which move freely. It therefore seems unlikely that phonon movement can play a significant role in dissemination of energy through the lattice of the solid mitochondrial membrane. If the solid state carrier of energy should be an exciton, this might be either free or localized.[25]

A different method of dissemination of an energy packet of this size is suggested by the dimensions of the mitochondrion (3.3μ long by 0.5μ radius for rat liver). Because the length of the mitochondrion is approximately one wavelength of this phonon energy packet, Cope[25] considered the possibility that the mitochondrion might act as a resonant cavity for IR electromagnetic waves, which could serve as a rapid and efficient method for dissemination of IR energy throughout the mitochondrion from generation sites to utilization sites. The mitochondrion would then be a small scale analog of a microwave cavity made from a shorted section of waveguide, as used in radar systems.

A serious objection to this idea is the fact that water, which is the principle constituent of the mitochondrial sap, absorbs IR energy strongly, so that IR radiation within the mitochondrion would be mostly absorbed by water and wasted, instead of being transmitted.

A variation of the above mechanism would allow the mitochondrion to avoid the IR absorption by water.[25] Suppose that the IR radiation does not pass into the aqueous sap but is contained within the lipid bilayer of the mitochondrial membrane. Suppose that IR electromagnetic waves are generated at the surface of the lipid bilayer and kept within the lipid bilayer by internal reflections from the adjacent layers of protein. The mitochondrion would then be analogous to a coaxial transmission line where the lipid bilayer is the dielectric and the adjacent protein layers are analogous to the metal surfaces of the central wire and of the outer metal sheath.[25] This coaxial transmission line, when shorted at both ends, forms a coaxial cavity which is resonant for any integral multiple of a half wavelength (the multiple is 2 for the mitochondrion for 3.24μ wavelength energy packet). The composition and geometrical structure of the mitochondrial lipid bilayer minimize absorption of IR waves by the lipid dielectric, so that this could be a highly efficient method for energy propagation throughout the mitochondrial membrane.

The first reason for expecting low absorption, and hence low wastage of IR energy within the lipid bilayer of the mitochondrial membrane results from its chemical composition.[25] Analysis of mitochondrial lipids reveals that they consist mostly of compounds with very low IR absorption, including 33 percent saturated straight-chains (16-18 carbons), and 52 percent straight chain (18-20 carbons) with 2 or 3 double bonds. Indeed, the IR absorption of saturated straight-chain hydrocarbons is so low that such compounds (Nujol) are commonly used to make slurries of crystals for IR spectroscopy. The only significant IR absorption in saturated

straight chains is the C—H stretching frequency, which is located near 3.3μ. In unsaturated carbon chains, there is also an IR absorption band due to the C=C stretching frequency, which is very weak, although it becomes more intense when conjugation occurs with multiple double bonds.

Even though IR absorption in the mitochondrial lipid bilayer must already be low because of the chemical composition of the lipid, it must be reduced lower by the particular geometrical arrangement of lipid molecules relative to the geometrical pattern of the electric vector, which is produced in a coaxial cavity of this type.[25]

The electric field configuration to be expected in the IR coaxial cavity consisting of the mitochondrial membrane may be deduced easily from the theory of coaxial transmission lines. For a coaxial transmission line, at a wavelength (λ) longer than the cutoff wavelength (λ_c), only the principle transverse electromagnetic (TEM) mode can be propagated, where λ_c is given approximately by

$$\lambda_c = \sqrt{\epsilon}\,\pi\,(r_1 + r_2) \tag{33}$$

where r_1 and r_2 are the inner and outer radii of the coaxial transmission line, and ϵ is the dielectric constant.[25] For the rat liver mitochondrion, radius $\cong 0.5\mu$ and the thickness of the lipid bilayer dielectric is relatively small (60 Å = $6\times10^{-3}\mu$), so that $r_1 \cong 0.5\mu$. If we take the dielectric constant (ϵ) of the lipid bilayer as one, then we may substitute the numbers in equation 33 to obtain the cutoff wavelength for the mitochondrion $\lambda_c = 3.0\mu$. Because the wavelength of the energy packet for phosphorylation is 3.24μ which is longer than λ_c, only the principle TEM mode can be propagated in the mitochondrial membrane.[25] Higher order modes with other field configurations cannot exist.

The field configuration for the principle TEM mode in a coaxial transmission line has the electric vector (E) directed radially and the magnetic (H) directed circumferentially, which must therefore be the situation the mitochondrial membrane. According to the Danielli model of the lipid bilayer membrane, the carbon chains of the lipid molecules are directed perpendicular to the membrane surface, so that in the mitochondrial membrane, the carbon chains of the lipids are directed radially, which is parallel to the direction of the E vector. The C—H bonds are perpendicular to the chains and are therefore perpendicular to the E vector. As mentioned before, the principle IR absorption of straight carbon chain hydrocarbon molecules is the C—H stretching frequency. It has been shown by both theory and experiment that IR absorption by a molecular group is a minimum (which may be zero) when the E vector is perpendicular to the direction of the molecular vibration. It is therefore to be expected that the absorption of IR energy by the lipid bilayer of the mitochondrial membrane which already must be low because of the chemical composition, must be even lower because the C—H bonds are perpendicular to E. This expected

low IR absorption implies that dissemination of IR phosphorylating photons by the coaxial resonant cavity mechanism may be extremely efficient, because of very low losses expected from absorption in the lipid dielectric.[25]

In summary, it seems likely that the mitochondrial enzyme system, which operates in an organized solid membrane, functions by an integrated set of solid state processes. Oxidation by cytochrome oxidase occurs by solid state conduction of polarons, which yield phonons which perform phosphorylation of ADP to ATP. The phonon energy is disseminated rapidly and with low loss throughout the entire mitochondria membrane by infrared electromagnetic waves in the lipid bilayer of the mitochondrial membrane, so that the mitochondrian as a whole acts as an infrared resonant coaxial cavity.

D. Nerve. Nerve fibers consist of a solid matrix of protein and lipid with intersitial water containing various small ions, such as sodium (Na), potassium (K), and chloride (Cl). When a nerve fires, a complicated set of movements of these ions occurs through the water in the nerve. Extensive measurements of these ion movements have been made, and much of the experimental data has been put together (i.e. the experimental data has been curve fitted) by a complicated set of equations called the Hodgkin-Huxley theory.[117]

The Hodgkin-Huxley theory is not an explanation of nerve conduction in terms of the principles of physical chemistry. Rather, it is merely an ingenious curve fit of much experimental data on ion flows in nerve water. It ignores completely the possibility of solid state events within the solid protein-lipid matrix of the nerve.

Evidence is now available for several different solid state physical processes in the solid matrix of nerve. These include electron conduction over activation energy barriers, superconduction, piezoelectric phenomena, and transmission of infrared electromagnetic waves in the lipid bilayer. It seems reasonable to suppose that these solid state processes take part in transmission of the nervous impulse down the nerve fiber, and are integrated with the ionic events which take place in the nerve water.

Electron conduction across activation energy barriers in nerve is evidenced by the experimental observation of Chalazonitis[118] as analyzed by Cope[119] that decay of photoconductivity in pigmented invertebrate nerve conforms to the Elovich equation, the derivation and significance of which was discussed in Section IIIB of this review.

A role for superconduction in nerve function is suggested by several types of evidence. These include (a) the temperature dependence of certain neural processes is characteristic of single electron superconductive tunneling,[56] (b) certain other neural processes show *negative* temperature dependences, which are difficult to explain except from the hypothesis of two electron superconductive tunneling,[56] (c) numerous behavioral effects

on organisms are caused by magnetic fields smaller than 2 Gauss, for which no physical mechanism of adequate sensitivity is known, except the superconductive Josephson effect,[59,60] (d) dilute superconductivity has been observed experimentally[49-51] in various bile acids at temperatures as high as 277°K, and extrapolation of this data leads to the prediction[52] the cholesterol should superconduct as physiological temperatures and above. Cholesterol is a major constituent of the solid matrix of nerve. In addition, solid state magnetic phenomena suggestive of superconduction have been observed experimentally in the presence of high electric fields.[53] Nerve possesses thin lipid layers (containing cholesterol) in which high electric fields exist. The superconductivity predicted for cholesterol at zero electric field might be enhanced by these high fields,[53] so that superconduction could become of significant magnitude and play a role in nerve function.

Piezoelectricity and pyroelectricity in nerve are suggested by the following evidence. The temperature dependence of the resting membrane potential of an invertebrate nerve cell shows a temperature dependence for which log of the activation energy is a linear function of temperature, which conforms to theory of peizoelectric resonance.[92] A square pulse of increased temperature often produces in nerve systems two response transients of opposite sign at the start and end of the temperature pulse (Fig. 1). This is characteristic of a pyroelectric process.[100] It is seen in the fish thermoreceptor, which also shows proportionality between the time derivative of response and temperature, which is predicted from pyroelectric theory.[100] The muscle stretch receptor shows linearity of neural response with the logarithm of applied mechanical force. This is predicted from the concept that the neural response is governed by a piezoelectric effect in an elastic polymer macromolecule.[100] In addition, nerve is observed to be pyroelectric.[156]

Infrared (IR) transmission of electromagnetic energy by a coaxial transmission line mechanism in nerve fibers (axons) seems possible.[25] Like in mitochondria, the probable immobility of IR phonons will limit the transfer of energy along the axon, where high mobility would be useful to move energy along the great distances of axon length. Like in mitochondria, the cylindrical lipid bilayer of the axon membrane seems well constructed to serve as a coaxial transmission line for rapid and efficient transfer of IR electromagnetic waves along the axon within the lipid dielectric.[25] A bundle of axons in the nerve could then be regarded as a coaxial IR fiber optic system. Supporting this concept is experimental observation of emission of IR radiation from nerve during excitation.[120]

Some nerve fibers are larger in diameter than mitochondria, and consequently will have longer cutoff wavelengths and lower impedances than mitochondria. For an A-nerve fiber, such as commonly found in a mammalian motor nerve, a radius of 10μ might be typical, from which

one may calculate using equation 33 that the cutoff wavelength (λ_c) will be 60μ. Hence, in a typical motor nerve axon for wavelengths over most of the IR range, higher order modes will carry a significant fraction of the total IR energy, so that longitudinal transmission of IR energy will be less efficient than in mitochondria or in smaller nerve fibers, and dielectric losses may be somewhat higher because E is not always perpendicular to the C—H bonds of the lipid chains. In a C-nerve fiber, such as one might find in the sympathetic system, a radius of 0.25μ might be found, which substituted in equation 33 leads to a cutoff wavelength (λ_c) of 1.5μ, which makes for efficient longitudinal IR transmission and low dielectric losses.[25]

Impedance of a coaxial transmission line is given by (if resistive losses are small)[25]

$$Z = 138 \sqrt{\mu_r/\epsilon}\, \log_{10} (r_2/r_1) \tag{34}$$

where Z is impedance in ohms, r_1 and r_2 are inner and outer radii of the coaxial line, μ_r is permeability (= 1 except for ferroelectrics), and ϵ is dielectric constant of the lipid bilayer. The impedance (Z) for IR transmission will be different for different nerve fibers because of differences in radius, although the thickness of the dielectric lipid layer is probably much the same in all nerves and in mitochondria, and will here be considered a constant (= 0.006μ) as for mitochondria.[25] For a C-nerve fiber, with an inner radius (r_1) of 0.25μ, using equation 34, we may calculate impedance (Z) of 1.4Ω. However, for a A-nerve fiber with a radius of 10μ, we calculate[25] impedance (Z) of 0.036 Ω.

Because for different nerve fibers, radius varies markedly but thickness of the dielectric lipid bilayer remains approximately constant, it is instructive to show the simple approximate relationship between the radius of a nerve and its impedance for transmission of IR waves.[25] We use the approximate equation (derived by Clark[121] and Cope[122])

$$\log_e \left[\frac{\chi + \Delta}{\chi} \right] \cong \left[\frac{\Delta}{\chi + \Delta} \right] \cong \left[\frac{\Delta}{\chi} \right] \tag{35}$$

where $\chi > 0$ and $\Delta \ll \chi$. If we let χ = r (inner radius) $\cong$ r (mean radius of nerve fiber) and Δ = thickness of dielectric lipid bilayer, using 0.434 for the ratio of $\log_{10} x$ over $\log_e x$, we may substitute equation 35 in equation 34 and obtain

$$Z \cong 60 \sqrt{\mu_r/\epsilon} \left[\frac{\Delta}{r} \right] \tag{36}$$

where Z is axon impedance for IR transmission in ohms and the other symbols are as previously defined. This shows that, approximately, the axon impedance is inversely proportional to its radius.

The impedances for coaxial IR transmission for nerve fibers (1.4 Ω for C-fibers and 0.036 Ω for A-fibers) are much lower than the 75 Ω which is usual in man-made coaxial transmission lines for radio frequency waves. Most efficient energy transfer between generator, line and load occurs when impedance of the line equals that of generator and load. One may speculate that therefore the generators and absorbing systems for IR energy in nerve should have low load impedances to match the nerve transmission line, and might be of fundamentally different character than the relatively high impedance devices ordinarily used in man-made systems. Pertinent to the possible nature of the low impedance nerve generator and loads is the evidence for superconductive phenomena in nerve at physiological temperatures as discussed in previous paragraphs of this section. Superconductive junctions (Josephson junctions) have been fabricated which will generate and detect electromagnetic energy in the microwave and IR range of wavelengths.[123,124] These superconductive generating and absorbing systems have been observed[32,125] to have impedances in the range of 1 Ω. The expected low impedance of a superconductive IR generator or load in nerve might therefore be a reasonably good match to the calculated low impedance of an IR coaxial nerve transmission line.

Larger nerve fibers have lower impedances, with impedances inversely proportional to radius (see equation 36). Therefore, for efficient IR energy transfer, impedances of generators and loads should be correspondingly lower in larger nerve fibers. One might speculate[25] that if the generators and loads were uniformly distributed as sites over the circumferential area of the nerve with the same density in all nerve fibers, the number of sites per unit length of nerve would be proportional to radius, and the reciprocal of the total impedance of the unit length would be proportional to the sum of reciprocals of impedances of individual sites, whose number is proportional to circumferential area. Therefore, total impedance of generator or load sites per unit length of nerve would be inversely proportional to nerve radius, so that an equally good match of generator or load to transmission impedance could be obtained for nerves of all diameters using the same type and density of generator and load sites for all nerves. The hypothesis just expressed that sites of IR generation and absorption might be continuously distributed along the surface of the nerve lipid bilayer implies the possibility of repeated absorption and re-emission of the energy by the conductive walls (protein) as the IR energy is transmitted along the length of the nerve fiber within the dielectric lipid bilayer.[25]

IV. Application of Solid State Physical Concepts to Ionic Phenomena in Cell Water

We may consider the cell to resemble a sponge, consisting of a solid skeleton of membranes and particles constructed of lipids and proteins, in

which electron currents may flow, governed by the laws of solid state physics.[92] The interstices of the sponge are filled with water, in which reside dissolved proteins and small ions. NMR evidence[126-128] indicates clearly that cell water possesses more structure than liquid water, and that much of the Na^+ and K^+ in the cell is not free in aqueous solution, but is associated with charged sites on macromolecules.[129-133] The quantity of Na^+ and K^+ dissolved in tissue water is low, because of the structuring of the water. One may then make an analogy between the aqueous portion of the cell and a solid semiconductor. One may regard complexed Na^+ and K^+ as analogous to valence band electrons in a semiconductor, and free cations as analogous to conduction band electrons.[134,135] The complexed ions exchange rapidly with, but are only slightly soluble in, the structured water. Conduction, diffusion, and potential equations for ionic processes in cell water therefore resemble those for electronic conduction in a semiconductor solid. Experimentally useful predictions regarding ion transport have been obtained from this approach.[134,135]

An ionic form of solid state activation energy barrier kinetics has been developed by Cope[135,135] which predicts that Na^+ and K^+ leakage from cells should obey the Elovich equation, which agrees with experimental observation. This theory requires that there be an activation barrier to ion conduction at the cell surface. The cell surface must resemble a liquid-solid interface like an electrode surface. Since the extracellular space is presumably liquid, the intracellular phase must have solid-like properties if the theory is correct. Specifically, it is necessary to assume that cell water has more structure than liquid water and consequently a low solubility for Na^+ and K^+, and that Na^+ and K^+ exist in cells mostly associated with macromolecules rather than in free solutions. During the last few years, excellent evidence for cell water structuring from nuclear magnetic resonance (NMR)[126-128] and from water absorption studies[136,137] has become available and this has become the basis for an NMR method of cancer diagnosis.[138,139] It has been shown that the metabolism of the cell produces much less energy than is required to operate the Na^+ and K^+ pumps that are required to maintain ionic concentrations in the cell for the liquid state model of the cell.[140-143] Therefore, the liquid-state-free-cation model of the cell is thermodynamically impossible, but the solid state, or ion exchange resin, or structured water and associated cation model of the cell is compatible with all the evidence and with thermodynamics. An entire issue of the Annals of the N.Y. Academy of Sciences[144] was recently devoted to this problem.

Therefore, the weight of the experimental evidence supports strongly the analogy of the cell surface to a liquid-solid interface. Therefore, the application of solid state physical theory to the kinetics of ion transport

across the cell surface seems appropriate. Cope's solid state theory of cell water and ions is probably equivalent to a simplified form of the association-induction hypothesis of Ling[141,145] and the ion exchange theory of Damadian.[146,147]

V. The Future

New and better experimental techniques are needed for solid state biology. Biological processes function only when the system is complex, impure, noncrystalline and wet. The conventional experimental techniques of solid state physics are not usable under these conditions.

New experimental techniques suitable for solid state biology are beginning to be developed. Measurements of electron mobilities within wet protein particles by Hall effect at microwave frequencies have begun.[13-22,148] A pulsed electron beam method for measurement of electron mobilities in wet proteins has been developed in Russia.[5,9] Methods for measurement of dilute superconductivity, applicable to organic solids[49-51,177] and perhaps to biological systems have been developed.

When the experimental techniques of solid state physical biology become as well developed as those of liquid state biology, the author expects that solid state processes will be found to be equally as important for biological functions as liquid state processes.

A REVIEW OF THE FERROELECTRIC MODEL OF MICROTUBULES

J. A. BROWN* and J. A. TUSZYŃSKI

Department of Physics, University of Alberta, Edmonton, AB, T6G 2J1, Canada

(Received 8 June 1998; In final form 9 July 1998)

It has been 25 years since the piezoelectric properties of the microtubule were first discussed. Subsequent to the discovery of its piezoelectric properties, its consequences have been observed in experiments which have shown microtubules to align under the influence of electric fields. In this regard, our investigations have sought to determine in which situations the ferroelectric properties are important for the function of the microtubule, and in addition, how the microtubule may be affected by the transient endogenous electric fields of living cells. We report a summary of recent findings and discuss their implications.

1. INTRODUCTION

Microtubules have recently generated much interest well beyond the biological community[1-3] because they demonstrate how physical interactions are important within living systems. The microtubule is a polymer of a protein known as tubulin which is common to most animal, plant and protist cells. Microtubules are one of three main structures which form the cytoskeleton that supports the cell. Microtubules perform many functions related to both their structural strength and flexibility. Other than serving as a cellular backbone, they act as a railroad for the transportation of cellular materials. For this purpose the orientation of the microtubule is essential since the motor proteins which carry materials toward or away from the cell body may travel in only one direction along a microtubule. Hence, the permanent dipole moment of the tubulin molecules may be important in the guidance of molecules, known as motor proteins, that *walk* along the microtubule surface. More recently, microtubules have been implicated in

* Corresponding author.

simple signalling within the cell. In protists, which are single-cell organisms, information processing cannot occur through any sort of multicellular neural networking, microtubules have been proposed as the most likely organelle to accomplish this task. These curious possibilities are explained in this review from the standpoint of ferroelectrics.

The piezoelectric properties of the microtubule were first discovered by Athenstädt, who was searching for piezoelectric effects in living systems.[4] The measurement of its piezoelectric properties and subsequent classification as a piezoelectric polymer declared the existence of a permanent electric dipole on the microtubule. Since the microtubule is composed of many identical subunits ($\alpha-\beta$ tubulin dimers), each much itself possess a permanent dipole. This has been confirmed by the experiments of Vassilev *et al.*[5] and subsequently by Kaimanovich *et al.* [6, 7] and White *et al.* [8] which have shown that arrays of microtubules may be oriented by electric fields and have gone on to speculate that intracellular electric fields may induce microtubule orientation. Further experiments have demonstrated that the tubulin dimer of which the microtubule is composed has two different conformational states within the microtubule.[9] When guanosine triphosphate (GTP) hydrolysis occurs, the length of the tubulin dimer is reduced from 8.3 nm to 8.0 nm. With any atomic reorganization such as that involved in a conformational change of a molecule, the electrons must also be redistributed. Given that the surface of tubulin is strongly negatively charged at cellular pH and that its size changes by a significant amount on the scale of electronic interactions, this structural compression must result in a change of the dipole moment. This electron redistribution has also spurred interest in charge conduction along microtubules.[10] However, the length scale of tubulin implies that microtubules lie in the gray area between quantum and classical physics. To the best of our knowledge, the first theoretical model of ferroelectricity in microtubules has been proposed by Satarić *et al.*[11] and it was based on an effective field approximation in the continuum limit giving rise to travelling ferroelectric domain walls.

Our present model of ferroelectric phases in microtubules is simply a classical Ising model where: (a) the interaction constants are determined by classical dipole–dipole electromagnetic forces; (b) the 2D lattice is periodic in one direction so as to form a tube; and (c) the dipole moment has only two possible orientations, though they are not precisely opposite to each other. The last property shall be important when interactions between the dipole of tubulin and transient endogenous electric fields are considered; the dipole moment must have a radial component so that the dipole interaction with the external field is non-zero.

Some of the interest in microtubule ferroelectric properties has been sparked by their unusual assembly properties, their special arrangement in cells of various types, their involvement with cell division and their suspected role in some cellular signalling. We elaborate upon these examples of microtubule structure and function.

- *In vitro*, microtubules experience a form of stochastic assembly known as dynamic instability.[12] Typically, individual microtubules are either undergoing slow steady growth or extremely rapid shortening, known as a catastrophe event. The entire pool of tubulin in the cell, however, exhibits smooth oscillations in the quantity of tubulin which is assembled. Electromagnetic interactions resulting from dipoles on assembled microtubules and on free tubulin dimers have been proposed as one coupling mechanism to describe the transition from individual to ensemble dynamics. In addition, the catastrophe event may be explained. The idea is that the dipole interactions induce a conformation with some *fault* energy. At some point, the fault energy is sufficient to induce a catastrophe event.
- The arrangement of microtubules in cells is always such that the negative end is closest to the center of the cell and the positive end extends toward the cell membrane, or down the long extension of a nerve cell known as an axon.[13] The positive end of the microtubule should not be confused as denoting the direction in which a microtubule's dipole is pointing since at this point the direction has not been experimentally determined. However, this convention is consistent with the biological literature on the subject and the plus end indicates the orientation of the structure. Perhaps 5% or fewer microtubules will typically be improperly oriented. Given that cell membranes have a resting potential caused by ionic gradients across the membrane, it is unlikely that the electrical potential drops precisely to zero immediately inside the membrane. There is a small residual electric field on the order of $1-10\,\mathrm{V/m}$, which one suspects aids in the efficient alignment of microtubule orientation within the cell. This alignment is crucial to motor proteins which travel along microtubules and specifically carry material toward or away from the centrosome which is located close to the cell nucleus.
- In cells which are undergoing division, microtubules align themselves from the two poles of the cells and extend toward the metaphase plate which will ultimately divide the two daughter cells. Pairs of chromosomes are held together along the plate with two microtubules, one anchored near each pole. The pattern of microtubules is highly reminiscent of the

field lines between a positive and negative charge. This has reinforced the speculation that electromagnetic effects are at work, given that it is known that microtubules may be ordered by electric and magnetic fields [14] and has driven investigators to study charge flow in the cell membrane before and during cell division. More intriguing than the array of microtubules which forms is the ability of the microtubules to synchronize chromosome separation and subsequently initiate the segregation process as the microtubules themselves disassemble. It seems necessary for the microtubules to interpret or carry some signal in this process since a signal carried by a chemical messenger, through diffusion, could not arrive at the chromosomes with the perfect synchrony that is observed. If the signal is mechanical, then the structure which supplies the push or pull on the microtubules must be found, an alternative explanation in terms of piezoelectric or ferroelectric coupling seems more reasonable.

Finally, it has recently been shown that microtubules and associated members of the cytoskeleton play a role in intracellular signalling. [15, 16] The mechanism of signal transduction is not understood at present and may again be intimately associated with the ferroelectric properties of the polymer.

2. THE MICROTUBULE LATTICE

The lattice of the microtubule is helical. Within cells, it is most commonly composed of 13 columns, known as protofilaments. The outer ring of protofilaments is 25 nm in diameter, the inner ring 15 nm (Fig. 1). The interior of a microtubule is hollow and they may have an arbitrary length; however, microtubules with a length of a few microns are not uncommon. Since the length of each dimer is about 8 nm, the typical microtubule has perhaps 100–1000 rows. Each α–β tubulin dimer is composed of two nearly identical monomers, individually known as α and β tubulin. This lattice is arranged such that there is an upward offset between neighbouring protofilaments of 0.92 nm (12 nm/13) when moving around the microtubule in a left-handed sense. Since the monomer spacing along a protofilament is 4 nm, this represents a rise of 3 monomers for each loop of the helix. However, there are two types of lattice which have been described in the literature, known as the A lattice and the B lattice. If one follows the helix with the small 0.92 nm offset (known as the $\bar{3}$ start helix), the monomers alternate (α–β–α–β–$\cdots$) in the A lattice but remain the same in the B lattice (α–α–α–α–$\cdots$), except at the seam, where there is an α–β link.

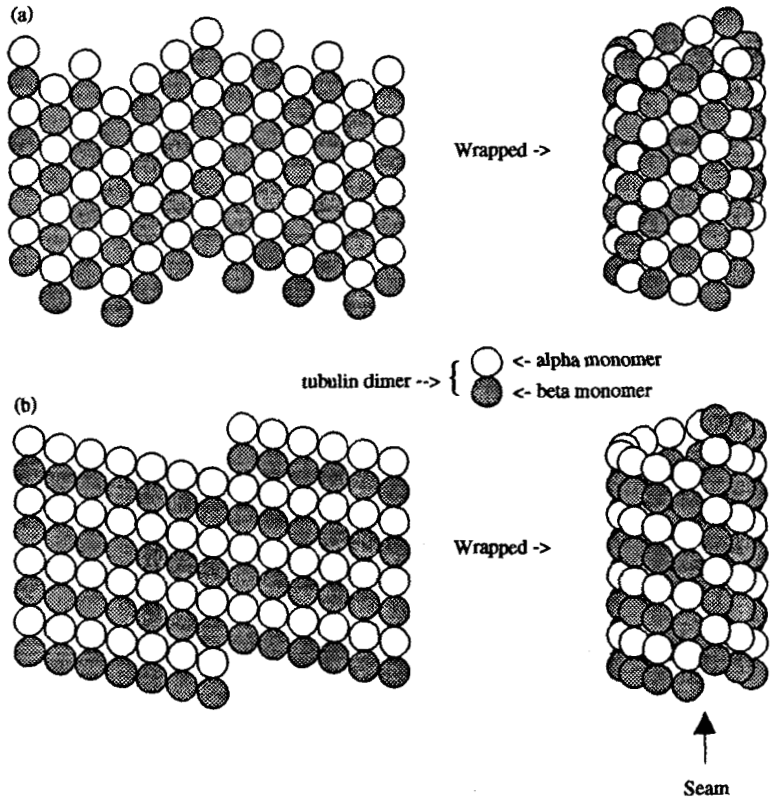

FIGURE 1 The two possible microtubule lattices are depicted. Typical microtubules are much longer than these which are shown with a length of only 4 dimers along each of the 13 protofilaments (columns). (a) The A lattice, which has helical symmetry. (b) The B lattice, which has a seam where a line following the α-monomers around the microtubule meets a β-monomer. The left side depicts unwrapped (non-physical) microtubules; the figures resulting from our simulations are given in a similar manner.

Thus the A lattice has complete helical symmetry which the B lattice does not possess. So, the monomer lattices are identical but the dimer lattices are quite different. Since the dimer is the fundamental unit from which microtubules are constructed, the dipole is associated with each dimer and the lattice change means that interactions are quite different between the two geometries.

Our model of ferroelectric effects in microtubules was inspired by the cellular automaton model of Hameroff *et al.*[2] Within our model, there is no net charge on each dimer but there is a dipole associated with each dimer,

and consequently the overall structure has an electric polarization. One orientation of the dipole points along the protofilament axis, this is the up state (Fig. 2). We have some freedom to choose the direction of the dipole in the down state since the electric dipole has not been measured in each of tubulin's conformational states. We have chosen the down state's orientation in a direction which is roughly opposite to the direction of the up state but which is 29° from the vertical and points out radially away from the microtubule. This choice is based on the geometry of microtubule ends that are splaying apart during disassembly. Under these conditions, tubulin adopts a different conformation with curved protofilaments.[17] The results of simulations presented here have been carried out with $\phi = 29°$ down states. Some degree of tilting is necessary if action potentials are to influence the dipole dynamics because the non-tilted dipole is entirely axial and the electric field of the action potential is purely radial.[18] Consequently, there would be no interaction unless one of the states has some radial component since the interaction energy between a dipole and an electric field is simply

$$U_{\text{int}} = -\bar{p} \cdot \bar{E}, \tag{1}$$

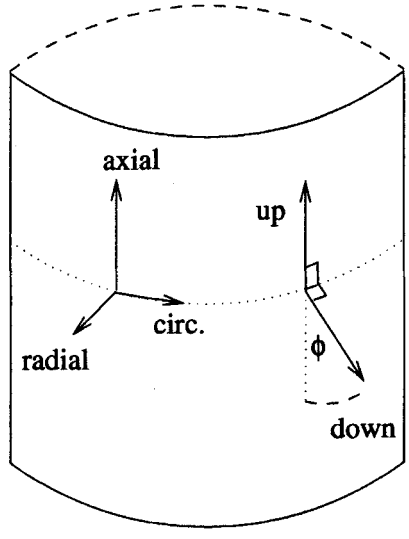

FIGURE 2 This view of the outer surface of a microtubule identifies the directions of fields we consider. The axial or vertical direction in this diagram points away from the cell body. At the right, the up and down directions which were selected for tubulin's dipole moment are shown ($\phi = 29°$).

where $\bar{p}$ is the dipole moment and $\bar{E}$ is the electric field. The interaction energy between two elementary dipoles is given by the following well-known formula: [19]

$$U_{\text{int}} = \frac{1}{4\pi\varepsilon\varepsilon_f} \frac{\bar{p}_1 \cdot \bar{p}_2 - 3\,(\bar{p}_1 \cdot \bar{n})(\bar{p}_2 \cdot \bar{n})}{r^3}, \tag{2}$$

where ε is the relative permittivity of the medium, ε_f is the permittivity of free space, $\bar{n}$ is the normal vector pointing from the position of the first dipole to the second dipole and r is the distance separating the dipoles. Consider the interaction between dipoles of the microtubule lattice: From a purely structural point of view, the lattice type may seem insignificant, as one does not expect that it will change assembly dynamics or elastic properties much. However, from the point of view of dipole interaction, the lattice type is crucial. In the B lattice, dimers are aligned in nearly tangential rows (Fig. 3). As a result, there is a strong interaction between neighboring protofilaments which favours antiparallel dipole orientations. In the A lattice, the neighboring protofilaments are shifted vertically such that identical orientation of the dipoles is favoured. In either case, there is a strong interaction along individual protofilaments which favours similarly oriented dipoles. The effect of the dipole interactions is that the lattice of up and down dipoles will self-organize into an energetically favourable configuration. At high temperatures, the lattice has a random state – each individual dimer can be found in the up or down state in a rather arbitrary fashion. At lower temperatures, the interaction energy dictates the dipole

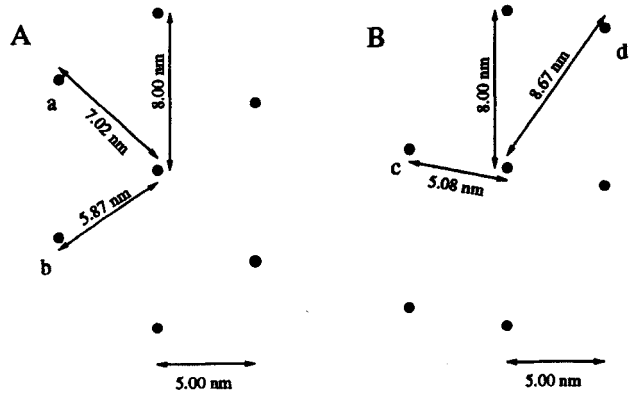

FIGURE 3 View of lattice structures. Note that the A lattice on the left is nearly perfectly triangular while the B lattice on the right is nearly rectangular. Shown as a planar lattice in the diagram, the lattice curls around in a cylindrical fashion to form the hollow microtubule.

arrangement and the lattice becomes ordered. Our task is to investigate this transition in order to determine the likely state of a microtubule under physiological conditions.

The lattice dynamics in our model are simulated using a standard Monte Carlo technique.[20] For each timestep, the energy of the present state and the opposite state are calculated. A change of state is a random event; the probability of its occurrence is determined by the temperature. There are two numbers which are put into the model by hand. One is the relative permittivity of tubulin in cytoplasm, ε and the other is the magnitude of the dipole moment of tubulin. The dielectric constant of dry tubulin or of tubulin in solution has not been found in the literature although some experiments give permittivities in excess of 100 for some other proteins in solution. [21] Our choice of these parameters allows us to compare results with previous modelling attempts. All of this dependence can be accounted for by a single parameter, Q, where

$$Q = p^2/\varepsilon \,. \tag{3}$$

The dynamics of the model are unaffected by the choice of Q but it simply scales with the temperature. Larger values of Q increase interaction strengths and thereby increase the transition temperature. We have chosen $Q = 12 \times 10^{-56} \mathrm{C}^2 \cdot \mathrm{m}^2 \simeq 10800$ (Debye)^2. For a dipole corresponding to an electronic charge, with a charge separation of one dimer unit, 8 nm, $\varepsilon \simeq 13$ given this choice. Such a value for the dipole moment has the same order of magnitude as some other globular proteins.[21] This may be a conservative estimate as Athenstädt has reported the dipole moment of another fibrous molecule, collagen, to be about 15 000 Debye. The important number is not the total dipole but the change in the dipole, consequently the smaller figure that we report seems reasonable. The precise value of the dipole moment depends on the pH of the surrounding medium. The following results are derived from these estimates of the tubulin dimer's dipole moment. We shall comment on how any changes to these parameters affect the results of our simulations.

3. RESULTS

The results presented represent a summary of our work, and the most important features are highlighted. A more extensive look at the microtubule lattices and their ferroelectric ordering may be found in our

previous publications.[22–24] We are plotting an order parameter, P, representing scaled polarization, which is defined over the N lattice sites by

$$P = \frac{1}{N}\sum_{i,j}\sigma_{ij}, \tag{4}$$

where the σ_{ij} is $+1$ or -1 and describes the conformation of the dipole labelled (i, j) of the 2D cylindrical lattice. The results for the 13A lattice and the 13B lattice (as illustrated in Fig. 1) are shown in Figures 4 and 5. In addition, the polarization *versus* temperature graph is displayed for the 13A lattice as a function of an applied external electric field in Figure 6. We have also computed polarization curves in the case of lattice defects, both impurities and microtubules with alternative protofilament numbers (12 and 14 being the most common of such defects).

Along a protofilament, head to tail alignment of dipoles is preferred, so that the positive end of one dipole is next to the negative end of the adjoining dipole. Consequently, dipoles will seek parallel alignment along a protofilament at low temperature when the microtubule lies in its ground state. In the microtubule lattice, each dimer has six nearest neighbours due to the triangular nature of the lattice. Consider the two nearest neighbouring dimers which are located on the protofilament directly to the left of the protofilament of the dimer, labelled a and b (Fig. 3). Relative to the

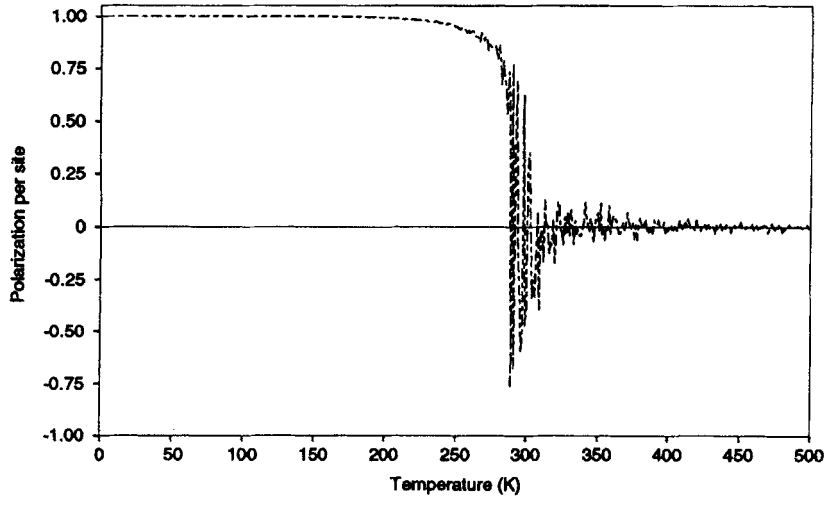

FIGURE 4 Relative electric polarization of the microtubule 13A lattice as a function of temperature, obtained from Monte Carlo modelling.

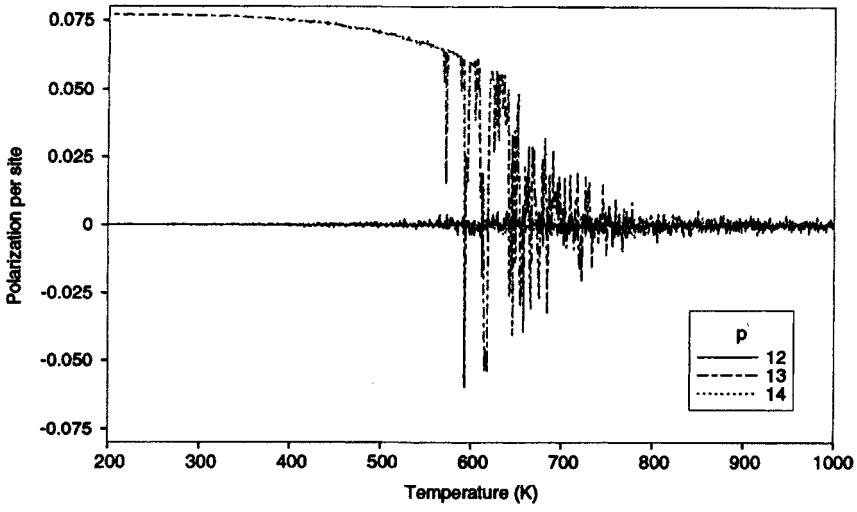

FIGURE 5 Polarization of the microtubule 12B, 13B and 14B lattices as a function of temperature. The 12B and 14B lattices show only random fluctuations about zero relative polarization because the ordered low temperature state consists of antiferroelectric protofilaments. In the 13B lattice, one protofilament of 13 must be unpaired, resulting in a finite polarization.

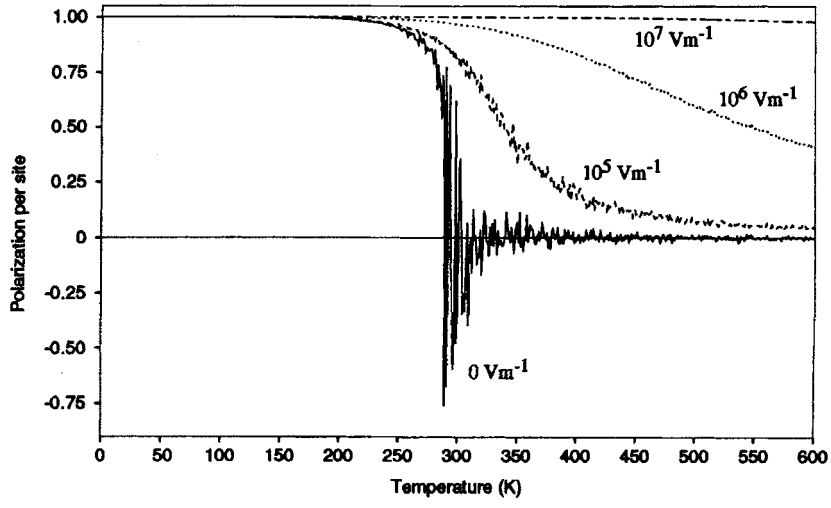

FIGURE 6 Polarization of the microtubule 13A lattice as a function of temperature as an electric field is applied in the direction of the up moment.

interaction along the protofilament, J, there is an interaction of strength 0.35 J along the direction a, and an interaction of strength -0.22 J along the direction b. Both of these are smaller than the interaction along the

protofilament, so indeed parallel alignment along the protofilament is expected. Of the off-protofilament interactions, the larger interaction (a) is ferroelectric so neighbouring protofilaments adopt a configuration of parallel dipoles. Consequently, the ground state consists of all dipoles in parallel alignment (Fig. 8a). In the B lattice, the situation is changed; there is an interaction of strength -1.76 J along the direction c, and an interaction of strength 0.39 J along the direction d (Fig. 3). This direction, c, must have alternating dipoles. Given that dipoles alternate along the helix defined by the d direction, the other two interactions are conflicting but the interaction along the protofilament is larger. As a result, dipoles are still in parallel alignment along the protofilament. The entire lattice now consists of alternating protofilaments (Fig. 8b).

3.1. Lattice Defects

In addition to the effects of lattice type and applied fields upon the ordering of the lattice, there is also the question of how defects in the lattice have an impact upon dipole ordering. Firstly, consider lattice defects where the protofilament number is different than the usual 13. In the case of such a microtubule, there is now a seam for both the A and B lattices. In the 14A lattice, the interaction at the seam is now B-lattice-like. As a result, at the

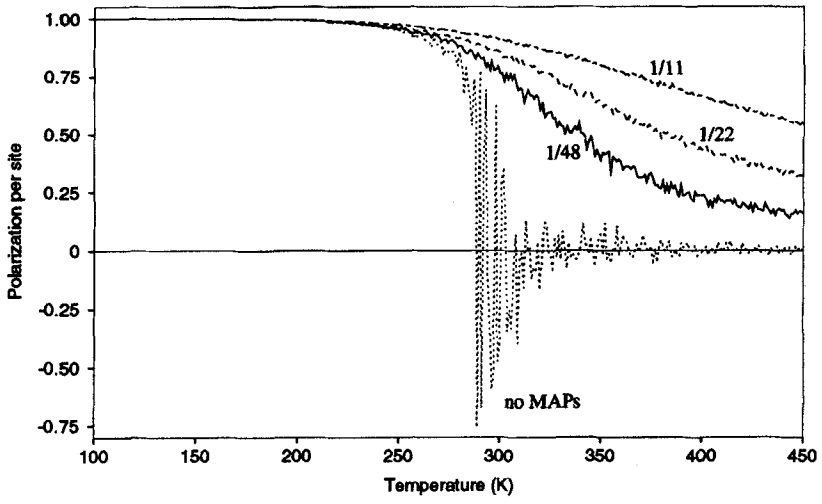

FIGURE 7 Polarization of the microtubule 13A lattice as a function of the ratio of microtubule-associated proteins to tubulin dimers. Ratios taken from Dustin [25] and 1/22 means one in each 22 dimers is attached to a MAP and held in the up conformation.

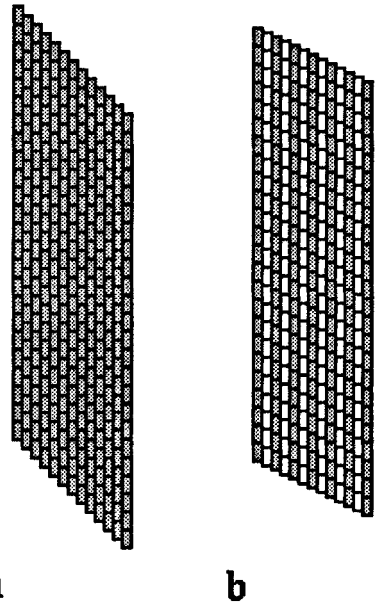

FIGURE 8 (a) Ground state of the microtubule 13A lattice, which is completely ferroelectric. Dimers are illustrated and dark boxes and light boxes indicate states of opposite dipole moments. (b) Ground state of the microtubule 13B lattice, which demonstrates antiferroelectric order between neighbouring protofilaments. Dimers are illustrated as in (a).

seam the ordering between the neighbouring protofilaments favours antiparallel ferroelectric order. These two protofilaments adopt the antiparallel ferroelectric ordering and the remaining protofilaments have some flexibility. That is, a ferroelectric seam must exist on the microtubule due to the dipole frustration. It should be distinguished from the seam we have discussed up until this point, which was structural; its location is immaterial since it does not have an energetic consequence. So, one drawback to such a lattice is the relative lack of order since dipole interactions alone do not make all microtubules with 14 protofilaments and an A lattice alike. Similarly, if we consider the 14B lattice, the bulk of the lattice imposes that neighbouring protofilaments should have alternating dipole orientations; but at the structural seam which closes the microtubule cylinder the preferred interaction is of antiparallel dipole orientations. The ground state occurs when the frustration is localized at the structural seam; however, the net polarization of the microtubule defined by Eq. (4) is zero since the numbers of dimers in the up state and in the down state are equal. Since the dipole of the up state and down state are not exactly opposite, the

microtubule does retain a small polarization. Thus the lattice type and the boundary conditions of the structural seam play an important role in determining the ordered state of the polymer.

We have also studied the impact which microtubule associated proteins (MAPs) have on dipole ordering in microtubules. MAPs attach themselves to microtubules in periodic patterns.[25] Their function is to stabilize the assembly properties of the microtubule. Our hypothesis is that this is accomplished by preventing the conformational change of the tubulin dimer to which it is attached. The net effect of such MAPs has been simulated given this assumption, and the result is qualitatively similar to the application of an electric field (Fig. 7). This may be understood by viewing the fixed conformation dipoles as seeds of order. In the limit where one could connect a MAP to each tubulin dimer in a microtubule, the lattice would be ordered at all temperatures.

One thing which has not yet been experimentally established is the magnitude of the dipole moment on the tubulin dimer. It seems quite likely that it is sufficiently large for dipole interactions to cause ordering of the molecular conformations of the microtubule. Indeed, it is even possible that, due to the shielding of the microtubule by ordered water, the effective temperature experienced by the polymer would be somewhat lower and dipolar effects would be even more important.

Our investigations show that the microtubule is also sensitive to electric fields of the order 10^5 V/m; this may be more usefully understood as 100 mV/μm and is smaller than the typical electric field of 10^7 V/m measured across cellular membranes. If the MAPs function as we have hypothesized, then weaker fields would suffice. The significance of this observation comes mainly from the geometry of microtubules in nerve cells, which pass electrical signals (nerve impulses) along their membranes and give rise to transient electric fields. These short-lived fields may be sufficient to cause a wave of reordering along the microtubule, just as a wake follows a ship. It is essential that the microtubule has a highly ordered resting state if such signals are to be interpreted by receptor proteins at the synaptic junction between two nerve cells. That is to say, a signal could not be distinguished from the background unless the background was relatively smooth. This may indeed be the function of the dipole interactions.[18] Our simulations show signal processing or transmission as possibilities but rule out the storage of information as Hameroff *et al.*[2] have hypothesized. The main problem with information storage through particular patterns of dipole states is the need to shield the system from thermal fluctuations. In our model this means operation below the transition temperature. Below the

transition temperature, signals are only transient because the microtubule must ultimately reside in its ground state.

4. DISCUSSION

The ferroelectric properties of the microtubule seem to be important in determining the orientation of the microtubule, may be important in directing the traffic of motor proteins on their outer surface and are also essential if signals are passed along the microtubule by a wave of conformational change. While the electromagnetic hand may not be required for this direction, it does simplify the explanation of certain signalling properties such as a synchronizing signal prior to chromosome separation or signal propagation along an axonal microtubule. The phase transition from a disordered to an ordered lattice of dipoles is not necessarily observable within a living cell, since one expects that the microtubule would always remain ordered to retain its function. However, the transition temperature does determine the magnitude of the dipole required for electromagnetic interaction to be the dominant influence on lattice dipole dynamics. The larger the dipole, the more important both the dipole–dipole interaction and the interaction with external electric fields.

Currently investigation is underway to examine the conduction properties of the microtubule. Should the microtubule be found to have semiconductor properties, this electron mobility will lend much weight to the ferroelectric explanation of microtubule function.

Amplification of Superpositional Effects Through Electronic–Conformational Interactions

MICHAEL CONRAD

Department of Computer Science, Wayne State University, Detroit, MI 48202, USA

Abstract—Electronic–conformational interactions allow for a speedup of biomolecular structure formation that derives from the quantum mechanical superposition principle. Changing phase relationships among electronic states of different energy lead to perturbative interactions between non Born–Oppenheimer electrons and atomic nuclei that can have a self-amplifying (positive feedback) character. Conformations that satisfy the conditions for such an interaction are inherently unstable. The term "conformational soliton" refers to nuclear configurational changes that ripple through macromolecular lattices in a manner that preserves informational integrity. The model suggests that such states of ordered conformational motions are generic to polymacromolecular organizations of the type that occur in biological cells.

1. INTRODUCTION

Conformational changes appear to accompany all biomolecular recognition-action processes. An enzyme, for example, may be pictured metaphorically as interacting with a substrate in a lock–key manner; if the shapes fit together a catalytic action occurs. In reality, the shape of the enzyme changes during the course of the reaction and the response is enabled and modulated by a variety of milieu features (including control molecules). The formation of the complex is typically attributed to diffusive motion ("Brownian search") and shape fitting augmented by conformational motion. Recent years have also seen efforts to develop a variety of dynamic pictures in which nonlinear interactions, such as electronic–conformational coupling, play a self-organizing role [1–7].

In previous publications the author has argued that the rates of complex formation and decomposition (the docking and undocking of the interacting molecules) depend on interactions between electronic and nuclear degrees of freedom that are inherently unstable [8–10]. The purpose of the present paper is to show how such interactions can draw on the parallelism inherent in the quantum mechanical wave function to generate conformational changes that propagate over long distances in macromolecular networks in biological cells. Cytoskeleton would be a prominent example; DNA strands and the bilayer membrane itself are other possible media. The term "conformational soliton" is intended to evoke the picture of an electronic-conformational instability that perpetuates itself over substantial distances in a macromolecular network in a way that requires no net dissipation. The term "self-perpetuating conformational change" could also be used, since the propagation processes resulting from electronic–conformational interactions are in many respects quite different from those of conventional solitons.

2. QUALITATIVE PREVIEW

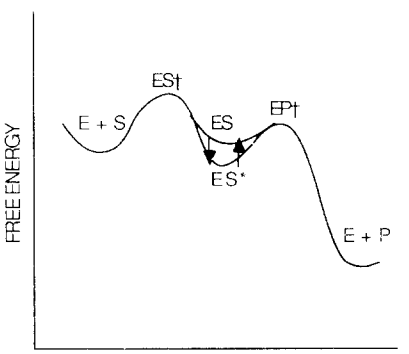
2.1. *Dynamic free energy surfaces*

Let us begin with an informal description of the physical principles underlying docking speed. As noted above diffusion and dynamic shape fitting play a role. The probability that a "molecular lock" and a "molecular key" would find each through random collisions should decrease as the specificity of the fit increases. To achieve both specificity and speed it is necessary that the molecules dynamically draw each other into the required relative orientation. The conformational changes that accompany recognition reflect this requirement. The greater the "drawing in" effect the lower the free energy of the complex. The likelihood of decomposition due to purely thermal agitation must then decrease. This implies that specificity and speed are conflicting requirements in a purely thermal model of enzyme catalysis.

Enzymatic reactions are nevertheless both quite specific and quite fast. This can be achieved if the complex is inherently unstable [3, 11]. The thermodynamic picture is that of a dynamic free energy surface (Fig. 1). The substrate molecule bounces into the enzyme, undergoes a catalytic modification, and then bounces out. A bouncing ball provides a simple example of such a nonthermal motion. The elasticity of the ball allows an exchange between potential and kinetic energy. In the model to be presented the exchange occurs between the electronic and nuclear coordinates. The nuclear system transfers (perturbation) energy to the electronic system, which in turn transfers it back to the nuclear system. In the presence of suitable nonlinearities (with a positive feedback character) the effect is self-amplifying.

2.2. *Quantum speedup principle*

The quantum mechanical superposition principle plays the key role in this exchange. The wave function of the interacting molecules constitutes a set of possible states that interfere with each other. Let us divide the entire system—for example, enzyme and substrate—into electrons, atomic nuclei, and hydrogen bonds (which may either be shared or mobile protons). The de Broglie wavelength of the atomic nuclei is too small for wave properties



$$E + S \rightleftharpoons ES \rightleftharpoons E + P$$

Fig. 1. Unstable free energy surface. E represents enzyme and S represents substrate. ES‡ and EP‡ are activated states. ES represents the enzyme–substrate complex. ES*, which is not explicitly represented in the reaction scheme, is a second form of the complex that has lower energy than ES. The double potential surface indicates that ES and ES* are connected by a nonthermal motion (e.g. an electronic–conformational interaction).

to play an important role. The possible positions of the nuclei converge to a definite value, and consequently the superposition of states is of negligible significance. The "shape state" of the complex is defined in terms of the coordinates of the nuclei, but even if we considered individual nuclei the superposition of states would be of only minor significance. The important point is that definite shape is alien to the superposition principle. Consequently quantum features cannot speed up the docking process if the configuration of the nuclei is the only factor considered, even if dynamic changes in the configuration are allowed.

The situation is entirely different for the electrons, and to some extent for the hydrogen bonds. The possible positions of an electron can differ significantly. When a measurement is made, the electron jumps into one of its states with some probability. The possible states interfere with one another, but the probability of finding the electron in any particular state is independent of time as long as the states are all of the same energy [12]. This corresponds to a stationary state. When states of different energy contribute significantly to the superposition, the probability of finding the electron in any particular state changes, corresponding to time development. The change in probability is due to constructive and destructive interference among the possible states of differing energy (the phase relationships among the different possible states would stay the same if they all had the same energy). The nuclei will be agitated by the resulting variations in the electronic charge distribution. In the model to be developed this agitation contributes to the speed of complex formation. In the presence of suitable nonlinearities the electronic states that contribute to the superposition are further spread out in energy by the motions they induce in the nuclei, leading to a self-amplifying effect that allows the nuclear configuration to jump out of local minima. This speeds the discovery of a unique minimum (or family of minima) in the case of molecular self-assembly and speeds both the formation and decomposition of the complex in the case of enzyme catalysis. Conformational solitons result when the conformation changes triggered in one macromolecule lead to unstable conformational interactions with a neighboring macromolecule.

2.3. *Breakdown of Born–Oppenheimer*

At first glance the above scenario is incompatible with the fact that the energy differences between different electronic states in biological macromolecules appear to be too great to allow for a speedup effect of the type described. Clearly self-assembly and enzyme catalysis occur in the dark. Thus in order for superpositional speedup to occur it would be necessary for the electrons of biological macromolecules to undergo transitions in response to the infrared radiation field. This appears to contradict the fact that the infrared spectra are ordinarily attributed to the vibration and rotation of the atomic nuclei. This is probably why models of the type described have not previously been seriously considered.

The above objection rests on the Born–Oppenheimer approximation, that is, on the assumption that the electrons are tightly enough bound to the atomic nuclei so that the potential due to their charge can be wrapped into the nuclear potential. This is not true for delocalized electrons. Such electrons will experience some motion relative to the nuclei, hence some accelerations that are not rigidly tied to the thermally induced accelerations of the nuclei. Accordingly, such electrons should make a contribution to the infrared radiation normally attributed to the thermal motions of the nuclei that deviates from the contribution they would make if Born–Oppenheimer were strictly accurate. Since the electrons and nuclei form a bound system the electronic levels must at the same time be discrete. Consequently closely spaced transitions must in fact exist. This would be of no significance in a system in which the nuclei are undergoing a periodic motion. Complex formation and

decomposition is a time dependent process that is not periodic, however. The infrared spectra of a complex should change in the course of its self-assembly, since degrees of freedom become constrained in different ways as the complex forms. If the Born–Oppenheimer assumption fails, some component of this change will then be due to closely spaced electronic transitions.

There is now substantial evidence that electrons can tunnel over significant distances in proteins, for example by tunneling through hydrogen bonds [13]. Surface electrons and some highly delocalized bonds or highly polarizable electrons (such as the electrons in the polar head groups of lipids) are probably also attached to the atomic nuclei in a sufficiently loose manner for Born–Oppenheimer to become an inadequate approximation. Paralled spin electrons that ordinarily are well approximated by Born–Oppenheimer could conceivably also be transiently delocalized if the nuclei to which they are attached are forced, in the process of complex formation, to be much closer together than their unconstrained equilibrium separation. The confinement of such electrons would serve to correlate their motions during short periods of downward fluctuation in thermal energy (over longer periods spin flipping through the spin-orbit interaction would be the more likely fate). During these short periods the electrons will behave as a pair with an energy that is lower than the unpaired ground state energy [2, 3, 11]. In this way states of different energy would be available; additionally the correlated motion of the pair would exert a perturbative effect on nuclei.

A more general argument, based on the principle of microscopic reversibility, implies that even mildly delocalized electrons should undergo transitions to different energy states in the course of complex formation. When the nuclear conformation changes, the potential to which electrons are subjected changes; the energy levels of the electrons thus change in the course of complex formation [14]. It might at first be thought that this is consistent with Born–Oppenheimer, since the change in the electronic levels follows the nuclear motion. However, according to the principle of microscopic reversibility the time reversed process should also be possible. In this case the changes in the electronic levels would lead the nuclear motions, and would therefore influence them. In short, if it is possible to follow it is possible to lead. (The effect of the electrons on the nuclei should not be analogized to the effect of a football on the earth, since the electromagnetic forces exerted by the two systems are equal and independent of mass. The difference between the masses of the two systems only controls the speed with which the follower system follows.)

2.4. *Quantum versus thermal fluctuations*

A second objection also suggests itself, namely that the quantum effect would be small as compared to the thermal effect. This would be true on a static potential surface. For a dynamic surface, such as the one schematically pictured in Fig. 1, the effects of thermal and quantum fluctuations are incommensurable. If the electronic–conformational interaction opens up a new pathway on the surface the controlling factor will be the barrier presented by this pathway; the issue is not whether a quantum effect is more effective than thermal agitation for jumping over (or tunneling through) a given barrier at room temperature, but whether it is more effective in allowing for reduction or sidestepping of the barrier. Here is where the nonlinearity of the interaction between the electronic and nuclear wave functions plays the crucial role. The quantum speedup effect outlined above is in a sense a thermal effect, since thermal (infrared) agitation initially spreads out the energies of the possible electronic states. The nonlinear interaction between nuclear conformation and the charge variations which result from the interference of possible

electronic states of different energy amplifies this initial thermal influence, a feature that is uniquely dependent on the superposition principle.

3. FORMAL REPRESENTATION

3.1. *Superposition principle*

The time development of the whole system (complex plus heat bath) is governed by some true time independent potential $V(x)$. Here x schematically denotes coordinates of all relevant particles—electrons, nuclei, and particles of the heat bath. This potential is unknown, and is in any event useless since it provides too much information about the time development of the system (we are not interested in the heat bath). At each stage of development we can suppose that some features of this true potential become relevant. We can denote this time dependent potential by $V(x_e, x_n, t)$, where x_e denotes the coordinates of the electrons of the interacting macromolecules and x_n denotes the coordinates of their nuclei. The time evolution of the potential function means that some information about it is absorbed into the heat bath and represented in terms of a statistical description.

Let us denote the electronic wave function of the complex by $\Psi_e(x_e, t)$, and the nuclear wave function by $\Psi_n(x_n, t)$. For the purposes of eliciting the speedup and instability inherent in electronic–conformational interactions it is sufficient to regard these as notational wave functions—that is, we need not here attempt to represent the detailed character of the electronic or configurational states. Also, we will work with wave functions rather than density matrices; the latter would make it possible to include thermal statistical effects more elegantly, but at the expense of losing focus on the quantum statistical effect that is here to be proposed.

If the potential energies (or Hamiltonians) of the electronic and nuclear systems were additive we could write

$$\Psi(x_e, x_n, t) = \Psi_e(x_e, t)\Psi_n(x_n, t). \tag{1}$$

This is not possible in a system in which the potentials share coordinate dependencies. In ordinary atomic or molecular problems the nuclear wave function, expressed in center of mass coordinates, is considered constant; hence the electronic levels can be static and governed by a fixed potential that is determined by the interaction between electrons and nuclei and between electrons and electrons. This is equivalent to assuming the complete absence of an electronic–conformational interaction. In our case the latter interaction is the main point of interest, and consequently the clean splitting described by equation (1) cannot be strictly accurate since the electronic and nuclear wave functions must mix to some extent.

The time scales of electronic and nuclear transitions are very different, however. Our idealization assumption is that the difference is so great that we can treat the wave functions as being sufficiently separable so we can make a quasi-independence assumption. When the molecules come into contact the wave functions are modified by an interaction term that requires them to be updated. Updating continues until the wave functions converge to mutual consistency (in which case the complex stabilizes) or until they diverge (in which case the complex breaks up). Quasi-independence means that the updating can be done independently—that is, the electronic wave function can evolve for a while, then the nuclear wave function changes, then the electronic wave function evolves again, and so forth. Apart from the updating points the potential function can then with reasonable approximation be split into two parts

$$V(x_e, x_n, t) = V_n(x_e, x_n, t) + V_e(x_e, x_n, t), \tag{2}$$

where V_e denotes the potential controlling the behavior of the electronic system and V_n denotes the potential controlling the behavior of the nuclear system. The reversal of subscripts relative to those of the corresponding wave functions (e.g. V_n is the potential for Ψ_e) is intended to indicate that the positions of nuclei make a more significant contribution to the potential governing the time evolution of the electronic system than do interactions among the electrons and that the distribution of electrons makes a contribution to the potential governing the time evolution of the nuclear configuration that is not entirely attributable to the strong and weak bonding interactions among the nuclei (taken in the sense of the interactions used in a molecular dynamics calculation). The idealization is that the potentials do not significantly depend on the same coordinates between the updates. All the nonlinearity is thus concentrated at the updating points; between these points the time development is linearizable. These are extreme simplifications. If we can elicit a significant electronic–conformational effect under these conditions it is reasonable to assume that the effect would even be stronger if the wave functions are less separable and the nonlinearity operative at all times.

For simplicity suppose that the complex has two accessible families of nuclear configurations, labeled by I and II, and two accessible families of electronic states, also labeled by I and II. Suppose that these families (or conformations) are both separated by potential barriers, at least initially. Also for simplicity we will think in terms of two wave functions, one for all the electrons of the interacting macromolecules and one for all the nuclei. In reality, of course, the potential surface would be much more complicated and the wave functions of each of the interacting molecules would ordinarily be treated as independent of one another to a good approximation; but for the purposes of exhibiting the speedup effect in a formal way it is the interaction between electronic and nuclear wave functions that is the main point of interest.

The electronic wave function can then be expressed as a superposition of the form

$$\Psi_e(x_e, t) = \sum_{e \in \mathrm{I}} a_e(t) e_e(x_e) \exp(-iE_{e(\mathrm{I})} t/h) + \sum_{e \in \mathrm{II}} a_e(t) e_e(x_e) \exp(-iE_{e(\mathrm{II})} t/h) \qquad (3)$$

where the e_e are eigenfunctions of the electronic system that are most naturally associated with nuclear conformation I, the e_e are eigenfunctions most naturally associated with nuclear conformation II, the a_e and a_e are expansion coefficients, and we assume that the wave function can be split into time independent and time dependent parts. The $E_{e(\mathrm{I})}$ and the $E_{e(\mathrm{II})}$ are the electronic energies associated with the eigenfunctions e_e and e_e.

Any complete set of orthonormal basis functions could be used to express $\Psi_e(x_e, t)$. The choice of eigenfunctions allows for the most natural association between individual basis functions and particular conformations. Since the potential is time dependent it is necessary to choose the set of eigenfunctions at some particular point in time and in a way that allows for the associations noted above. A natural choice is the initial point in time, assuming the true potential is operative. Alternatively, we can regard the electronic eigenfunctions as defined over the initial potential $V_e(x_e, x_n; t = 0)$ and the nuclear eigenfunctions as defined over the initial potential $V_n(x_e, x_n; t = 0)$. In the present case we are considering a coupled double well potential. Consequently the electronic eigenfunctions are determined by the double well potential representing the two possible nuclear conformations, and similarly the nuclear eigenfunctions would be determined by the double well representing the two possible families of electronic states. These are of course purely conceptual definitions. It would never be possible to actually ascertain the mathematical form of these eigenfunctions starting with the double surfaces. But in principle the eigenfunctions exist and this is sufficient for the present purposes.

Some of our "notational eigenfunctions" might not be assignable in an unambiguous way to either conformation I or conformation II. This class of eigenfunctions would contribute to speedup, due to the fact that they extend over a larger region of the potential surface. If this class is ignored we can think of the superposition in a more practical way as built up from eigenfunctions calculated in the individual wells. For the purpose of demonstrating the speedup effect we can ignore the ambiguous eigenfunctions, since their presence would in fact enhance the effect.

The wave function for the collection of nuclei may, in accordance with the above conventions, be expressed as

$$\Psi_n(x_n, t) = \sum_{r\varepsilon \mathrm{I}} b_r(t) n_r(x_n) \exp(-iE_{n(r)}t/\hbar) + \sum_{s\varepsilon \mathrm{II}} b_s(t) n_s(x_n) \exp(-iE_{n(s)}t/\hbar). \tag{4}$$

The n_r are the eigenfunctions of the nuclear system when it is in conformation I, the n_s are the eigenfunctions when it is in conformation II, and the $E_{n(r)}$ and $E_{n(s)}$ are the energies associated with these eigenfunctions. However, the nuclear system, because of its large mass, should with high probability be assigned to a definite state. Thus if it is initially in conformation I all the b_s can for all practical purposes be set to zero. To make matters as unfavorable as possible to the speedup effect we can also assume that the nuclear configuration is initially in a single eigenstate, so that all the b_r apart from one can initially be set to zero. Practically speaking this is reasonable since the average values associated with the different n_r should peak very sharply due to the large mass.

For the electrons it is not possible to ignore superposition effects. An electron, because of its small mass, might with reasonable probability be found in a location more naturally associated with II than with I even if the nuclei are in conformation I. To make matters as unfavorable to the speedup effect as possible, let us assume that initially all the a_s are negligible and that the electronic system is initially in a single eigenstate, so that only one of the a_r is initially nonnegligible.

If some of the electrons are not tightly bound to the nuclei it will be possible for perturbations, arising for example from the radiation field, to induce transitions to eigenfunctions with energies close to that of the energy of the initial eigenfunction. The probability distribution of electronic coordinates will then be given by

$$p(x_e, t) = \sum_r a_r^*(t) a_r(t) e_r^*(x_e) e_r(x_e) + \sum_r \sum_{r'} a_r^*(t) a_{r'}(t) e_r^*(x_e) e_{r'}(x_e) \exp\left(\frac{(-iE_{e(r)} - iE_{e(r')})t}{\hbar}\right), \tag{5}$$

where $r \neq r'$. This explicitly demonstrates the statement made earlier that the electronic charge density will change with time due to interference among the eigenfunctions of different energies, since these are associated with different frequencies of vibration. Our simplifying assumption that the wave function can be split into time independent and time dependent parts serves to elicit this well known quantum mechanical feature in an explicit manner; but in fact the assumption is more restrictive than necessary.

Equation (5) can be used to give more precise meaning to the phrase "parallelism of the quantum mechanical wave function". The structure of the wave function is determined by two factors: the choice of the basis functions and the superposition of these basis functions. The contribution of these two factors to the "possibility space" of a system cannot be separated. Even a single basis function, say an eigenfunction, will allow for penetration into the classically forbidden region of a barrier. It might therefore appear that the quantum speedup effect could occur without interference between states of different energy. This is not the case, however, since interference inevitably occurs if the time

evolution of the system is considered. Suppose, for example, that an electron initially has a high amplitude to be in a particular potential well. With time the amplitude for being in a second well increases. The energy of the electron at the later time will be smaller, since the space in which it can reasonably be found will be larger. (This can be seen from the position–momentum uncertainty principle. An increase in the spatial range of the electron allows for a decrease in the uncertainty of its momentum, and therefore for a decrease in the kinetic energy fluctuations it exhibits.) Consequently the time evolution will involve interference among states of different energy regardless of the initial choice of basis functions. The treatment that follows will emphasize superposition, since interference is definitive of time evolution. However, the intimate connection between the choice of basis functions and their superposition must be kept in mind, since the interference pattern, and all physical properties, are independent of any acceptable choice.

3.2. *Self-consistent field*

The electronic and nuclear wave functions (equations 3 and 4) must be consistent with each other. This suggests a Hartree-type self-consistent field approach. Ordinarily this is viewed as an approximation procedure. For example, the electronic wave function of a multi-electron atom is approximated by starting with an initial trial wave function and potential and iterating until convergence is achieved. The steps toward convergence are ordinarily not viewed as representing the self-organization of the multi-electron atom, and accordingly the trial wave function need not represent any physical reality; questions about how such atoms organize themselves are not ordinarily considered. The objective is to obtain a description of a final, static system of electrons which presumably forms so rapidly and in a way so controlled by energy that questions about the formation process are not of major phenomenological interest. The situation is completely different for the formation of macromolecular complexes, such as the enzyme–substrate complex. The self-organization and self-disorganization of the complex, and the specificity of these processes, are the phenomenological features of greatest importance.

The idea, then, is to use a Hartree-like self-consistency scheme to represent, in a conceptual way, the evolution of the complex to a self-consistent state (which may ultimately be the dissociated state if no self-consistent complex is possible). Could it be that inconsistencies are possible in nature? The answer is certainly yes. A room controlled by a thermostat exhibits an inconsistency between the state of the room (ambient temperature) and the state of the thermostat (curvature of a piece of metal). If the relation between these two states is one of negative feedback the ambient temperature converges to a constant value, with some slight oscillation about this value. If the relation is one of positive feedback the temperature diverges. From the point of view of nonlinear dynamics the state of the room and the state of the thermostat are of course inconsistent in a consistent way. Our hypothesis is that the state of the electronic and nuclear systems can be inconsistent in just this fashion, that is, can be in a relation of either positive or negative feedback.

From the assumption (equation 2) that the potentials can be split in an additive manner we can express the electronic and nuclear wave functions as solutions of the Schrödinger equations

$$-\sum_i \frac{\hbar^2}{2m_i}\nabla_i^2\Psi_e(x_i, t) + V_e(x_i, x_n, t)\Psi_e(x_i, t) = i\hbar\frac{\partial\Psi_e(x_i, t)}{\partial t} \tag{6a}$$

$$-\sum_n \frac{\hbar^2}{2M_n}\nabla_n^2\Psi_n(x_n, t) + V_n(x_i, x_n, t)\Psi_n(x_n, t) = i\hbar\frac{\partial\Psi_n(x_n, t)}{\partial t} \tag{6b}$$

Here m_e is the mass of the electron, ∇_j^2 is the Laplacian operator of the jth electron, M_k is the mass of the kth nucleus, and ∇_k^2 is the Laplacian operator of the kth nucleus.

The complex must form from a large fraction of the initial conditions that correspond to initial contacts. The initial potentials governing the electronic and nuclear systems, since they are time dependent, would in fact then not be independent of the initial conditions. Let us suppose some initial arbitrary contact between the interacting molecules. We suppose that it is possible in principle to construct initial potentials corresponding to this initial arrangement. The initial electronic and nuclear wave functions are in principle given by the equations (6a) and (6b). The average positions of the electrons are then obtained from equation (5), and the average positions of the nuclei may be obtained analogously (except that interference effects should not be noticeable). The first cycle is completed by using these new average positions to update the potentials. The process is repeated until convergence is achieved (corresponding to mutually consistent electronic and nuclear wave functions) or until the system diverges to a self-consistent state. Divergence means jumping from one metastable state to another, leading eventually to a self-consistent complex. It is entirely possible that no self-consistent complex exists, apart from the dissociated state. Two interacting molecules could in this case jump, through a series of divergent processes, to a unique minimum that is suited to a particular catalytic function and then diverge to a dissociated state.

The updating of the potentials may be expressed notationally by writing

$$V_e(x_e, x_n, t) = V_e(\Psi_e(x_e, t), \Psi_n(x_n, t)) \tag{7a}$$

$$V_n(x_e, x_n, t) = V_n(\Psi_e(x_e, t), \Psi_n(x_n, t)), \tag{7b}$$

where the functional notation expresses the fact that V_e and V_n depend on features of both the electronic and nuclear wave functions. As noted above the updated functional forms utilize the probabilities

$$p(x_e, t) = \Psi_e^*(x_e, t)\Psi_e(x_e, t) \tag{8a}$$

and

$$p(x_n, t) = \Psi_n^*(x_n, t)\Psi_n(x_n, t). \tag{8b}$$

But of course some criteria would have to be used for obtaining adequate potentials from these probabilities; for example, interactions may be considered irrelevant if the likely coordinate values are such that the particles are more than some specified distance apart, or some averaging may be done beyond a certain distance. Updating the potentials in this manner does not represent any process inherent in the phenomena—in particular it does not imply that wave function reduction is occurring. New potentials could, with some less intuitive procedure, be obtained without calculating probabilities from the wave function. To construct a theoretical demonstration of the speedup effect it is only necessary to assume that relevant potentials exist in principle.

To formally express the scheme it is convenient to write the Schrödinger equations (6a) and (6b) in the abbreviated form:

$$\Psi(x, t + \tau_b) = \Psi(V(x, t + \tau_a), t + \tau_b). \tag{9}$$

Here $\Psi(x, t + \tau_b)$ is the (electronic or nuclear) wave function at time $t + \tau_b$, $t + \tau_a$ (with $\tau_b > \tau_a$) is the time at which the (nuclear or electronic) potential $V(x, t + \tau_a)$ is turned on, and $\tau_b - \tau_a$ is the time interval over which this potential remains applicable. The assumption that time dependent perturbation theory is adequate for dealing with any changes in the potential functions during the intervals means that the potentials take the

form

$$V(x, t) = V'(x) + v(x, t), \tag{10}$$

in a piecewise continuous manner, where $V'(x)$ is a time independent unperturbed potential applicable during the interval $\tau_{ik} - \tau_{ii}$ and $v(x, t)$ is a small time dependent perturbation that develops over this interval. Written explicitly in terms of what we have called the potentials for the electronic and nuclear subsystems

$$V_e(x_e, x_n, t) = V'_e(x_e, x_n) + v_e(x_e, x_n, t) \tag{11a}$$

$$V_n(x_e, x_n, t) = V'_n(x_e, x_n) + v_n(x_e, x_n, t). \tag{11b}$$

This assumption, as noted above, is more restrictive than necessary, but it allows us to separate the solution of the Schrödinger equations for $V'(x)$ into time independent and time dependent components

$$\Psi'(x, t) = \psi'(x)\phi(t), \tag{12}$$

in a piecewise continuous manner and therefore to represent the vibratory terms in equations (3) and (4) in an explicit manner. The $\Psi(x, t)$ can then be written in terms of $\Psi'(x, t)$ with time varying coefficients. (Note: we have here put the prime on the unperturbed potential so as to avoid carrying it through in the discussion to follow.)

Let the time interval $t_{i+1} - t_i$ denote the ith cycle of nuclear–electronic interactions. The electronic system is pictured as undergoing an evolution over some time interval τ and then as remaining constant while the nuclear system follows over a time interval $\tau_{i+1,0} - \tau_{i,i+1}$. The subscript $(i0)$ associates these intervals with the start time of the cycle. The time evolution of the complex may be described by an iterative (recursive) process of the following form:

$$\Psi_e(x_e, t_i + \tau_{i,i+1}) = \Psi_e(V_e(\Psi_e(x_e, t_i), \Psi_n(x_n, t_i)), t = t_i + \tau_{i,i+1}) \tag{13a}$$

$$\Psi_n(x_n, t_i + \tau_{i,i+1}) = \Psi_n(V_n(\Psi_e(x_e, t_i + \tau_{i,i+1}), \Psi_n(x_n, t_i)), t = t_i + \tau_{i,i+1}) \tag{13b}$$

In each interval the potential comprises a time independent part and a small time dependent perturbation, in accordance with equations (11a) or (11b). The sequence of cycles is initially entered by setting the potentials at time t_{i0}, which subsumes initial wave function Ψ_e and Ψ_n at time t_{i0}. These potentials are used to solve for Ψ_n at time $t_i + \tau_{i,i+1}$. The time index $i = 0$ is then updated to $i = 1$, $\Psi_e(x_e, t_i)$ and $\Psi_n(x_n, t_i)$ in equation (11a) are set equal to $\Psi_e(x_e, t_i + \tau_{i,i0})$ and $\Psi_n(x_n, t_i + \tau_{i,i0})$, respectively, and the cycle thereby re-entered. The potential V_e is updated and used to solve for $\Psi_e(x_e, t_i + \tau_{i,i+1})$, and so on.

The term "solving" could be replaced by "evolving in accordance with" since we are interested in a conceptual representation of the complex formation and decomposition process. A bona fide calculation scheme would have to introduce auxiliary procedures for approximating the wave functions and potentials. For example, the initial potentials and wave functions at time t_{i0} should represent the true situation. In principle these potentials and wave functions exist, but in practice they would have to be calculated or in some way measured; this auxiliary calculation process would have no necessary relationship to the self-organizing dynamics of the molecules.

In a practical calculation specific reference to different time intervals between significant changes in either the electronic or nuclear state might be dispensed with, since there would be no way of knowing what these time intervals are in advance without some kind of look-ahead procedure (e.g. using the change in the probability distribution of the electrons as a criterion). The intervals could be made arbitrarily small, so that one could simply switch back and forth between equations (6a) and (6b). However, these intervals serve to

highlight the feature that the nuclear motion is slower than the electronic motion. The electrons adjust rapidly to a change in the nuclear coordinates (in which case $\tau_{e(u)}$ is small), but they can also exert a leading effect due to the charge variations accompanying interference. A more descriptive notational picture might therefore utilize two electronic time constants—a fast one for the rapid readjustment to the change in the nuclear configuration and a slow one for the interference effect [8, 10]. In the present formalism the evolution from $\Psi_e(x_e, t_u)$ to $\Psi_e(x_e, t_u + \tau_{e(u)})$ on re-entering equation (13a) represents both rapid readjustment and the slower developing interference effect.

In reality the division into two interacting subsystems, electrons and nuclei, is a great oversimplification. The hydrogen bonds should be treated as a subsystem in their own right. As noted earlier, the de Broglie wavelength is large enough to allow for some tunneling motions. At the same time hydrogen bonds serve as preferred pathways for electron tunneling. The tunneling electrons are highly delocalized and therefore good candidates for exhibiting interference effects among possible states that are accessible through infrared perturbation. The hydrogen bonds are the nuclei that will be most agitated by the consequent variations in the charge distribution, and therefore the first nuclei to amplify the perturbation to the electronic system. As the variations in the charge distribution increase, the heavier nuclei will be increasingly affected, further contributing to the amplification effect. The possible sequences of events are much more complicated than in the two component schemes described by equations (13a, b). The scheme would obviously be even more complicated if the particular orbital characteristics of the various electrons were taken into account.

3.3. *Processing the wave function*

The iteration scheme (equations 13a, b) processes the superpositions of electronic and nuclear states (equations 3 and 4). Let us consider what can happen as these superpositions are iterated. Recall that the possible nuclear states are so closely spaced in energy that the fact of superposition can be ignored in favor of a classical description. The worst case assumption is that the electronic system is in a single eigenstate associated with nuclear conformation I. Conceivably the electronic wave function is consistent with the nuclear wave function. Conformation I will then be metastable, and could for all practical purposes be stable. For example, we can suppose that II is a lower energy state, but that the barrier between I and II is sufficiently high that thermal fluctuations are very unlikely to trigger a transition; quantum fluctuations in the static case would even be more unlikely to trigger a transition.

Suppose, however, that the perturbation to the electronic system induces transitions to other electronic states. The magnitude of the initial nonnegligible expansion coefficient will decrease, and the magnitude of one or more other expansion coefficients will increase. The nuclei will be agitated by the changing phase relationships among electronic states, since more than one state now has a nonnegligible probability amplitude. The initial perturbation may be from the radiation field, but the resulting agitation of the nuclei serves as an additional source of perturbation. This means that the expansion coefficients of the electronic subsystem will have a functional dependence on the expansion coefficients of the nuclear system, since both contribute to V_n.

Let us trace through some possible "execution sequences" of the wave functions in a more formal way. The original electronic wave function is determined, according to our maximally unfavorable assumption, by a single expansion coefficient $a_r(t_0)$. Due to infrared perturbations and variations of the potential due to thermal motions of the nuclei this is converted to a superposition with some set of nonnegligible expansion coefficients:

$$a_i(t_0) \rightarrow \{a_i(t_0 + \tau_{i(i)}),\ a_{i'}(t_0 + \tau_{i(i')}),\ a_{i''}(t_0 + \tau_{i(i'')}) \ldots\} \tag{14a}$$

Here i, i', i'' ... all belong to the index set of conformation I. The number of elements in this set is at least two, since by assumption one or more electrons are not closely tied to the nuclei. Interference phenomena, including charge variations, thus appear. The wave function of the nuclei is determined by an equivalence class of eigenfunctions that are hardly distinguishable from the macroscopic point of view. To keep the notation simple we will ignore this distinction and, as previously indicated, denote the nonnegligible expansion coefficient by a single expansion coefficient. Because of the electronic charge variations the initial nonnegligible equivalence class $b_i(t_0)$ undergoes the transition

$$b_i(t_0) \rightarrow b_{i'}(t_0 + \tau_{i(i')}). \tag{14b}$$

The wave function defined by the new equivalence class of coefficients $b_{i'}$ corresponds to a new configuration of the nuclei, which we suppose (so as not to beg the question) is still assignable to conformation I. The electronic system undergoes transitions to new states in response to the nuclear motions:

$$\{a_i(t_0 + \tau_{i(i)}),\ a_{i'}(t_0 + \tau_{i(i')}),\ a_{i''}(t_0 + \tau_{i(i'')}) \ldots\}$$

$$\rightarrow \{a_{i'}(t_0 + \tau_{i'(i')}),\ a_{i''}(t_0 + \tau_{i'(i'')}),\ a_{i'''}(t_0 + \tau_{i'(i''')}) \ldots\} \tag{14c}$$

This corresponds to re-entry into the second cycle, and therefore involves a fast readjustment of the electrons to the new nuclear potential ($V_{i'}$ at time $t_0 + \tau_{i(i')}$) and also the slower interference effect. The latter effect now has three sources: the infrared radiation field and thermal motions of the nuclei, as before, and in addition the agitation of the nuclei that results from the interference itself. This additional source of perturbation remains after the fast readjustment unless it is assumed that all the transitions go directly to a single electronic state. In reality of course the agitation of the nuclei begins at time t_0 and acts reciprocally on the electrons on a continuous time scale. All this is represented (conceptually) in the updated $V_{i'}$ at $t_0 + \tau_{i(i')}$, or equivalently at time t_1. The time $t_0 + \tau_{i(i'')}$ and time $t_1 + \tau_{i'(i'')}$ sets might be entirely disjoint, or there may be some overlap.

Completing the $n = 1$ cycle

$$b_{i'}(t_0 + \tau_{i(i')}) \rightarrow b_{i'}(t_0 + \tau_{i(i')}) \tag{14d}$$

and entering the $n = 2$ cycle

$$\{a_{i'}(t_0 + \tau_{i(i')}),\ a_{i''}(t_0 + \tau_{i(i'')}),\ a_{i'''}(t_0 + \tau_{i(i''')}) \ldots\}$$

$$\rightarrow \{a_{i'}(t_1 + \tau_{i'(i')}),\ a_{i''}(t_1 + \tau_{i'(i'')}),\ a_{i'''}(t_1 + \tau_{i'(i''')}) \ldots\} \tag{14e}$$

The wave function defined by the equivalence class of coefficients $b_{i'}$ might still be assignable to conformation I, but conceivably they are assignable to II. If so the $t_1 + \tau_{i'(i'')}$ set should also be predominated by coefficients belonging to conformation II, since the electronic system should make a fast readjustment to the new conformation. The molecule will then be locked in conformation II, assuming that this can eventually evolve to a self-consistent state or to a cycle of quasi-consistent states all of which belong to conformation II. If II does not admit such a state or set of states the complex will eventually switch back to conformation I (since the example has been unrealistically restricted to only two conformations).

Feedback between a quantum and a classical system is the important feature illustrated by the above sequence. *The superposition of possible electronic states serves as the channel through which motions of the nuclear system are fed back into the nuclear system.* If the feedback is positive the motions of the nuclei will be self-amplifying. The complex will exhibit increasingly agitated motion, and then undergo a sudden significant change of form

If the feedback is negative the electronic and nuclear system evolve to mutual consistency. Negative here means that the charge variations resulting from inteference push the nuclei back towards their initial arrangement. The nuclei will then oscillate around some equilibrium configuration. The vast majority of molecules fall to a state of lowest energy that is for all practical purposes completely consistent and time independent. From our point of view the feedback loops are present but of negligible importance in these cases. They are unmasked only in those molecules in which the nuclear motions are intricately constrained in three dimensions (conformation is important) and in which electrons are present that can move somewhat independently of the nuclei.

From equations (6a, b) and (7a, b) it can be seen that the potentials are, through the updating procedure, functionally dependent on each other. This is an alternative way of looking at the time dependence of the expansion coefficients and the coupling of these coefficients.

3.4. *Connection to fluctuation-dissipation*

Fluctuation is necessary to induce transitions of the electronic system to states of different energy. The time development of a perturbed molecule would then ordinarily involve dissipation of energy into the heat bath in accordance with the equipartition of energy. The nonlinearity of the electronic–conformational interaction allows this dissipation to be focused into selected degrees of freedom of the nuclear configuration. The self-amplifying (positive feedback) form of the interaction is driven by fluctuation in a focused way over an extended period of time. The agitation of the nuclei can serve to bounce energy back to the electronic system in a selective way, but the self-amplification would die out in the absence of heat bath fluctuation.

Fluctuation-dissipation is concomitant to all chemical reactions, since fluctuation is the source of collisions that drive reactions over activation barriers. No macroscopic work is performed. What is controlled, as in all catalytic processes, is the rate at which work is performed and the selectivity of the pathway.

4. COUPLED INSTABILITIES

So far we have pictured the complexing of two molecules, at least one of which must be a macromolecule. The formation of the complex is described by a dynamic free energy surface. The parallelism inherent in the quantum mechanical wave function (i.e. in the superposition of electronic states) speeds the search of this potential surface, and also greatly increases the likelihood of finding a unique minimum that is independent of the initial conditions. It does so by agitating the nuclei in a positive feedback fashion, thereby opening up new pathways for formation or decomposition, or lowering or narrowing existing barriers. If the complex that is formed is self-consistent, or if it allows for cycling among a family of conformationally equivalent states, we have self-assembly. The folding of an individual protein fits into this situation. The folded protein maybe viewed as self-organizing from the interactions among the different regions of a single covalently bonded sequence of amino acids. Enzyme–substrate interactions correspond to the situation of an unstable complex. If the enzyme recognizes the substrate it makes or breaks a particular covalent bond and then ejects it; if it does not recognize the substrate it dissociates without taking an action. Conformational switching in response to control molecules (allosteric control) can be interpreted in a similar manner.

Let us now turn to supermacromolecular complexes. We can think of these as highly structured arrangements of macromolecules that self-assemble in jigsaw puzzle fashion.

Such polymacromolecular constructions are ubiquitous in biology. They come in the form of extensive sheets (membranes), localized but highly intricate constructions (chloroplasts, mitochrondria, ribosomes), wide ranging but highly structured networks (the cytoskeleton), and linearly oriented architectures (chromosomes). These structures exhibit motions that help to choreograph the flow of components in the cell at all levels, ranging from directed movement of electrons in chloroplasts and mitochondria to the micromuscular activities of the cytoskeleton. In all likelihood they also serve as channels for signal flows that coordinate distant events.

For simplicity we will picture these polymacromolecular constructions as lattices, with each lattice point occupied by a macromolecule. Each molecule potentially interacts with any of its immediate neighbors. The interaction can be viewed in analogy to the interaction between an enzyme and substrate, except that in this case we are not concerned with the making or breaking of a covalent bond. The "substrate" acts solely as a control molecule that switches the enzyme into a particular conformation. The macromolecules of the lattice can thus act as control molecules relative to one or more of their neighbors and can act as controlled molecules relative to one or more neighbors.

Figure 2 illustrates in schematic fashion how interactions of the type proposed in the previous section could lead to a propagating conformational change in a one-dimensional lattice built from a single type of macromolecule. Each molecule has two conformations available to it, I and II, as in our previous discussion. Conformation I is represented by a left handed arrow and conformation II by a right handed arrow. Conformation I is self-consistent (stable) except when it complexes with a conformation II molecule, in which case it undergoes a transition to conformation II (complexing is represented by two arrowheads pointing towards each other). Similarly conformation II is stable except when it complexes with conformation I, in which case it reverts to conformation I. The initial conformational switch is triggered by an externally imposed input on the far left hand side of the chain. The conformational change propagates through the chain until it reaches the right hand side, where it triggers an effector molecule into an active state.

To the above lattice we have attributed properties inherited from the superposition-amplification model described in the previous section and characteristic of the biological examples mentioned above. The subsumed conformational changes are significant, they have a high degree of directional specificity, and the rate of propagation is high. The changes can propagate over substantial distances in a homogeneous lattice in a manner that maintains their original form. In an inhomogeneous lattice the conformation change would

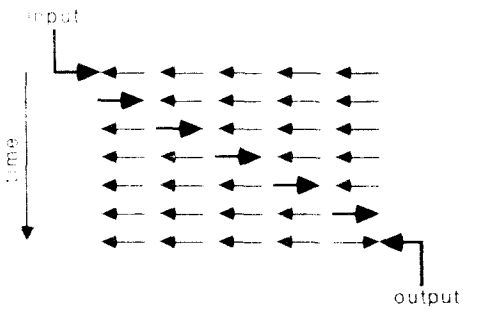


Fig. 2. Schematic representation of a conformational soliton propagating through a one-dimensional polymacromolecular lattice. The first frame (top line) represents the presence of an external input that triggers the initial switch in conformation. Each subsequent frame represents the migration of the switch to the next lattice position. The last frame (bottom line) represents the triggering of an output action.

itself change in character depending on the particularities of the neighboring molecules, but could do so without losing its informational integrity.

The above properties are incompatible from a classical point of view, but are generic to superposition–amplification models since in these the time development is generated by inherent instabilities. In a classical model purely thermal fluctuations could lead to switching between significantly different conformational states, but the potential barriers would have to be low and consequently the directional specificity with which the conformation changes ripple through the lattice could not be high. If the potential barriers were high enough to confer high selectivity on the propagation patterns, the rate of propagation would be low. In the absence of high specificity and high speed the spatial range over which it would be possible to maintain informational coherence would be compromised. But according to our superposition-amplification model the chance that a macromolecular aggregate exhibits these properties simultaneously becomes more rather than less likely as the architectural complexity of the aggregate increases, since the chance of satisfying self-consistency conditions decreases as the number of constraints that have to be satisfied increases.

5. CONCLUDING REMARKS

The new feature of our model is the manner in which the linear superposition principle is embedded in a nonlinear interaction. The nonlinear interaction between the electrons and nuclei constitutes a feedback loop, but one that cannot be treated in its entirety as if all elements are describable by classical variables. The rich structure of the quantum mechanical wave function is drawn into the loop and hence contributes to specificity and speed.

The nonlinearity is here built on top of linear quantum mechanics, not built into it in a fundamental way. It enters in the same way as it would if Newton's equations were used—by focusing attention on major components of a system and ignoring details of the heat bath. Our analysis begins with the standard Schrödinger equation. In complete microscopic detail the admissable solutions would be confined to unitary transformations (translations and rotations in Hilbert space, no stretching or folding). The time dependence of the potentials in our model and the treatment of the nuclear configuration in classical terms rests on the departure from a completely detailed description. The time development of the system of interest—the interacting molecules *sans* heat bath—is no longer confined to unitary transformations. Exotic dynamic phenomena can occur that would appear to be excluded by the Schrödinger equation.

Sensitive dependence on initial conditions suggestive of chaos is an example. Divergence of trajectories (stretching) can be physically interpreted in terms of the spreading out of the electronic wave function. The consequent interference induces an irregular motion of the nuclei. This is the phase of the electronic–conformational interaction in which the electrons lead. Confinement of trajectories to some domain (folding) can be interpreted in terms of the adjustment of the electronic levels to changes in the nuclear configuration. This is the phase of the interaction in which the electrons follow. If the number of nonnegligible eigenfunctions is very small the electronic structure will approximate time independence; if it is very large an ergodic, statistically regular regime will be approached. Between these extremes the nuclei should undergo a series of configurational changes that are highly irregular and initial condition sensitive. If folding (confinement) dominates the series will belong to a single conformation. This is the negative feedback situation. If stretching (divergence) dominates jumping to a new conformation (basin of attraction) will occur. This is the positive feedback situation.

The model makes a number of experimental predictions of a general nature. Sustained low frequency radiation should affect the rate of complex formation by inducing closely spaced transitions among possible electronic states. It should be possible to introduce color groups into proteins in such a way that folding and complex formation are disrupted in the presence of visible light, but not in the dark. It should be possible to alter the rate of complex formation by replacing hydrogen atoms by deuterium or tritium; the effect would be pronounced for those hydrogen bonds that provide preferred pathways for electron tunneling. If confinement of parallel spin electrons can augment superpositional speedup by inducing transient delocalization this should be detectable as a short-lived alteration of a spin resonance signal prior to a shift in conformation.

AN IMPROVED NANOSCALE TRANSMISSION LINE MODEL OF MICROTUBULE: THE EFFECT OF NONLINEARITY ON THE PROPAGATION OF ELECTRICAL SIGNALS

Dalibor L. Sekulić, Miljko V. Satarić

University of Novi Sad, Faculty of Technical Sciences, Novi Sad, Serbia

Abstract. *In what manner the microtubules, cytoskeletal nanotubes, handle and process electrical signals is still uncompleted puzzle. These bio–macromolecules have highly charged surfaces that enable them to conduct electric signals. In the context of electrodynamic properties of microtubule, the paper proposes an improved electrical model for divalent ions (Ca^{2+} and Mg^{2+}) based on the cylindrical structure of microtubule with nano–pores in its wall. Relying on our earlier ideas, we represent this protein–based nanotube with the surrounding ions as biomolecular nonlinear transmission line with corresponding nanoscale electric elements in it. One of the key aspects is the nonlinearity of associated capacitance due to the effect of shrinking/stretching and oscillation of C–terminal tails. Accordingly, a characteristic voltage equation of electrical model of microtubule and influence of capacitance nonlinearity on the propagation of electrical pulses are numerically analyzed here.*

1. INTRODUCTION

Biological systems at the nanoscale are rich in electrical activity. Besides the well–known pathways of biochemical regulation, there exist additional pathways of biological communication governed by electrical signals [1]. Recently, *in silico* demonstration has shown that the microtubules (MTs), essential cellular biopolymers, are the source of electromagnetic fields in the form of the electric pulses, playing an important role in the intracellular signaling and information processing [2]. MTs are self–assembling protein mesostructures made up of electrically polar tubulin heterodimer subunits, α– and β–tubulin monomers. Each dimer, 8 nm in length, possesses two highly flexible C–terminal tail regions, by one of each monomer, which can extend up to 4.5 nm from the surface, see Fig. 1a. *In vivo* MT is generally made up of 13 parallel, loosely connected chains, or

protofilaments, formed by polymerization of the tubulin heterodimer molecules so as to result in a helical structure. Cryo–electron microscopic analyses indicate that the single MT resembles a hollow tube with its external and internal diameters of 25 nm and 15nm, respectively, see Fig. 1b, while its length typically varies in the range of few tens of nanometers to several micrometers. Due to the shape and spacing of the tubulin heterodimers, the MT possesses small, nanometer size pores between the outer environment and the inner MT's lumen. Two different types of these nano–pores exist within MT's wall.

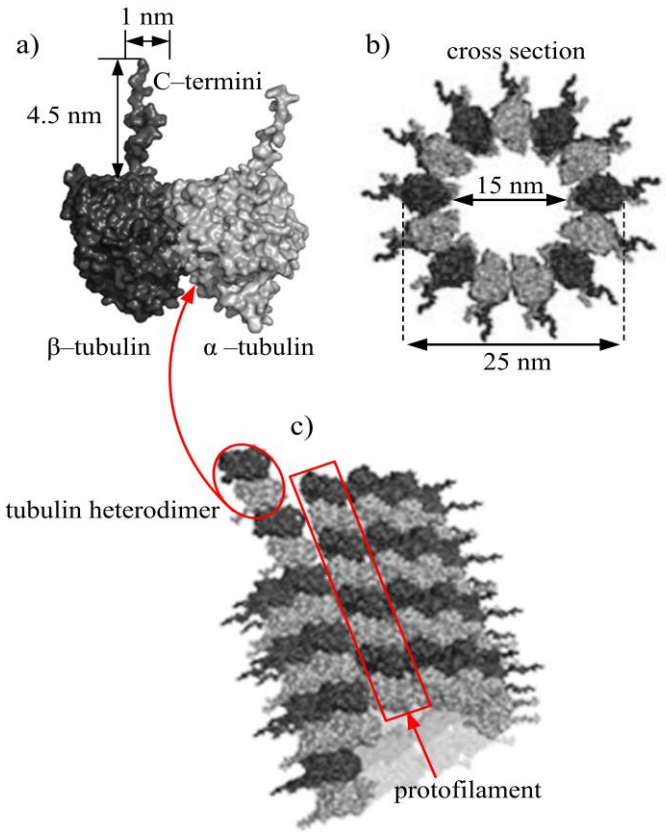

Fig. 1 a) The topology of tubulin heterodimer with dimensions of the C– terminal tail regions b) Cross–sectional view of microtubule c) Microtubule tube–like structure with marked protofilament

MT functionalization plays a critical role in making the jump from *in vivo* intracellular transport to *in vitro* nanoscale device applications [3]. The potential of this protein structure for application in novel bio–inspired nanoelectronic components was recently demonstrated [4]. In addition, the process of formation of MTs by polymerization of αβ–tubulin heterodimers, which can be controlled by physical (temperature) and chemical (pH, concentration of protein and ions), can result to the production of closely or widely spaced MTs, centers, sheets, rings and other structures [5], thus facilitating fabrication of

nanowires, nodes and networks in the future for bionanotechnological applications. Interestingly, MTs are self–assembling protein–based nanotubes with mechanical behavior similar to carbon nanotubes despite their very different chemical composition: proteins and non–covalent interactions in the case of MTs; carbon and covalent bonds in the case of carbon nanotubes [6].

In view of the key role of MTs in intracellular electrodynamic signaling and information processing, the objective of this study is to provide a framework for the analysis of propagation of electric pulses along this biological transmission line. More specifically, for this purpose we improve our previous electrical model [7] based on polyelectrolyte concept applied to the molecular structure and geometry of these nanotubes. The initial motivation for the model of MT as electrical transmission line was the experimental evidence [8], which revealed that these biopolymers are good conductors of electrical signals at nano–level. Here, we will focus on the specific importance of this mechanism for intracellular transportation of divalent ions, in the first place Ca^{2+} and Mg^{2+} as the most important ions in human body. The particular attention will be paid to the role of nonlinearity parameter that arises from structure and dynamics of C– terminal tails.

2. Electrodynamic Properties and Characterization of MT

The conductance of MTs is the result of their electrostatic and structural properties. On the basis of detailed molecular dynamics computations, it was recently demonstrated that the outer surface of tubulin heterodimer is mostly electrostatically negative charged, whereby a specifically large negative charge is located on the C–terminal tail regions [9]. As a result, overall surface of MT is predominantly negative charged, as one can see from Fig. 2, while the ends of this nanotube possess a different amount of net charge. Accordingly, it can be readily concluded that the MT supports an intrinsic electric field [5]. The average linear charge density of single MT is estimated to be 52.2 electronic charges (e) per dimer or approximately 85 e/nm [10]. Also, recent experimental observation was showed that the MT conductivity in a solution is on the order of 10 nS [8], indicating a high level of ionic conductivity along this biopolymer.

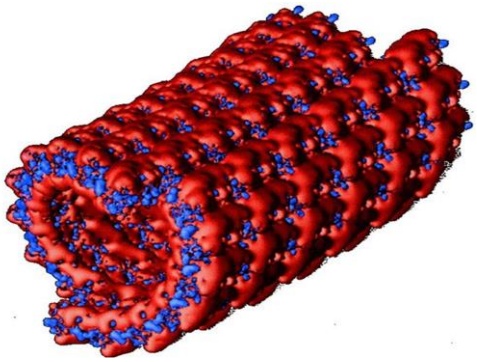

Fig. 2 Charge distribution on the surface of microtubule (color red indicates negative charges, blue positive charges and white neutral regions) [9]

In the context of the above–mentioned findings, it is possible to consider MT like one–dimensional polymer that behaves as highly charged polyelectrolyte [7, 10]. In a solution, positive ions are attracted to the negative charged surface of the MT, while negative ions are repelled, creating a positive condensed ionic cloud (CIC) localized around the MT's landscape. In the presence of an applied voltage, the loosely held CIC is free to migrate along MT, creating an ionic flow and an associated electrical current [11]. In accordance with Manning's condensation theory of polyelectrolytes [12], negative ions in solution are repelled at the distance called the Bjerrum length (l_B), which is defined by the balance between electrostatic attraction energy of the ions and the pertaining thermal energy:

$$l_B = \frac{ze^2}{4\pi\,\varepsilon_r\varepsilon_0 k_B T}. \tag{1}$$

The particular emphasis is paid on the divalent ions (z = 2) such as Ca^{2+} and Mg^{2+}, which are primary attracted by the MT's surface. Their flows around MTs play fundamental roles in auditory processes as well as in the cardiac muscles action. For these important ions in human body, the width of such "depleted layer" sandwiched between two charged regions is l_B = 1.34 nm at physiological temperature T = 310 K. Other parameters used in the estimation of Bjerrum length are the elementary electric charge e = 1.6×10^{-19} C, the dielectric constant of cytosol ε_r = 80, the permittivity of vacuum ε_0 = 8.85×10^{-12} F/m and Boltzmann's constant k_B = 1.38×10^{-23} J/K.

Based on Manning's approach, the thickness of CIC λ around the rod–like filamentous polyon of radius r is given by the following expression:

$$\lambda = \mathcal{A}\left(rl_{Db}\right)^{1/2};\quad \mathcal{A}<1,\ \ l_{Db}^{-1} = \left(8\pi\, nl_B\right)^{1/2}. \tag{2}$$

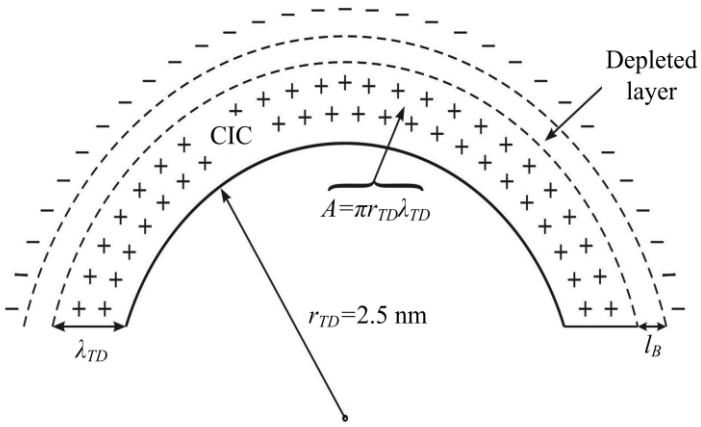

Fig. 3 Schematic illustration of a tubulin dimer with its condensed ionic cloud (CIC), depleted layer and the geometry of "coaxial cable" with the dimensions. *A* is the cross section area of a CIC around tubulin dimer.

Using the above equation, the corresponding values for tubulin heterodimer (TD) and C– terminal tails (CT) are λ_{TD} = 2.96 nm and λ_{CT} = 0.92 nm, respectively, for equilibrium ionic concentration $n = 1.5\times10^{23}$ m^{-3} and parameter $\mathcal{A}$ = 0.5. The estimated depleted layer between CIC and repelled negative ions (anions) plays the role of a dielectric medium between charged plates in "coaxial cable", see Fig. 3. It provides resistive and capacitive components for the behavior of the tubulin heterodimer that make up the MT.

2.1. Electrical parameters of the MT model

Bearing in mind the CIC around the MT's cylinder, this protein–based nanotube may act as biological "electrical wire" which can be modeled as nonlinear transmission line [7, 11]. In this section, we describe the nature and estimate the value of electrical components at nanoscale that make up transmission line model that mimics the behavior of MT in solution. Due to symmetry of this biopolymer, it is plausible to consider just one of thirteen MT's protofilaments and to introduce the so called elementary electric unit, which is a single tubulin dimer with its two C–terminal tails and two different types of nano–pores in MT's wall.

In order to estimate the total static capacitance of elementary electric unit for the case of divalent ions, we firstly consider the contribution of a tubulin heterodimer as half–cylindrical capacitor which has the value

$$C_{TD} = \frac{\pi\varepsilon_r\varepsilon_0 l}{\ln\left(1+\frac{l_B}{R}\right)} = 0.75\times10^{-16}\ \text{F}. \tag{3}$$

Here l = 8 nm is the length of tubulin dimer, and the parameter $R = r_{TD} + \lambda_{TD}$ = 5.46 nm represents the outer radius of respective CIC, see Fig. 3, while the other parameters are already mentioned and used. In a similar way, viewing an extended C–terminal tail as a smaller cylinder with $r = r_{CT} + \lambda_{CT}$ = 1.42 nm, one obtains its capacitance as follows

$$C_{CT} = \frac{2\pi\varepsilon_r\varepsilon_0 l^{\text{eff}}}{\ln\left(1+\frac{l_B}{r}\right)} = 0.14\times10^{-16}\ \text{F}, \tag{4}$$

where $l^{\text{eff}} = l_{CT} - \lambda_{TD}$ = 1.54 nm is the corresponding effective length of the part of C–terminal not plunged in λ_{TD}. Since each tubulin heterodimer has two C–terminal tails, and keeping in mind that the capacitances of tubulin dimer and C–terminal tails are in parallel arrangement [13], it implies that total maximal static capacitance of the elementary electric unit is readily estimated as the simple sum of above determined components:

$$C_0 = C_{TD} + 2\times C_{CT} = 1.03\times10^{-16}\ \text{F}. \tag{5}$$

It is evident that the capacitance in our model represents the charge distribution in the region from CIC to approximately one l_B away perpendicularly to the surface of the MT. Since the ions in this layer are assumed to be condensed, the charge of this capacitor will vary in a nonlinear way with voltage as follows:

$$Q_n = C_0[1-\Gamma\Omega(t-t_0)-bv_n]v_n \ . \tag{6}$$

The non–stationary term $\Gamma\Omega(t–t_0)$ reflects the fact that the presence of extra ions injected within the ionic cloud affects the local concentration during the time compared with the characteristic charging time of localized C–terminal's capacitor. The nonlinear parameter b represents the change of capacitance of elementary electric unit with an increasing concentration of condensed cations due to the flexibility of the C–terminal tails (their shrinking/stretching). This expression (6) was derived and explained in detail in the previous version of electrical model of MT [7].

In order to estimate the conductance of nano–pores, we rely on the detailed atomic–scale *in silico* calculations using 3D Brownian dynamics [14]. In accordance with these numerical results, the conductance of both nano–pores is estimated to be G = 10.7 nS, which is determined as a sum of pretty different components reflecting difference in two types of nano–pores [7, 13]. Using the same numerical calculation, the resistance of the parallel flow of ions along elementary electric unit is $R = 6.2\times10^7$ Ω, neglecting the ionic current which leaks through the depleted layer. Finally, in the earlier simplified version of the electrical model of MT [11], we found that corresponding inductance of elementary electric unit is small enough that its role can be safely ignored in this improved model.

3. ELECTRICAL MODEL OF MT AS BIOMOLECULAR NONLINEAR TRANSMISSION LINE

On the basis of above estimations for the components of elementary electric unit of the MT, we are now in the position to establish the corresponding electrical model. Electric circuit that simulates single MT's protofilament is presented in Fig. 4.

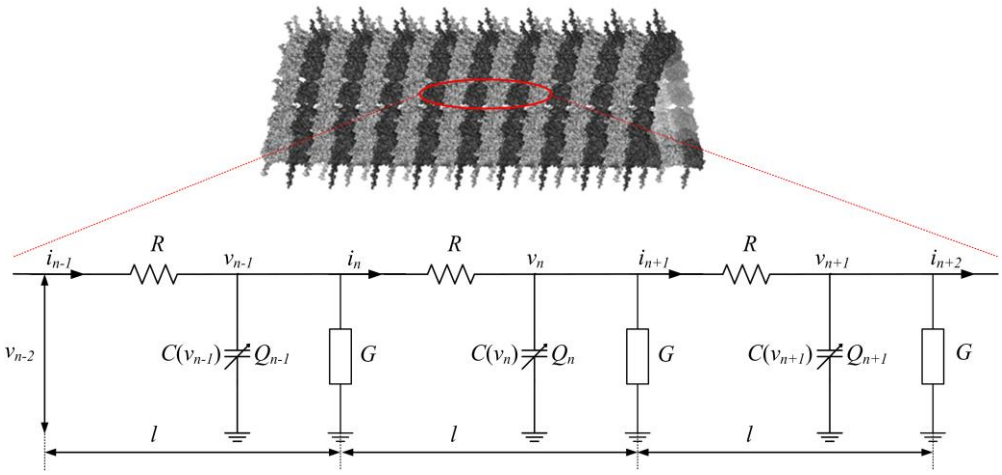

Fig. 4 A scheme describing the corresponding electrical model of MT

In order to derive the characteristic voltage equation of model, we begin by introducing the discrete potential in one section of the MT where Kirchhoff's laws for the currents and voltages read as follows

$$i_n - i_{n+1} = \frac{\partial Q_n}{\partial t} + G v_n , \qquad v_{n-1} - v_n = R i_n . \tag{7}$$

We then introduce new function $u_n(x, t)$ unifying voltage and its accompanying current along a MT as follows

$$u_n(x,t) = Z^{1/2} i_n = Z^{-1/2} v_n, \tag{8}$$

where Z is characteristic impedance of the elementary electric unit corresponding to characteristic frequency $\omega = 2\pi/(RC_0)$

$$Z = R + \left(\frac{G^{-1}}{C_0^2 \omega^2 G^{-2} + 1} \right) \left(1 + \frac{C_0^2 \omega^2}{G^2} \right)^{1/2} . \tag{9}$$

This expression for Z is much more accurate compared to the previous that was used in [7]. Assuming that a large number of tubulin heterodimer along the protofilament of MT, the next step is to go over to the continuum approximation with respect to space variable x and as a result we get the following voltage equation of established model of MT

$$\frac{\partial^3 u}{\partial \xi^3} + 3\left(\frac{ZC_0 s}{T} - 2 \right) \frac{\partial u}{\partial \tau} + 3ZC_0 \Gamma\Omega \left(\xi - \xi_0 \right) \frac{\partial u}{\partial \xi} + 6 \frac{Z^{3/2} b C_0 s}{T} \left(u \frac{\partial u}{\partial \xi} \right) + 3(ZG + Z^{-1} R - ZC_0 \Gamma\Omega) u = 0. \tag{10}$$

Here, the first term is dispersive one arising from diffusive spreading of ions within the pulse. The second one with negative sign ($ZC_0 s < 2$) resembles the corresponding time dependent term in Fick's diffusion law. Third term reflects the non–stationary change of capacity due to the ratchet mechanism. Fourth term represents nonlinearity that competes with dispersion. The key point here is that the last term accounts the competition between energy expenditure due to ohmic losses and energy supply by non–local ratchet mechanism. This term can be discarded as being very small due to the balance of above competition. In characteristic voltage equation (10), the characteristic charging (discharging) time of the elementary capacitor through the elementary resistance is given by $T = RC_0$, while the dimensionless variables of space ξ, time τ and velocity s are defined as follows:

$$\xi = \frac{x}{l} - \tau , \quad \tau = s \frac{t}{T} , \quad s = \frac{\mathrm{v}}{\mathrm{v}_0} , \quad \mathrm{v}_0 = \frac{l}{T} , \tag{11}$$

where parameter $\mathrm{v}_0 = l/T$ represents the characteristic cut–off velocity, and l is the length of one tubulin heterodimer.

3.1. Numerical analysis of the voltage equation

Since one of the key aspects of electrical model of MT as transmission line is the nonlinearity of capacitance of elementary electric unit, the characteristic voltage equation and effect of capacitance nonlinearity on the propagation of ionic pulses along MT are numerically analyzed. Numerical simulations are based on a finite–difference time–domain method applied to the differential equation (10) governing the voltages of proposed nonlinear circuit [15]. A circuit simulator is implemented in *Matlab* software package.

In Fig. 6 is shown the numerical results of voltage equation $u(\xi, \tau)$ for estimated values of electric components of the established model and different values of capacitance nonlinearity.

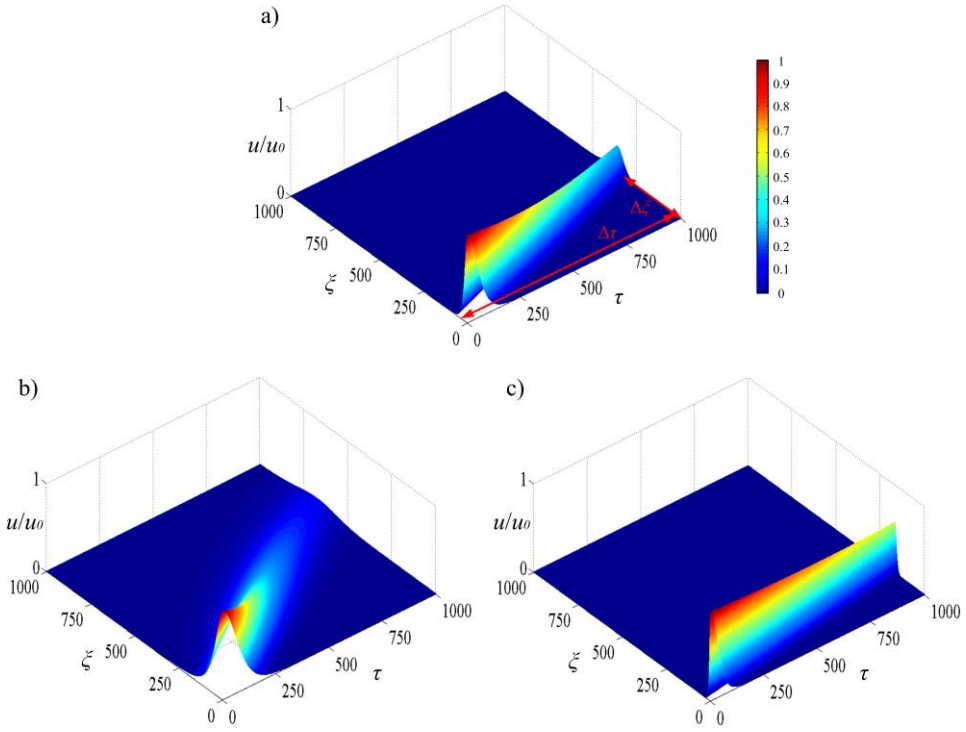

Fig. 5 Numerical solution of the voltage equation $u(\xi, \tau)$ for the set of estimated electric components of the established model and a) capacitance nonlinearity of 0.05 V^{-1}, b) lower value of capacitance nonlinearity of 0.01 V^{-1} and c) higher value of capacitance nonlinearity of 0.1 V^{-1}

For reasonable value of the nonlinearity parameter of 0.05 V^{-1}, the pulse appears in the form of soliton–like wave exhibiting the slowly decaying amplitude and an almost constant velocity of propagation. This wave possesses the energy losses due to ohmic resistance, but it preserves the stable localized form. Using the values of time and space units, the average velocity of localized voltage pulse can be estimated from the obtained graphic shown in Fig. 5a as follows:

$$\langle \mathrm{v} \rangle = \frac{\Delta\xi}{\Delta\tau} = \frac{280l}{1000T_{\mathrm{CT}}} \cong 3\frac{\mathrm{cm}}{\mathrm{s}}, \tag{12}$$

where l is length of elementary electric unit that is one tubulin heterodimer. The parameter T_{CT} represents a swing period of C–terminal tail which is given by the following expression [10]

$$T_{\mathrm{CT}} = 6\pi \frac{ZC_0}{ZG + Z^{-1}R} \cong 0.72 \times 10^{-7}\,\mathrm{s}. \tag{13}$$

The obtained propagation velocity of voltage pulse is the order of several cm/s that is close to experimental findings [8] and it depends on the electrical papameters of established circuit model of MT. It is also possible to estimate that the pulse width is of the order of 10 elementary units. This fact supports the validity of continuum approximation. The range of this soliton–like localized pulse is about $280 \times l \approx 2.24$ μm, which is of the order of cell's diameter.

In the case of lower value of nonlinearity parameter of 0.01 V^{-1} presented in Fig. 9b, the amplitude of pulse decreases significantly faster so that over about 350 elementary units it becomes negligible. The graphic shows the deceleration of the soliton–like pulse along its path. For higher value of capacitance nonlinearity of 0.1 V^{-1}, the voltage pulse exhibits not only a higher localization, but also a slower decay of its amplitude and greater robustness compared to the previous two cases. Also, Fig. 5c indicates that the propagation velocity is lower than the average velocity of 3 cm/s for the case of nonlinearity parameter of 0.05 V^{-1}. Overall, the performed numerical analysis of the voltage equation demonstrates that the role of capacitance nonlinearity is of decisive importance for the stability and localized character of Ca^{2+} and Mg^{2+} pulses along MTs.

4. Discussion and Conclusion

In this paper, we have developed an improved electrical model of MT that provides qualitative framework for the observations of propagation of Ca^{2+} and Mg^{2+} signals along this charged polar biopolymer. In summary, the geometric symmetry of MT provided the opportunity that one MT's protofilament can be approximately seen as a "coaxial cable" with the "charged plates" composed of counterions of solution with a depleted layer of water molecules in between. It enabled that the series of tubulin heterodimers with pertaining C– terminal tails could be observed as series of identical elementary electric units with estimated capacitance and resistance, including the conductance of two different types of nano–pores existing in MT's wall. The background for the proposed model is the molecular structure of MT and its polyelectrolyte properties.

Numerical analysis of characteristic voltage equation of model showed that the nonlinearity of capacitance, arising from structure and dynamics of C– terminal tails, is essential important parameter for the character propagation of Ca^{2+} and Mg^{2+} signals along MT. For reasonable value of the nonlinearity parameter of 0.05 V^{-1}, numerical results indicated stable and localized soliton–like pulses which propagate with a velocity value close to experimental findings and cross the distance of cell's size despite ohmic dissipation. Velocities of these pulses are of the order of several cm/s, depending on the amount of the injected ions and valence of the ions. Under physiological conditions, this effect is much faster than the process of propagation of the ions by pure diffusion (a few μm/s). Interestingly, if we compare the estimated velocity with the drift velocity of electrons in a typical semiconductor, we get the same order of magnitude at current density of order of A/mm^2. However, the velocity of establishing a local field around the protein biopolymers is much lower due to heaviness of the ions, which are much more massive than electrons.

Finally, we believe that our predictions may have important consequences for understanding of MT's ability to conduct electrical signals, which may affect the neuronal computational capabilities, among other known functions. Also, our findings could encourage experimentalists to conduct more subtle assays in an attempt to elucidate this important aspect of cellular activities. On the other hand, the much–needed experimental validation of presented results would undoubtedly lead to exciting new opportunities in the development of biological nanoscale electronic applications.

This paper is concerned with the nature of perturbation theory in very high order. Specifically, we study the Rayleigh-Schrödinger expansion of the energy eigenvalues of the anharmonic oscillator. We have developed two independent mathematical techniques (WKB analysis and difference-equation methods) for determining the large-n behavior of A_n^K, the nth Rayleigh-Schrödinger coefficient for the Kth energy level. We are not concerned here with placing bounds on the growth of A_n^K as n, the order of perturbation theory, gets large. Rather, we consider the more delicate problem of determining the precise asymptotic behavior of A_n^K as $n \to \infty$ for both the Wick-ordered and non-Wick-ordered oscillators. Our results are in exact agreement with numerical fits obtained from computer studies of the anharmonic oscillator to order 150 in perturbation theory.

I. INTRODUCTION

This paper reports an intensive study of the behavior of perturbation theory in very high order for the anharmonic oscillator.[1] We give a detailed treatment of the new mathematical techniques we have developed to obtain this behavior and we discuss the related physical ideas.

The quantum anharmonic oscillator is described by the time-independent Schrödinger equation

$$\left[\frac{d^2}{dx^2}+\frac{x^2}{4}+\frac{\lambda x^4}{4}-E(\lambda)\right]\psi(x)=0 \tag{1.1}$$

with the associated boundary condition

$$\lim_{|x|\to\infty}\psi(x)=0\,. \tag{1.2}$$

The boundary condition selects out a discrete set of energy eigenvalues $E^K(\lambda)$, $K=0,1,2,\ldots$, whose perturbation expansions take the form

$$E^K(\lambda)\sim K+\tfrac{1}{2}+\sum_{n=1}^{\infty}A_n^K\lambda^n\,. \tag{1.3}$$

We refer to Eq. (1.3) as the Rayleigh-Schrödinger series and A_n^K as a Rayleigh-Schrödinger coefficient. We investigate the behavior of A_n^K as n, the order of perturbation theory, becomes large.

The anharmonic oscillator is also expressible as a $(\lambda\phi^4)_1$ quantum field theory.[2] The Hamiltonian for the theory may be written as

$$H=\tfrac{1}{2}\dot{\phi}^2+\tfrac{1}{2}m^2\phi^2+\lambda\phi^4\,, \tag{1.4}$$

where

$$[\phi,\dot{\phi}]=i\,. \tag{1.5}$$

The energy levels $E^K(\lambda)$ are the eigenvalues of H:

$$H|K\rangle=E^K(\lambda)|K\rangle\,. \tag{1.6}$$

For all m, the field-theoretic perturbation series takes the form

$$E^K(\lambda)\sim m\left(K+\tfrac{1}{2}+\sum_{n=1}^{\infty}A_n^K(\lambda m^{-3})^n\right). \tag{1.7}$$

One can recover Eq. (1.3) by setting $m=1$ in Eq. (1.7).

Viewing the anharmonic oscillator as a quantum field theory, we can express A_n^K in terms of Feynman diagrams.[3] A_n^0 is the sum of all connected diagrams having n vertices and no external legs. A_n^K is the K-particle pole of the $2K$-point Green's function. Thus, the problem of determining the large-n behavior of A_n^K corresponds to studying diagrams with many vertices. There has already been an intensive study of the properties of many-vertex diagrams in higher-dimensional quantum field theory[4] as well as in the anharmonic oscillator.[5] However, these studies give only bounds on the growth of the Rayleigh-Schrödinger coefficients and do not reveal much about the mathematical and physical nature of these theories. In this paper we completely by-pass the problem of obtaining bounds. Instead, we solve here the much more formidable problem of determining the precise asymptotic behavior of A_n^K for large n.

This paper will conform to the following outline: In Sec. II we use dispersion techniques to derive an exact relation between the nth Rayleigh-Schrödinger coefficient and the lifetimes of the unstable states of a negatively coupled anharmonic oscilla-

tor ($\lambda = -\epsilon$, $\epsilon > 0$). Section III contains a WKB derivation of approximate lifetimes for small ϵ. In Sec. IV we combine the results of Secs. II and III to find the leading behavior of A_n^K for large n. In Sec. V we discuss the relation between the WKB analysis of Sec. III and other WKB results we obtained in a previous paper. Then we compute the corrections (of order n^{-1}) to the leading behavior of A_n^K given in Sec. IV. A completely independent derivation of the results of Sec. IV for the two lowest energy levels is given in Sec. VI. This derivation uses difference-equation and generating-function methods. Finally, in Sec. VII we define and discuss the large-order perturbation behavior of the Wick-ordered version of the Hamiltonian in Eq. (1.4). The Appendix gives a short and physically intuitive derivation of the material in Sec. III.

The results of this paper may be summarized in two equations. For large n,

$$A_n^K = \frac{(-1)^{n+1}12^K\sqrt{6}}{K!\pi^{3/2}}\,3^n\Gamma(n+K+\tfrac{1}{2}) \times\left[1-\frac{1}{n}\left(\frac{95}{72}+\frac{29K}{12}+\frac{17K^2}{12}\right)+O(n^{-2})\right] \tag{1.8}$$

and

$$\frac{A_n^K}{B_n^K} = e^{-3}\left(1+\frac{1+3K}{n}+\frac{\frac{71}{6}+31K+23K^2}{4n^2}+O(1/n^3)\right), \tag{1.9}$$

where B_n^K is a Rayleigh-Schrödinger coefficient for the Wick-ordered perturbation series. These results have been verified: On a computer we have carried out perturbation theory to order $n = 150$ (the limiting factor is the amount of available core memory), performed numerical fits,[6] and obtained spectacular agreement.

In this paper we have established an easily generalized mathematical framework for determining the large-order behavior of perturbation theory for more complicated models. Three such models have already been successfully investigated: The anharmonic oscillator with a λx^{2N} perturbation,[7] the anharmonic oscillator with an arbitrary polynomial interaction of the form[8]

$$\lambda(x^{2n}+ax^{2N-2}+bx^{2N-4}+cx^{2N-6}+\cdots),$$

and the N-mode problem (N-coupled anharmonic oscillators).[9] This last problem involves applying WKB methods to partial differential equations and is thus far more difficult and profound than the problem considered here. We hope to extend these methods to infinite-mode problems and thereby obtain results for higher-dimensional quantum field theories.

II. DISPERSION RELATION FOR $E^K(\lambda)$

In this section we use a once-subtracted dispersion integral to establish an exact relation between A_n^K, the nth Rayleigh-Schrödinger coefficient for the Kth energy level, and the lifetime of the Kth (unstable) state of a negatively-coupled anharmonic oscillator. This relation follows from three rigorous properties of $E^K(\lambda)$ in the cut λ plane (cut along the real λ axis from $-\infty$ to 0): (a) $|E(\lambda)| \sim |\lambda|^{1/3}$ as $|\lambda|\to\infty$; (b) $E(\lambda)$ is analytic; and (c) the series in Eq. (1.3) is asymptotic. Property (a) is a consequence of a simple scaling argument known as the Symanzik transformation applied to Eq. (1.1).[10] Property (b) is a profound result obtained by Loeffel and Martin.[11] Property (c) was established by Loeffel, Martin, Simon, and Wightman.[12]

Properties (b) and (c) were originally established heuristically by us.[13] They follow directly from a study of Eqs. (1.1) and (1.2) in the complex x plane. The boundary condition Eq. (1.2) holds in a pair of sectors of angular opening $\frac{1}{3}\pi$ centered about the real x axis. As λ rotates into the complex λ plane ($\arg\lambda$ increases from 0), the sectors rotate clockwise. (A full description of the rotating sectors is given in BW.) The distant turning points[2] at $x_1 \sim \pm i\lambda^{-1/2}$ rotate clockwise and faster than the sectors rotate. The turning points enter the sector when $\arg\lambda = \pi$ (λ is negative). When $\arg\lambda < \pi$ WKB methods[2] give the asymptotic series in Eq. (1.3). When $\arg\lambda > \pi$ the WKB results are completely different[2] and predict nonanalyticity (branch points at which level crossing occurs) of $E^K(\lambda)$ in the λ plane. Thus, at $\arg\lambda = \pi$ (and $-\pi$), the distant turning point which enters the sector marks the edge of the region in the λ plane where the series in Eq. (1.3) is asymptotic and where the nonanalyticity of $E(\lambda)$ appears. While not rigorous, these are strong arguments for the truth of properties (b) and (c).

We proceed to derive the dispersion relation. Properties (a), (b), and (c) motivate the definition

$$F^K(\lambda) \equiv [E^K(\lambda) - K - \tfrac{1}{2}]\lambda^{-1}. \tag{2.1}$$

In the cut λ plane, $F^K(\lambda)$ is analytic and

$$\lim_{|\lambda|\to 0} \lambda F(\lambda) = 0, \tag{2.2}$$

$$|F^K(\lambda)| \sim |\lambda|^{-2/3} \text{ as } |\lambda|\to\infty. \tag{2.3}$$

Equation (2.2) is a consequence of property (c).

Since $F^K(\lambda)$ is analytic in the cut λ plane, we use the Cauchy theorem to write

$$F^K(\lambda) = \frac{1}{2\pi i}\oint_C \frac{F^K(x)}{x-\lambda}\,dx. \tag{2.4}$$

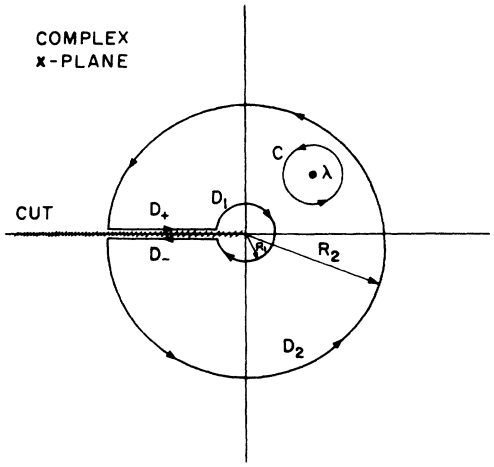

FIG. 1. Change of contour in the x plane used to derive the dispersion relation in Eq. (2.5).

The contour C may be shifted to the contour $D = D_+ + D_- + D_1 + D_2$ (see Fig. 1). Letting $R_1 \to 0$ and $R_2 \to \infty$, the contributions from the curves D_1 and D_2 vanish as a consequence of Eq. (2.2) and (2.3). Thus,

$$F^K(\lambda) = \frac{1}{2\pi i}\int_{-\infty}^{0} \frac{D^K(x)}{x-\lambda}dx\,, \tag{2.5}$$

where

$$D^K(x) \equiv \lim_{\epsilon\to 0}[F^K(x+i\epsilon) - F^K(x-i\epsilon)]\,. \tag{2.6}$$

Equation (2.5) is the once-subtracted dispersion relation we have sought.

Finally, we insert the identity

$$\frac{1}{x-\lambda} = \sum_{n=0}^{\infty}\frac{\lambda^n}{x^{n+1}}$$

into Eq. (2.5), compare the resulting series in powers of λ with that in Eq. (1.3), and obtain

$$A_n^K = \frac{1}{2\pi i}\int_{-\infty}^{0} D^K(x)x^{-n}\,dx\,. \tag{2.7}$$

Equation (2.7) is an exact and rigorous result.[14]

Physically, the relation in Eq. (2.7) may be understood by comparing two potentials with positive and negative anharmonic terms:

$$V_1(x) = \frac{x^2}{4} + \frac{\lambda x^4}{4}, \quad \lambda > 0$$

$$V_2(x) = \frac{x^2}{4} - \frac{\epsilon x^4}{4}, \quad \epsilon > 0\,.$$

These potentials are shown on Fig. 2. The first potential has bound states. The second potential has only unstable states (having complex energy). If ϵ is very small, the real part of the energy of an unstable state of V_2 is approximately equal to the energy of the corresponding bound state of V_1.

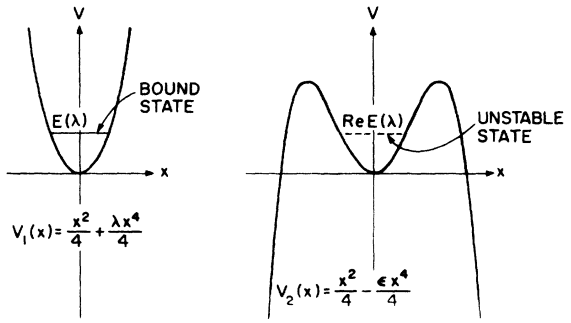

FIG. 2. Comparison of potentials having positive and negative anharmonic terms.

$\mathrm{Im}E(\epsilon)$ is very small and is related to the lifetime of the state which is very long. Equation (2.7) relates the Rayleigh-Schrödinger coefficients of the perturbation expansion of $E(\lambda)$ to the inverse moments of $\mathrm{Im}E(\epsilon)$.

Equation (2.7) is the basis for most of the approximations used in this paper. When n is very large, the contribution to the integral in Eq. (2.7) comes entirely from the region near $x = 0$. Thus, it is necessary to compute approximately $\mathrm{Im}E(\epsilon)$ for small ϵ. This will be done in the next section using WKB techniques.

III. WKB ZEROTH ORDER AT $\arg\lambda = \pi$

In the previous section it was shown that the large-order behavior of the perturbation series for $E^K(\lambda)$ depends on the imaginary part of the energy for negative coupling constant. In this section we use WKB techniques to calculate $\mathrm{Im}E^K(\epsilon)$ to lowest order in powers of ϵ, where

$$\epsilon = -\lambda > 0\,. \tag{3.1}$$

Until now, WKB approximations to $E(\lambda)$ have been given for every value of $\arg\lambda$ except for $\arg\lambda = \pi$.[2] Well-known technical problems, such as the phenomenon of subdominance, associated with transmission through a potential barrier,[15] make this calculation an order of magnitude more difficult than all previous ones. However, we will show how, with extreme care, one may avoid the ambiguities of this transmission problem.

$E^K(\epsilon)$ is defined by the differential equation

$$\left[-\frac{d^2}{dx^2} + \frac{x^2}{4} - \epsilon\frac{x^4}{4} - E^K(\epsilon)\right]\Phi(x) = 0\,. \tag{3.2}$$

Equation (3.2) describes a particle in a potential well in a slightly unstable state (very long half-life). As ϵ becomes smaller, the lifetime of the state increases because the particle must pass through a higher potential barrier to escape. Thus, $\mathrm{Im}E^K(\epsilon)$, which goes as the reciprocal of the life-

time, is extremely small.

The wave function $\Phi(x)$ satisfies two boundary conditions. At the origin,

$$\Phi(0)=0 \quad \text{for odd-parity states}, \tag{3.3a}$$

$$\Phi'(0)=0 \quad \text{for even-parity states}. \tag{3.3b}$$

At $x=+\infty$, the boundary conditions are somewhat complicated because at first glance they seem to be undefined. It would appear that any linear combination of outgoing waves and incoming waves, $\exp(\pm i\epsilon^{1/2}x^3/6)$, would suffice. However, we recall that the analytic continuation of the energy levels into the complex λ plane is accomplished by simultaneously rotating x into the complex x plane.[2] When $\arg\lambda=\pi$, the sector in which the boundary condition, $\lim_{|x|\to\infty}\psi(x)=0$, applies is given by $-\frac{1}{3}\pi<\arg(\pm x)<0$. Thus it is necessary to pick that asymptotic behavior which vanishes exponentially if the argument of x lies between 0° and −60°. Hence, $\Phi(x)$ must obey the boundary condition

$$\Phi(x)\sim\left(\frac{\text{const}}{x}\right)e^{-i\epsilon^{1/2}x^3/6} \quad \text{as} \quad x\to+\infty. \tag{3.4}$$

For small ϵ the real part of $E^K(\epsilon)$ is approximately $K+\frac{1}{2}$ while the imaginary part is very small. Thus, to prevent $\mathrm{Im}E^K(\epsilon)$ from being eclipsed, it is necessary to separate Eq. (3.2) into its real and imaginary parts. For this purpose we let

$$E^K(\epsilon)=E_1^K(\epsilon)+iE_2^K(\epsilon)$$
$$\sim K+\tfrac{1}{2}+iE_2^K(\epsilon), \tag{3.5a}$$

$$\Phi(x)=\Phi_1(x)+i\Phi_2(x). \tag{3.5b}$$

Furthermore, for sufficiently large x in the range $0<x<\epsilon^{-1/2}$, $\Phi(x)$ consists of an increasing and a decreasing part (see Fig. 3). We choose the phase of $\Phi(x)$, without loss of generality, such that the *decreasing part is purely real.* [We will see that the decreasing part behaves like $D_K(x)$ in regions A and B, below.] From these considerations we have

$$\left(-\frac{d^2}{dx^2}+\frac{x^2}{4}-\epsilon\frac{x^4}{4}-K-\frac{1}{2}\right)\Phi_1(x)=0 \tag{3.6a}$$

and

$$\left(\frac{d^2}{dx^2}+\frac{x^2}{4}-\epsilon\frac{x^4}{4}-K-\frac{1}{2}\right)\Phi_2(x)=E_2\Phi_1(x). \tag{3.6b}$$

In Eq. (3.6a) we have neglected $E_2\Phi_2$ compared with $E_1\Phi_1$ (see Fig. 3).

Our procedure will be to solve for Φ_1 approximately using Eq. (3.6a) and then to use this result to solve Eq. (3.6b) for Φ_2 and ultimately E_2. Our approximation scheme is based on dividing the x axis into four regions (see Fig. 3): region A, where $x\gtrsim(4K+2)^{1/2}=O(1)$; region B, where $x\gg(4K+2)^{1/2}$ but $x\ll\epsilon^{-1/2}$; region C, where $x\lesssim\epsilon^{-1/2}$; region D, where $x\sim\epsilon^{-1/2}$.

A. Φ_1 in Region A

In region A, we approximate Eq. (3.6a) by

$$\left(-\frac{d^2}{dx^2}+\frac{x^2}{4}-K-\frac{1}{2}\right)\Phi_{1A}=0, \tag{3.7}$$

to lowest order in ϵ. The solution to Eq. (3.7) which decreases for increasing x (see Fig. 3) is[16]

$$\Phi_{1A}=D_K(x), \tag{3.8}$$

where we have chosen the normalization of Φ_{1A} without loss of generality. Note that[16]

$$D_K(x)=2^{-K/2}e^{-x^2/4}H_K(x/\sqrt{2}) \tag{3.9}$$

satisfies Eq. (3.3). When x is large[16] (x approaches region B)

$$\Phi_{1A}\sim x^K e^{-x^2/4}. \tag{3.10}$$

B. Φ_2 in Region B

In regions B and C we approximate Φ_1 using lowest-order WKB:

$$\Phi_{1\,\mathrm{WKB}}=C_1(x^2-\epsilon x^4-4K-2)^{-1/4}$$
$$\times\exp\left(-\tfrac{1}{2}\int_{x_0}^{x}(t^2-\epsilon t^4-4K-2)^{1/2}\,dt\right), \tag{3.11}$$

where

$$x_0=(4K+2)^{1/2}. \tag{3.12}$$

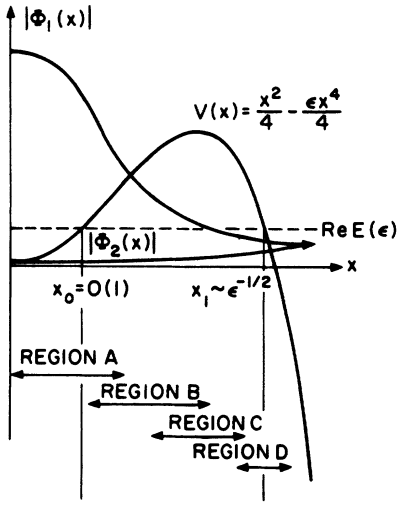

FIG. 3. Relative sizes of $|\Phi_1(x)|$ and $|\Phi_2(x)|$, which are exponentially decreasing and increasing functions of x. Regions A, B, C, and D and turning points at $x=x_0$ and $x=x_1$ are indicated.

In Eq. (3.11) we have only taken the *decreasing* exponential term (see Fig. 3). We will use the increasing exponential when we approximate Φ_2.

When x is near region B, we perform the integral in Eq. (3.11) approximately and get

$$\Phi_{1B} \sim C_1 e^{-x^2/4} x^K \exp\{\tfrac{1}{2}(K+\tfrac{1}{2})[1-\ln(K+\tfrac{1}{2})]\}. \tag{3.13}$$

Comparing Eqs. (3.10) and (3.13) gives

$$C_1 = \exp\{\tfrac{1}{2}(K+\tfrac{1}{2})[\ln(K+\tfrac{1}{2})-1]\}. \tag{3.14}$$

C. Φ_1 in Region C

When x is near the distant turning point at x_1,

$$x_1 \sim \frac{1}{\sqrt{\epsilon}}, \tag{3.15}$$

Equation (3.11) gives[17]

$$\Phi_{1C}(x) \sim (2x_1 - 2x)^{-1/4}\epsilon^{1/8} \times \exp[\tfrac{1}{3}\sqrt{2}\,\epsilon^{-1/4}(x_1-x)^{3/2} - 1/6\epsilon - (\tfrac{1}{2}K+\tfrac{1}{4})\ln(\tfrac{1}{4}\epsilon)], \tag{3.16}$$

where we have used Eq. (3.14).

D. Φ_1 and Φ_2 in Region D

In region D we substitute

$$r = (x_1 - x)(2\sqrt{\epsilon})^{-1/3}$$

into Eq. (3.2). Note that in region D we treat Φ_1 and Φ_2 at the same time – they are the same order of magnitude (see Fig. 3). In terms of r, Eq. (3.2) is approximately

$$\left(\frac{d^2}{dr^2} - r\right)\Phi_D(r) = 0, \tag{3.17}$$

which is the Airy equation.[18] Two linearly independent solutions to Eq. (3.17) are $\mathrm{Ai}(r)$ and $\mathrm{Bi}(r)$. Thus,

$$\Phi_D(x) = D_1\,\mathrm{Ai}(r) + D_2\,\mathrm{Bi}(r). \tag{3.18}$$

When we allow $x \to +\infty$, that is, $r \to -\infty$, we consult the formulas[19]

$$\mathrm{Ai}(-\rho) \sim \pi^{-1/2}\rho^{-1/4}\sin(\tfrac{2}{3}\rho^{3/2}+\tfrac{1}{4}\pi), \tag{3.19a}$$

$$\mathrm{Bi}(-\rho) \sim \pi^{-1/2}\rho^{-1/4}\cos(\tfrac{2}{3}\rho^{3/2}+\tfrac{1}{4}\pi), \tag{3.19b}$$

as $\rho \to +\infty$. However, Φ_D must have only decreasing phase as $x \to \infty$ [Eq. (3.4)]. From this requirement we obtain

$$D_1 = -iD_2 \equiv -iD. \tag{3.20}$$

Thus,

$$\Phi_D(x) = D[-i\,\mathrm{Ai}(r) + \mathrm{Bi}(r)]. \tag{3.21}$$

When $x \to 0$, $r \to +\infty$, and we consult the formulas[20]

$$\mathrm{Ai}(\rho) \sim \tfrac{1}{2}\pi^{-1/2}\rho^{-1/4}\exp(-\tfrac{2}{3}\rho^{3/2}), \tag{3.22a}$$

$$\mathrm{Bi}(\rho) \sim \pi^{-1/2}\rho^{-1/4}\exp(\tfrac{2}{3}\rho^{3/2}), \tag{3.22b}$$

as $\rho \to +\infty$. Recall that Φ_1, the real part of Φ, is decreasing as $x: 0 \to x_1$. We thus take D real and identify the decreasing and increasing solutions with the real and imaginary solutions:

$$\Phi_{1D}(x) = D\,\mathrm{Bi}(r), \tag{3.23a}$$

$$\Phi_{2D}(x) = D\,\mathrm{Ai}(r). \tag{3.23b}$$

Moreover, Eqs. (3.23a), (3.22b), and (3.16) enable us to match Φ_{1C} and Φ_{1D} asymptotically and thus to determine that

$$D = \epsilon^{1/12}\pi^{1/2}2^{-1/3}\exp[-1/6\epsilon - \tfrac{1}{2}(K+\tfrac{1}{2})\ln(\tfrac{1}{4}\epsilon)]. \tag{3.24}$$

Now that D is known, we easily calculate the asymptotic behavior of Φ_2 in region D for large r (that is, for $x < x_1$):

$$\Phi_{2D} \sim -\epsilon^{1/8}2^{-5/4}(x_1-x)^{-1/4} \times \exp[-\tfrac{1}{3}\sqrt{2}\,\epsilon^{-1/4}(x_1-x)^{3/2} - 1/6\epsilon - (\tfrac{1}{2}K+\tfrac{1}{4})\ln(\tfrac{1}{4}\epsilon)]. \tag{3.25}$$

E. Φ_2 in Region C

In regions B and C we neglect $E_2\Phi_1$ compared with $E_1\Phi_2$ in Eq. (3.6b). Thus, the WKB approximation to Φ_2 that applies in these regions is the same as that given for Φ_2 in Eq. (3.11). However, we choose a new constant C_2 and change the sign in the exponential because Φ_2 is an increasing function (see Fig. 3):

$$\Phi_{2\mathrm{WKB}} = C_2(x^2 - \epsilon x^4 - 4K - 2)^{-1/4}\exp\left(\tfrac{1}{2}\int_{x_0}^{x}(t^2 - \epsilon t^4 - 4K - 2)\,dt\right). \tag{3.26}$$

In region C, we approximate Eq. (3.26) by

$$\Phi_{2C} \sim C_2\epsilon^{1/8}(2x_1 - 2x)^{-1/4}\exp\{-\tfrac{1}{3}\sqrt{2}\,\epsilon^{-1/4}(x_1-x)^{3/2} + 1/6\epsilon - (\tfrac{1}{2}K+\tfrac{1}{4})[1 - \ln(\tfrac{1}{4}\epsilon) - \ln(K+\tfrac{1}{2})]\}. \tag{3.27}$$

Comparing this result with Eq. (3.25) gives

$$C_2 = -\tfrac{1}{2}e^{-1/3\epsilon}\exp\{-(K+\tfrac{1}{2})[\ln(\tfrac{1}{4}\epsilon) - \tfrac{1}{2} + \tfrac{1}{2}\ln(K+\tfrac{1}{2})]\}. \tag{3.28}$$

F. Φ_2 in Region B

Now that C_2 is known, we use Eq. (3.26) again to determine the asymptotic behavior of Φ_2 in region B. We find that

$$\Phi_{2B} \sim -\tfrac{1}{2} e^{-1/3\epsilon} e^{-(K+1/2)\ln(\epsilon/4)+x^2/4} x^{-K-1}. \quad (3.29)$$

G. Φ_2 in Region A

In region A, we must not neglect $E_2\Phi_1$ compared with $E_1\Phi_2$. However, we do neglect $\frac{1}{4}\epsilon x^4$ compared with $\frac{1}{4}x^2$. Thus, we must solve the differential equation

$$(-d^2/dx^2 + \tfrac{1}{4}x^2 - K - \tfrac{1}{2})\Phi_{2A}(x) = E_2\Phi_{1A}(x), \quad (3.30)$$

for the eigenvalue E_2. The boundary conditions on Φ_{2A} at $x=0$ are those given in Eq. (3.3). The large-x behavior of Φ_{2A} is given in Eq. (3.29).

To solve Eq. (3.30) we reduce it to a homogeneous equation as follows: Recall that E_2 is very small, and that Φ_{2A} is exponentially small compared to Φ_1 in region A. Then consider a perturbation expansion in powers of E_1 of the form

$$\Phi(x) = \Phi_{1A} + E_2\left(\frac{\Phi_{2A}}{E_2}\right) + \cdots. \quad (3.31)$$

$\phi(x)$ solves the equation

$$(-d^2/dx^2 - K - \tfrac{1}{2} - E_2 + \tfrac{1}{4}x^2)\phi(x) = 0. \quad (3.32)$$

To verify Eq. (3.32), observe that to lowest order in E_2, it reduces to Eq. (3.7); to next order in E_2 it is precisely Eq. (3.30).

The even- (and odd-) parity solutions of Eq. (3.32) [those obeying Eq. (3.3)] are[16]

$$\phi(x) = \tfrac{1}{2}[D_{K+E_2}(x) + (-1)^K D_{K+E_2}(-x)]. \quad (3.33)$$

The factor of $\frac{1}{2}$ comes from comparing Eq. (3.33) with the result for lowest order in E_2. That is, if we let $E_2=0$ in Eq. (3.33), the expression reduces to $\phi(x)|_{E_2=0} = \Phi_{1A}(x) = D_K(x)$, which agrees with Eq. (3.9).

To next order in E_2 we get

$$\frac{\Phi_{2A}}{E_2} = \frac{1}{2}\frac{\partial}{\partial E_2}[D_{K+E_2}(x) + (-1)^K D_{K+E_2}(-x)]\Big|_{E_2=0}. \quad (3.34)$$

E_2 will be determined by demanding that as $x \to \infty$, Eqs. (3.34) and (3.29) agree. The dominant large-x behavior of Φ_{2A}, which comes from the second term in Eq. (3.34), is[21]

$$\Phi_{2A}(x) = \left[\frac{E_2}{2}\frac{\partial}{\partial E_2}\ \frac{(2\pi)^{1/2}}{\Gamma(-K-E_2)} \times e^{(K+E_2)\pi i} x^{-(K+E_2+1)} e^{x^2/4}\right]\Big|_{E_2=0}. \quad (3.35)$$

Demanding that Eqs. (3.35) and (3.29) agree to lowest order in ϵ and E_2 gives the result

$$E_2 = \frac{4^{K+1/2}}{K!\sqrt{2\pi}} e^{-1/3\epsilon}\epsilon^{-K-1/2}. \quad (3.36)$$

Equation (3.36) is the result we have sought. Note that E_2 is exponentially small, which justifies *a posteriori* our neglecting of $E_2\Phi_1$ compared with $E_1\Phi_2$ in part E of this calculation. In the next section we use Eq. (3.36) and the dispersion integral of Sec. II to determine the large-order behavior of perturbation theory. In the appendix we give a very short and intuitive derivation of Eq. (3.36).

IV. LOWEST-ORDER WKB RESULTS

In this section we show how to use Eq. (3.36), the result of the lowest-order WKB calculation, to obtain the dominant large-n behavior of the Rayleigh-Schrödinger coefficients.

First, we compute $D^K(x)$ by combining Eqs. (2.1) and (2.6) with (3.6). We find that to lowest order in x (x is small and negative)

$$D^K(x) = -\frac{4^{K+1}i}{K!(2\pi)^{1/2}} e^{1/3x}(-x)^{-K-3/2}. \quad (4.1)$$

To compute the discontinuity D in Eq. (4.1), it is necessary to use a well-known property of $E^K(\lambda)$, namely,[2]

$$E^K(\lambda) = E^K{}^*(\lambda^*). \quad (4.2)$$

Next we substitute Eq. (4.1) into Eq. (2.7) and obtain for large n

$$A_n^K = \frac{-4^K\sqrt{2}}{K!\pi^{3/2}}\int_{-\infty}^{0} dx\, x^{-n} e^{1/3x}(-x)^{-K-3/2}. \quad (4.3)$$

Performing the integral in Eq. (4.3) exactly gives the leading large-n behavior of A_n (see Ref. 22):

$$A_n^K = \frac{(-1)^{n+1}12^K\sqrt{6}}{K!\pi^{3/2}} 3^n\,\Gamma(n+K+\tfrac{1}{2})[1+O(1/n)]. \quad (4.4)$$

We have indicated that the corrections to Eq. (4.4) are of order n^{-1}. This is verified in the next section, where we derive the next-higher-order WKB results. We emphasize here that *lowest-order WKB is sufficient to give the precise leading behavior of A_n^K for large n.* Successively higher-order WKB approximations to $\mathrm{Im}E^K(\lambda)$ do not change the results in Eq. (4.4); rather, they give the successive coefficients of inverse powers of n which multiply the leading behavior in Eq. (4.4). Equation (4.4) is the first term of a series in powers of n^{-1} (which may be asymptotic).

V. FIRST-ORDER WKB RESULTS

In this section we obtain the $O(n^{-1})$ corrections to Eq. (4.4). We could, of course, accomplish this task by carrying out the WKB calculations of Sec. III to order ϵ, plugging those results into Eq. (2.7), and evaluating the integral. Instead of presenting this extremely tedious and unenlightening calculation, we will rely on previous WKB calculations,[2] and, with a minimum of work, determine the $O(n^{-1})$ corrections. Our procedure will be to (A) compare the results of Sec. III with previous zeroth-order WKB calculations, and (B) use this comparison to find the first-order WKB result corresponding to Eq. (3.36).

A. Discussion of Zeroth-Order WKB

In Ref. 2 the approximate λ dependence of the energy levels $E^K(\lambda)$ was discovered through the use of WKB techniques. When $|\lambda|$ is small and $|\arg\lambda| < \pi$,

$$E^K(\lambda) = K + \tfrac{1}{2} + O(\lambda). \tag{5.1}$$

Thus, as $\arg\lambda$ increases from 0 to π, the energy eigenvalues stay very near the points $K+\frac{1}{2}$ on the positive real axis. As $\arg\lambda$ increases from π to $3\pi/2$, the eigenvalues move abruptly to the ImE axis. These trajectories in the complex E plane are governed by[2]

$$\frac{\Gamma(\frac{1}{4}+\frac{1}{2}E^K)}{\Gamma(\frac{1}{4}-\frac{1}{2}E^K)} = \exp\left(\frac{1}{3\lambda}+\frac{5\pi i}{4}-E^K\ln(\tfrac{1}{2}i\lambda)\right), \tag{5.2a}$$

for even-parity energy levels (K even), and

$$\frac{\Gamma(\frac{3}{4}+\frac{1}{2}E^K)}{\Gamma(\frac{3}{4}-\frac{1}{2}E^K)} = \exp\left(\frac{1}{3\lambda}-\frac{5\pi i}{4}-E^K\ln(\tfrac{1}{2}i\lambda)\right), \tag{5.2b}$$

for odd-parity energy levels.

As we emphasized in Sec. II, Eq. (5.1) is valid when $|\arg\lambda| < \pi$, and Eq. (5.2) is valid when $\pi < |\arg\lambda| \leq 2\pi$. When $|\arg\lambda| = \pi$, the point at which the distant turning point enters the sector in the complex x plane where the boundary condition $\lim_{|x|\to\infty}\psi(x) = 0$ holds, we have from Sec. III

$$\mathrm{Re}\,E^K(\lambda) = K + \tfrac{1}{2} + O(\lambda) \tag{5.3a}$$

and

$$\mathrm{Im}E^K(\lambda) = \pm\frac{4^{K+1/2}}{K!(2\pi)^{1/2}}\,e^{1/3\lambda}(-\lambda)^{-K-1/2}[1+O(\lambda)], \tag{5.3b}$$

where the $\pm$ corresponds to $\arg\lambda = \pm\pi$.

We raise the following question: What do we get from Eqs. (5.1) and (5.2) if they are assumed to be valid at $\arg\lambda = \pm\pi$? For this purpose, we must consider the real part and the imaginary part of $E^K(\lambda)$ separately because, as seen from Eq. (5.3), for $|\arg\lambda| = \pi$, the imaginary part is exponentially small compared with the real part. Consider the real part first. Equation (5.3a) agrees trivially with Eq. (5.1) for $|\arg\lambda| = \pi$. Furthermore, for $\arg\lambda = \pi$, the right-hand sides of Eqs. (5.2a) and (5.2b) are exponentially small and hence may be neglected. Accordingly, we get Eq. (5.3a) once again from Eqs. (5.2a) and (5.2b).

It is much more interesting to compare the imaginary parts. If Eq. (5.1) is assumed to hold for $|\arg\lambda| = \pi$, then, since the coefficient of every power of λ is real, we must conclude that

$$\mathrm{Im}E^K(\lambda) = 0. \tag{5.4}$$

More care must be taken with Eq. (5.2). Consider first the even-parity energy levels,

$$E^K = E^{2J} = 2J + \tfrac{1}{2} + iE_2, \tag{5.5}$$

where E_2 is assumed to be exponentially small (of order $e^{1/\lambda}$, for λ negative real). We approximate the left-hand side of Eq. (5.2a) as follows[23]:

$$\frac{\Gamma(\frac{1}{4}+\frac{1}{2}E^K)}{\Gamma(\frac{1}{4}-\frac{1}{2}E^K)} \sim \frac{\Gamma(J+\frac{1}{2})}{\Gamma(-J-iE_2/2)} \sim \frac{\Gamma(J+\frac{1}{2})\Gamma(J+1)\sin(\pi J+\pi iE_2/2)}{-\pi}$$

$$\sim i\sqrt{\pi}\,2^{-2J-1}E_2(-1)^{J+1}(2J)!\,. \tag{5.6}$$

The right-hand side of Eq. (5.2a) is approximately

$$e^{1/3\lambda}e^{5\pi i/4}(-\tfrac{1}{2}\lambda)^{-E^K}e^{-E^K\ln(-i)} \sim ie^{1/3\lambda}e^{5\pi i/4}(-\tfrac{1}{2}\lambda)^{-2J-1/2}e^{(2J+1/2)\ln i} \sim e^{1/3\lambda}(-1)^{J+1}(-\tfrac{1}{2}\lambda)^{-2J-1/2}, \tag{5.7}$$

where we have chosen that branch of the ln function for which $\ln i = \frac{1}{2}i\pi$. Combining Eqs. (5.6) and (5.7) gives

$$E_2 \sim \frac{\sqrt{2}\,4^{2J+1/2}}{\sqrt{\pi}\,(2J)!}\,e^{1/3\lambda}(-\lambda)^{-2J-1/2}. \tag{5.8}$$

By an analogous procedure, we have

$$E_2 \sim \frac{\sqrt{2}\,4^{2J+3/2}}{\sqrt{\pi}\,(2J+1)!}\,e^{1/3\lambda}(-\lambda)^{-2J-3/2}, \tag{5.9}$$

for odd-parity energy levels of the form

$$E^K = E^{2J+1} = 2J + \tfrac{3}{2} + iE_2.$$

Equations (5.8) and (5.9) verify the assumption that E_2 is exponentially small.

Finally we combine Eqs. (5.8) and (5.9) into one:

$$\mathrm{Im}E^K(\lambda)\sim\frac{\sqrt{2}\,4^{K+1/2}}{\sqrt{\pi}\,K!}\,e^{1/3\lambda}(-\lambda)^{-K-1/2}. \tag{5.10}$$

Again we observe a disagreement with Eq. (5.3b) – the imaginary part of the energy in Eq. (5.10) is too large by a factor of 2. Specifically, this factor arises from the equations for the asymptotic behavior of the Airy functions [see Eqs. (3.19) and (3.22)]. However, factors of 2 appear quite generally in Stokes' related discontinuous phenomena. In our case the discontinuity occurs when the distant turning point crosses a Stokes line of the asymptotic expansion of $\psi(x)$ for large x. The Stokes line is the edge of the sector in which $\psi(x)\to 0$ for large x.

A simple example illustrating this discontinuous phenomenon is a contour integral in the complex plane where the contour is shifted so that it passes through a simple pole. When the pole lies on the contour there is a discontinuity in the value of the integral which may be obtained by the principal-parts method. If we average the integrals for the pole lying inside and outside the contour, we obtain the principal-parts result.

Keeping these comments in mind, we are now not surprised to observe that Eq. (5.3b) is precisely the average of Eqs. (5.4) and (5.10). This averaging phenomenon is quite general. We will use it in Sec. V B to determine $E^K(\lambda)$, $\lambda<0$, to first order in λ by averaging the first-order versions of Eqs. (5.4) and (5.10).

Finally, we point out one further way of understanding this averaging. With reference to Sec. II, suppose we take the cut not along the $\arg\lambda=180°$ direction, but at $\arg\lambda=179°$. Then the discontinuity is given by

$$E^K(\arg\lambda=179°)-E^K(\arg\lambda=-181°).$$

The first term can be computed from Eq. (5.1) and the second from Eq. (5.2). Some contributions such as $K+\frac{1}{2}$ cancel and we get the sum of Eqs. (5.4) and (5.10) after analytically continuing the discontinuity to 180°.

B. First-Order WKB Results

The first-order analog of Eq. (5.1) is

$$E^K(\lambda)=K+\tfrac{1}{2}+\tfrac{3}{4}(2K^2+2K+1)\lambda+O(\lambda^2). \tag{5.11}$$

Equation (5.11) follows from a straightforward application of Rayleigh-Schrödinger perturbation theory to Eqs. (1.1) and (1.2). The first-order analog of Eq. (5.2a) is[24]

$$\frac{\Gamma(\frac{1}{2}+\frac{1}{2}\nu)}{\Gamma(-\frac{1}{2}\nu)}=\exp\left(\frac{1}{3\lambda}+\frac{5\pi i}{4}-(\nu+\tfrac{1}{2})\ln(\tfrac{1}{2}i\lambda)+\lambda A+\lambda BE^2\right), \tag{5.12}$$

where

$$\nu\equiv E-\tfrac{1}{2}-3\lambda(E^2+\tfrac{1}{4})/2. \tag{5.13}$$

The values of A and B in Ref. 2 are incorrect. Their correct values are

$$A=\tfrac{67}{48},\quad B=\tfrac{17}{4}. \tag{5.14}$$

Equations (5.13) and (5.1) imply that for the Jth even-parity energy level,

$$\nu=2J+\eta, \tag{5.15}$$

where η is at most of order λ. We insert this result into Eq. (5.12) and find that (as in Sec. V A) the left-hand side reduces to η times a constant while the right-hand side is of order $e^{1/3\lambda}$. Thus, for negative real λ, η *is smaller than any power of* λ. Noting this result, we return to Eq. (5.13) and iterate it once to get an approximate expression for $E^K(\lambda)=E^{2J}(\lambda)$:

$$E^{2J}=2J+\tfrac{1}{2}+\tfrac{3}{4}\lambda(8J^2+4J+1)+\eta[1+\tfrac{3}{2}\lambda(1+4J)]. \tag{5.16}$$

Equation (5.16), the first-order version of Eq. (5.4), contains λ twice. Apparently, the real and the imaginary parts of E (η is imaginary, as will be seen shortly) express their higher-order corrections in separate and independent power series in λ.

Next, we use Eqs. (5.12), (5.15), and (5.16) to evaluate η. The left-hand side of Eq. (5.12) reduces to

$$\sqrt{\pi}\,2^{-2J-1}(-1)^{J+1}(2J)!\,\eta, \tag{5.17}$$

following the procedure of Eq. (5.5). The right-hand side of Eq. (5.12) is approximated by

$$e^{1/3\lambda}e^{5\pi i/4}[1+\lambda(A+BE^2)]\,e^{-(2J+1/2)\ln(i\lambda/2)}\sim e^{1/3\lambda}i[1+\lambda(A+BE^2)](-\tfrac{1}{2}\lambda)^{-2J-1/2}(-1)^{J+1}. \tag{5.18}$$

Combining Eqs. (5.17) and (5.18) gives

$$\eta=\frac{i\sqrt{2}\,4^{2J+1/2}}{\sqrt{\pi}\,(2J)!}\,e^{1/3\lambda}(-\lambda)^{-2J-1/2}[1+\lambda(A+BE^2)]. \tag{5.19}$$

Next, we combine Eq. (5.19) with (5.16):

$$E^{2J} = 2J + \tfrac{1}{2} + \tfrac{3}{4}\lambda(8J^2 + 4J + 1) + \frac{i\sqrt{2}\,4^{2J+1/2}}{\sqrt{\pi}\,(2J)!}\, e^{1/3\lambda}(-\lambda)^{-2J-1/2}\{1 + \lambda[\tfrac{3}{2} + 6J + A + B(2J + \tfrac{1}{2})^2]\}. \tag{5.20}$$

Finally, we replace $2J$ in Eq. (5.20) with K and have for all energy levels

$$E^K = K + \tfrac{1}{2} + \tfrac{3}{4}\lambda(2K^2 + 2K + 1) + \frac{i\sqrt{2}\,4^{K+1/2}}{\sqrt{\pi}\,K!}\, e^{1/3\lambda}(-\lambda)^{-K-1/2}\{1 + \lambda[\tfrac{3}{2} + 3K - A - B(K + \tfrac{1}{2})^2]\}. \tag{5.21}$$

The imaginary part of Eq. (5.21) is the first-order generalization of Eq. (5.10). Note that the real parts of Eqs. (5.21) and (5.11) are identical and that only Eq. (5.21) has a nonzero imaginary part (as was true of the zeroth-order counterparts of these equations).

As in Sec. V A we can now *average* the expressions in Eqs. (5.11) and (5.21) to obtain the true value of $E^K(\lambda)$ for $\lambda < 0$. This true value differs from Eq. (5.21) in that the $\sqrt{2}$ is in the denominator. From this result we obtain the discontinuity which was defined in Eq. (2.6):

$$D^K(x) = -\frac{4^{K+1} i}{K!(2\pi)^{1/2}}\, e^{1/3x}(-x)^{-K-3/2} \times [1 + x(\tfrac{95}{24} + \tfrac{29}{4}K + \tfrac{17}{4}K^2)], \tag{5.22}$$

where we have substituted the values of A and B given in Eq. (5.14).

We can now compute the $O(n^{-1})$ corrections to Eq. (4.4). Following the procedure of Sec. IV, we insert Eq. (5.22) into Eq. (2.7), perform the integral, and obtain for large n

$$A_n^K = \frac{(-1)^{n+1}12^K\sqrt{6}}{K!\,\pi^{3/2}}\, 3^n\Gamma(n + K + \tfrac{1}{2}) \times\left(1 - \frac{1}{n}(\tfrac{95}{72} + \tfrac{29}{12}K + \tfrac{17}{12}K^2) + O(n^{-2})\right). \tag{5.23}$$

This is the desired result which was stated in Sec. I. It is a generalization to all K of Eq. (4) in Ref. 1.

We conclude with two remarks. First, recall that in Ref. 2 there is a numerical fit of the first 75 Rayleigh-Schrödinger coefficients for the ground-state energy ($K = 0$).[25] There, the coefficient of n^{-1} is given as

$$-1.319\,453.$$

The decimal equivalent of $-\frac{95}{72}$, the exact answer in Eq. (5.23), is

$$-1.319\,444\cdots.$$

This agreement strongly testifies to the power of WKB analysis.

Second, recall that as pointed out in Sec. IV, A_n^K will in general be given by the result in Eq. (4.4) [and Eq. (5.23)] followed by a series in inverse powers of n. [This must be so because the corrections to the discontinuity $D^K(x)$, in Eq. (5.22), for example, are a power series in x.] The series for A_n^0 will thus take the form

$$A_n^0 \sim (-1)^{n+1}\frac{\sqrt{6}}{\pi^{3/2}}\Gamma(n + \tfrac{1}{2})3^n\left(1 - \sum_{j=1}^{\infty}\frac{a_j}{n^j}\right). \tag{5.24}$$

We would not be surprised if the series in Eq. (5.24) is asymptotic. In fact, we would not even be surprised to find that the coefficients a_j are all positive, rational fractions. We have calculated numerically some of the coefficients a_j and have obtained the following results[26]:

$$a_1 = \tfrac{95}{72},$$

$$a_2 = \tfrac{20\,099}{10\,368}\ (= 1.938\,560\,9_{567\,901\,234}),$$

$$a_3 = \tfrac{15\,422\,651}{2\,198\,748}.$$

These values for a_1, a_2, and a_3 were of course originally computed as decimals; afterward, we guessed the above fractional representations of which we are extremely confident. Note that the denominators are all products of powers of 2 and 3.

We have also computed these additional coefficients:

$$a_4 = 40.118\,943\,1,$$

$$a_5 = 305.5223,$$

$$a_6 = 2808.09,$$

$$a_7 = 0.2995 \times 10^5,$$

$$a_8 = 0.365 \times 10^6,$$

$$a_9 = 0.44 \times 10^7,$$

$$a_{10} = 1 \times 10^8.$$

It is not yet possible to determine the fractional representations for the above coefficients because they are not known to a sufficient number of significant figures.

VI. INDEPENDENT DERIVATION

We exhibit below a new and independent derivation of Eq. (4.4) for the ground-state ($K = 0$) energy. At the end of this section, we generalize these results to the first energy level. Our methods here are far more direct, although somewhat more involved, than those of Secs. II, III, and IV. We will find a *linear* difference equation which for large n asymptotically approximates the nonlinear differ-

ence equation [Eq. (6.3)] which generates nth-order perturbation theory. We then solve this linear difference equation. Our methods are nonrigorous; nonetheless, we feel that this analysis is extremely worthwhile because it clarifies the rather subtle and intricate perturbative structure of the anharmonic oscillator model.

We obtain the nonlinear difference equation which generates the ground-state energy perturbation series by substituting

$$E^0(\lambda) \sim \tfrac{1}{2} - \sum_{n=1}^{\infty} (-\lambda)^n C_n \tag{6.1}$$

and

$$\psi^0(x) \sim e^{-x^2/4}\left(1 + \sum_{n=1}^{\infty} (-\lambda)^n \sum_{j=1}^{2n} (\tfrac{1}{2}x^2)^j C_{n,j}\right) \tag{6.2}$$

into the differential equation in Eq. (1.1). Collecting powers of x and λ gives the desired difference equation[27]:

$$2jC_{n,j} = (j+1)(2j+1)C_{n,j+1} + C_{n-1,j-2} - \sum_{p=1}^{n-1} C_{p,1}C_{n-p,j}, \tag{6.3}$$

where $C_n = C_{n,1}$ and $C_{0,0} = 1$. The C_n are related to the Rayleigh-Schrödinger coefficients A_n^0 by the formula

$$A_n^0 = (-1)^{n+1} C_n . \tag{6.4}$$

The minus signs in Eqs. (6.1) and (6.2) are chosen so that the $C_{n,j}$ are all positive.

Figure 4 illustrates schematically how Eq. (6.3) iterates. The dots represent the nonzero entries in the matrix $C_{n,j}$. The dot in the circle represents the value of $C_{n,j}$ to be computed, that is, the left-hand side of Eq. (6.3). The underlined dots are the values of $C_{n,j}$ on the right-hand side of Eq. (6.3).

A glance at Fig. 4 indicates several general properties of Eq. (6.3). Each $C_{n,j}$ depends on all numbers above and to the right of it. Thus, the matrix in Fig. 4 must be filled out from right to left for fixed n; after each row is completed, n, the order of perturbation theory, is increased by unity. As is typical in perturbation theory, each new order is increasingly difficult to compute because it depends on *all* previous orders. Note, however, that it is easy to find exact formulas for the entries on the right-hand side of the matrix:

$$C_{n,2n} = \frac{1}{4^n n!}, \tag{6.5a}$$

$$C_{n,2n-1} = \frac{4n+5}{3\,4^n (n-1)!}, \tag{6.5b}$$

$$C_{n,2n-2} = \frac{16n^2+64n+87}{18\,4^n (n-2)!}. \tag{6.5c}$$

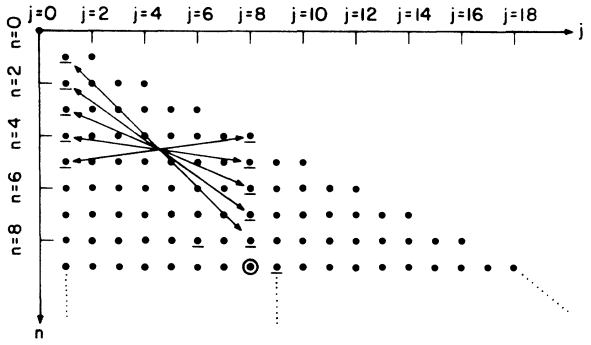

FIG. 4. Schematic representation of Eq. (6.3). The dots represent the nonzero values of $C_{n,j}$. The dot in the circle is the value of $C_{n,j}$ to be computed; the underlined dots are the values of $C_{n,j}$ which Eq. (6.3) requires for this computation. The arrows indicate those pairs of $C_{n,j}$ which are multiplied together.

Our problem is to find the large-n behavior of $C_{n,1}$, the entries in the first column of the matrix.

A. Linearization of Eq. (6.3)

The positivity of $C_{n,j}$ implies that the summation on the right-hand side of Eq. (6.3) is small compared with the other two terms. This suggests that Eq. (6.3) may be replaced by a sequence of *linear* equations, the Nth equation having the summation in

$$-\sum_{p=1}^{n-1} C_{p,1}C_{n-p,j}$$

replaced by $\sum_{p=1}^{N}$ and $\sum_{p=n-N}^{n-1}$, where $N=0$ means no sum is performed, and where the actual numerical values of $C_{p,j}$, $1 \le p \le N$ are calculated and then inserted into the summation. One would expect that as N increases one obtains a better approximation to $C_{n,1}$. This has been verified to order 150 on a computer where we found that

$$C_{n,1}/C_{n,1}(N=0) \sim 1 + O(1/n),$$

$$C_{n,1}/C_{n,1}(N=1) \sim 1 + O(1/n^2),$$

$$C_{n,1}/C_{n,1}(N=2) \sim 1 + O(1/n^3), \quad \text{etc.}$$

We now demonstrate analytically that the $N=0$ linear equation

$$2jC_{n,j} = (j+1)(2j+1)C_{n,j+1} + C_{n-1,j-2}, \quad C_{0,0} = 1 \tag{6.6}$$

gives the same leading behavior of $C_{n,1}$ for large n as in Eq. (4.4). The $N \ge 1$ equations have still not been solved analytically.

B. Approximation of the Linear Equation

Equation (6.6) may be further approximated. Detailed inspection of computer output shows that for large n,

$$(j+1)(2j+1)C_{n,j+1} \gg C_{n-1,j-2}, \quad \text{for } j=O(1) \tag{6.7a}$$

$$(j+1)(2j+1)C_{n,j+1} \ll C_{n-1,j-2}, \quad \text{for } j=O(2n). \tag{6.7b}$$

Equation (6.6) suggests the substitution

$$D_{n,j}=j\Gamma(j+\tfrac{1}{2})C_{n,j}, \tag{6.8}$$

which gives

$$D_{n,j}=D_{n,j+1}+\left(\frac{j}{2}+\frac{3}{8j-16}\right)D_{n-1,j-2}. \tag{6.9}$$

For large n, the term $3(8j-16)^{-1}$ can be dropped because for large j it is small compared with $\frac{1}{2}j$ and for small j Eq. (6.7a) shows that contribution from the $D_{n-1,j-2}$ term is negligible. Thus, we approximate Eq. (6.9) by

$$E_{n,j}=E_{n,j+1}+\tfrac{1}{2}jE_{n-1,j-2}. \tag{6.10}$$

However, this approximation is only good for large n. Furthermore, Eq. (6.10) is homogeneous (multiples of solutions are solutions). Therefore, we calculate the initial value $E_{0,0}$ by demanding that $E_{n,j}$ approximate $D_{n,j}$ for large n. It is simplest to require that

$$\lim_{n\to\infty}\frac{E_{n,2n}}{D_{n,2n}}=1. \tag{6.11}$$

$D_{n,2n}$ is obtained from Eqs. (6.5a) and (6.8). It is easy to see that $E_{n,2n}=E_{0,0}n!$. Thus,

$$E_{0,0}=\lim_{n\to\infty}\frac{2n\Gamma(2n+\frac{1}{2})}{4^n(n!)^2}=(2/\pi)^{1/2}. \tag{6.12}$$

Having established Eq. (6.12), we expect that for large n,

$$C_{n,1}=\frac{D_{n,1}}{\Gamma(\frac{3}{2})}$$

$$=\frac{2}{\sqrt{\pi}}D_{n,1}\sim\frac{2}{\sqrt{\pi}}E_{n,1}. \tag{6.13}$$

Finally, for convenience we define a new function $F_{n,j}$ which is a multiple of $E_{n,j}$ and obeys the equations

$$F_{0,0}=1, \tag{6.14a}$$

$$F_{n,j}=F_{n,j+1}+\tfrac{1}{2}jF_{n-1,j-2}, \tag{6.14b}$$

$$C_{n,1}\sim\frac{2\sqrt{2}}{\pi}F_{n,1}. \tag{6.14c}$$

C. Conversion to a Partial Differential Equation

To solve Eq. (6.14) we define the generating functions

$$F(x)=\sum_{n=1}^{\infty}\frac{F_{n,1}x^{n-1}}{(n-1)!}, \tag{6.15a}$$

$$G(x,y)=\sum_{n=1}^{\infty}\frac{x^n}{n!}\sum_{j=1}^{2n}y^{j+2}F_{n,j}, \tag{6.15b}$$

where

$$G(x,0)=G(0,y)=0. \tag{6.16}$$

Then we multiply Eq. (6.14b) by y^{j+2} and sum over j, multiply by $x^{n-1}/(n-1)!$ and sum over n, and use Eq. (6.15) to convert the result into the partial differential equation

$$\frac{\partial}{\partial x}G(x,y)+\frac{y^4}{2(1-y)}\frac{\partial}{\partial y}G(x,y)=\frac{y^3}{y-1}[y^2-F(x)]. \tag{6.17}$$

Note that unknowns appear on *both* sides of this equation

To solve Eq. (6.17) we introduce a new variable ξ, where

$$\frac{dy}{d\xi}=\frac{y^4}{2(1-y)}. \tag{6.18}$$

Integrating Eq. (6.18) gives

$$\xi(y)=\frac{3y-2}{3y^3}. \tag{6.19}$$

$\xi(y)$ is plotted on Fig. 5. Note that for $\xi>0$, $\xi(y)$ has a two-valued inverse. The inverse functions $g_1(\xi)$ and $g_2(\xi)$ are plotted on Fig. 6. In terms of x and ξ the solution of Eq. (6.17) is

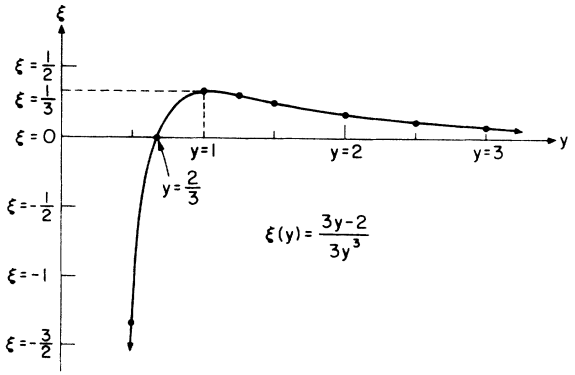

FIG. 5. Graph of $\xi(y)=(3y-2)/3y^3$ showing the two-valued inverse of $\xi(y)$ for $\xi>0$.

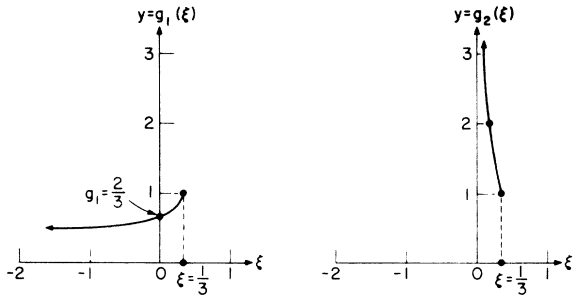

FIG. 6. Graph of the two inverse functions $y = g_1(\xi)$ and $y = g_2(\xi)$ which solve the equation $\xi(y) = (3y-2)/3y^3$.

$$G_{1,2}(x,\xi) = \int_0^x dx' \, \frac{g_{1,2}{}^3(\xi - x + x')}{1 - g_{1,2}(\xi - x + x')} \times [F(x') - g_{1,2}{}^2(\xi - x + x')], \tag{6.20}$$

where

$$G_{1,2}(x,\xi) = G(x, g_{1,2}(\xi)). \tag{6.21}$$

Note that Eq. (6.16) allows us to eliminate an arbitrary solution $V(x-\xi)$ of the homogeneous equation from Eq. (6.20).

The integral in Eq. (6.20) can be simplified by using Eq. (6.18) as follows:

$$-\int_0^x dx' \, \frac{g_{1,2}{}^5(\xi - x + x')}{1 - g_{1,2}(\xi - x + x')} = -2\int_0^x dx' \, g_{1,2}(\xi - x + x') \, \frac{dg_{1,2}(\xi - x + x')}{dx'} = -g_{1,2}{}^2(\xi) + g_{1,2}{}^2(\xi - x). \tag{6.22}$$

D. Conversion to an Integral Equation for $F(x)$

From Fig. 6 observe that $g_1(\frac{1}{3}) = g_2(\frac{1}{3})$. Hence, using Eq. (6.21), we find that

$$G_1(x, \tfrac{1}{3}) = G_2(x, \tfrac{1}{3}). \tag{6.23}$$

Combining Eqs. (6.20) and (6.23) then eliminates all reference to G and gives the following singular integral equation for F:

$$\int_0^x dx' F(x') \left[\frac{g_1{}^3(\frac{1}{3} - x + x')}{1 - g_1(\frac{1}{3} - x + x')} - \frac{g_2{}^3(\frac{1}{3} - x + x')}{1 - g_2(\frac{1}{3} - x + x')} \right] = g_2{}^2(\tfrac{1}{3} - x) - g_1{}^2(\tfrac{1}{3} - x). \tag{6.24}$$

E. Approximate Solution of the Integral Equation

Figure 6 shows that for small ξ, $g_2(\xi)$ is singular while $g_1(\xi)$ is finite. Indeed, Eq. (6.19) implies that for small ϵ,

$$g_1(\epsilon) \sim \tfrac{2}{3}, \tag{6.25a}$$

$$g_2(\epsilon) \sim \epsilon^{-1/2}. \tag{6.25b}$$

Equation (6.25) indicates that as x approaches $\frac{1}{3}$, the right-hand side of Eq. (6.24) becomes singular. We are thus motivated to identify the leading singularity in $F(x)$ which causes the equivalent divergence of the left-hand side. To this end, we substitute

$$x = \tfrac{1}{3} - \epsilon, \quad x' = \tfrac{1}{3} - \epsilon' \tag{6.26}$$

into Eq. (6.24). The resulting approximate integral equation is

$$\int_\epsilon^{1/3} d\epsilon' \, F(\tfrac{1}{3} - \epsilon') \left[\frac{g_1{}^3(\frac{1}{3} + \epsilon - \epsilon')}{1 - g_1(\frac{1}{3} + \epsilon - \epsilon')} - \frac{g_2{}^3(\frac{1}{3} + \epsilon - \epsilon')}{1 - g_2(\frac{1}{3} + \epsilon - \epsilon')} \right] \sim \frac{1}{\epsilon}. \tag{6.27}$$

Next we approximate the expression in square brackets in Eq. (6.27). Figure 6 shows that $g_{1,2}(\frac{1}{3}) = 1$. When ξ is near $\frac{1}{3}$ (y near unity) we can replace the differential equation in Eq. (6.18) by

$$d\xi \sim 2(1-y)\,dy. \tag{6.28}$$

Equation (6.28) integrates to

$$\tfrac{1}{3} - \xi = (1-y)^2. \tag{6.29}$$

Thus, using Fig. 6 to guide the choice of sign,

$$1 - g_1(\tfrac{1}{3} + \epsilon - \epsilon') \sim (\epsilon' - \epsilon)^{1/2}, \tag{6.30a}$$

$$1 - g_2(\tfrac{1}{3} + \epsilon - \epsilon') \sim -(\epsilon' - \epsilon)^{1/2}. \tag{6.30b}$$

From Eq. (6.30), we conclude that Eq. (6.27) may be further approximated by

$$\int_\epsilon^{1/3} d\epsilon' \, F(\tfrac{1}{3} - \epsilon') \frac{2}{(\epsilon' - \epsilon)^{1/2}} \sim \frac{1}{\epsilon}. \tag{6.31}$$

The leading singularity in F which causes the divergence of the right-hand side for small ϵ clearly has the form

$$F(\tfrac{1}{3} - \epsilon') \sim \frac{a}{\epsilon'^k}. \tag{6.32}$$

The substitution $\epsilon' = \epsilon/z$ yields $k = \frac{3}{2}$ and the equation

$$\int_{3\epsilon}^1 \frac{dz}{(1-z)^{1/2}} = \frac{1}{2a}.$$

Letting $\epsilon \to 0$ gives $a = \frac{1}{4}$. Hence, the leading singularity of $F(x)$ is given by

$$F(x) \sim \tfrac{1}{4}(\tfrac{1}{3} - x)^{-3/2}. \tag{6.33}$$

F. Recovery of $C_{n,1}$ for Large n

The actual behavior of $F(x)$ as given by Eq. (6.24) has the form

$$F(x) \sim \tfrac{1}{4}(\tfrac{1}{3}-x)^{-3/2} + \alpha(\tfrac{1}{3}-x)^{-1/2} + \beta(\tfrac{1}{3}-x)^{1/2} + \cdots . \tag{6.34}$$

However, when $F(x)$ is expanded into a power series in x, the *dominant* contribution to the coefficient of the x^n term for large n comes from the *most* singular term in Eq. (6.34). Thus, the analysis we have carried out is just sufficient to obtain the leading behavior of C_n for large n. Hence, using the binomial theorem to get the nth term in the expansion of $\frac{1}{4}(\frac{1}{3}-x)^{-3/2}$ and combining this result with Eqs. (6.15a) and (6.14c) gives the desired result

$$C_{n,1} \sim \frac{\sqrt{6}}{\pi^{3/2}}\, 3^n\, \Gamma(n+\tfrac{1}{2}) \tag{6.35}$$

or

$$A_n^0 \sim (-1)^{n+1} \frac{\sqrt{6}}{\pi^{3/2}}\, 3^n\, \Gamma(n+\tfrac{1}{2}), \tag{6.36}$$

which agrees with the result in Eq. (4.4) when $K=0$.

G. Discussion

We discuss below one subtle aspect of this derivation. At first glance it might appear that the delicate and intricate use of the multivaluedness of y as a function of ξ to eliminate the unknown generating functions G_1 and G_2 in Sec. V D was not necessary. It would seem that a more straightforward approach would use the relation

$$F(x) \equiv 1 + \frac{1}{2} \frac{\partial G(x,y)}{\partial y}\bigg|_{y=1}. \tag{6.37}$$

This identity may be proved by differentiating G in Eq. (6.15b) and letting $y=1$. The result is

$$1 + \frac{1}{2}\frac{\partial G}{\partial y}\bigg|_{y=1} = 1 + \sum_{n=1}^{\infty} \frac{x^n}{n!} \sum_{j=1}^{2n} \frac{j+2}{2} F_{n,j}$$

$$= 1 + \sum_{n=1}^{\infty} \frac{x^n}{n!} \sum_{j=3}^{2n+2} (F_{n+1,j} - F_{n+1,j+1}), \tag{6.38}$$

where we have shifted the j index and substituted Eq. (6.14b). The j summation in Eq. (6.38) collapses. Comparing with Eq. (6.15a) verifies Eq. (6.37).

Converting the identity to one involving the x and ξ variables gives

$$F(x) \equiv 1 + \lim_{\xi \to 1/3} \left(\pm(\tfrac{1}{3}-\xi)^{1/2} \frac{\partial G_{1,2}(x,\xi)}{\partial \xi} \right). \tag{6.39}$$

It would now appear that applying Eq. (6.39) to Eq. (6.20) is a far simpler way to eliminate the unknowns $G_{1,2}$ in favor of F. In fact, this procedure leads to a tautology – the resulting equation for F reduces to an identity. The apparently new and independent condition in Eq. (6.39) is *already* contained in Eq. (6.20). Thus, we are *forced* to follow the procedure of Sec. V D.

H. First Energy Level ($K=1$)

It is easy to repeat these techniques for the first energy level. We list below some intermediate $K=1$ results, which correspond with the $K=0$ results given above.

The linearized difference equation which corresponds with Eq. (6.6) is

$$2j\, C_{n,j} = (j+1)(2j+3) C_{n,j+1} + C_{n-1,j-2}, \tag{6.40}$$

where $C_{0,0}=1$ and

$$A_n^1 = 3(-1)^{n+1} C_{n,1}. \tag{6.41}$$

To derive Eq. (6.40) we have dropped the convolution term

$$-3 \sum_{p=1}^{n-1} C_{p,j}\, C_{n-p,1}$$

from the right-hand side. The substitution

$$D_{n,j} = j\Gamma(j+\tfrac{3}{2}) C_{n,j}$$

[see Eq. (6.8)] and some approximations give

$$F_{n,j} = F_{n,j+1} + \tfrac{1}{2}(j+2) F_{n-1,j-2}, \tag{6.42}$$

where $F_{0,0}=1$ and

$$A_n^1 = (-1)^{n+1} \frac{8\sqrt{2}}{\pi} F_{n,1}$$

[see Eq. (6.14)].

Instead of solving Eq. (6.42) let us consider a one-parameter family of such equations. Let M be arbitrary and $F_{0,0}=1$. Then we solve

$$F_{n,j} = F_{n,j+1} + \tfrac{1}{2}(j+M) F_{n-1,j-2} \tag{6.43}$$

by introducing the generating functions

$$F(x) = \sum_{n=1}^{\infty} \frac{x^{n-1}}{(n-1)!} F_{n,1} \tag{6.44a}$$

and

$$G(x,y) = \sum_{n=1}^{\infty} \frac{x^n}{n!} \sum_{j=1}^{2n} y^{j+M+2} F_{n,j}. \tag{6.44b}$$

The analog of Eq. (6.17) is

$$\frac{\partial}{\partial x} G(x,y) + \frac{y^4}{2(1-y)} \frac{\partial}{\partial y} G(x,y) = \frac{y^{M+3}}{y-1} \left(\frac{M+2}{2} y^2 - F(x) \right). \tag{6.45}$$

Following the analysis of Secs. V C–V D, we obtain

$$F(x)\sim\frac{\Gamma[\frac{1}{2}(M+3)]}{2\sqrt{\pi}\,\Gamma[\frac{1}{2}(M+2)]}\,(\tfrac{1}{3}-x)^{-(M+3)/2}, \tag{6.46}$$

which is the generalization of Eq. (6.33). Finally, we repeat the work of Sec. V F and find that

$$F_{n,1}=\frac{3^{n+(M+1)/2}\Gamma[n+\frac{1}{2}(M+1)]}{2\sqrt{\pi}\,\Gamma[\frac{1}{2}(M+2)]}. \tag{6.47}$$

The particular case $M=2$ in Eq. (6.42) reduces Eq. (6.47) to

$$A_n^1\sim(-1)^{n+1}\frac{12\sqrt{6}}{\pi^{3/2}}\,3^n\Gamma(n+\tfrac{3}{2}), \tag{6.48}$$

which is precisely the case $K=1$ in Eq. (4.4).

VII. LARGE-ORDER BEHAVIOR OF WICK-ORDERED PERTURBATION THEORY

It is *necessary* to Wick-order the Hamiltonian of a multidimensional field theory. Wick-ordering removes the divergence associated with the zero-point energies of the infinitely many degrees of freedom. Correspondingly, in perturbation theory, Wick-ordering removes those (divergent) diagrams having self-loops (lines with both ends connected to the same vertex). Because the anharmonic oscillator is a field theory having only *one* degree of freedom,[28] it is *not necessary* to Wick-order the Hamiltonian H in Eq. (1.4). In addition, the non-Wick-ordered diagrams in this field theory are finite and need not be eliminated. Nevertheless, to make a stronger connection with higher-dimensional field theory, we investigate the large-order behavior of the Wick-ordered perturbation series.

We begin by Wick-ordering the Hamiltonian in Eq. (1.4). To do this, we express the fields in the interaction picture in terms of creation and annihilation operators:

$$\phi=(2m)^{-1/2}(ae^{-imt}+a^\dagger e^{imt}), \tag{7.1a}$$

$$\dot\phi=(\tfrac{1}{2}m)^{1/2}(-iae^{-imt}+ia^\dagger e^{imt}). \tag{7.1b}$$

Then, in terms of a and $a^\dagger$, H is

$$H=m(a^\dagger a+\tfrac{1}{2})+g(2m)^{-2}(a+a^\dagger)^4. \tag{7.2}$$

The standard way to Wick-order H in Eq. (7.2) is to place all creation operators to the left of all annihilation operators.

To elucidate this definition we use the commutation relation

$$[a,a^\dagger]=1. \tag{7.3}$$

Equation (7.3) allows us to express Wick-ordered quantities simply in terms of non-Wick-ordered ones, to wit:

$$:\phi^2:=\phi^2-\frac{1}{2m}, \tag{7.4a}$$

$$:\phi^4:=\phi^4-\frac{3}{m}\,\phi^2+\frac{3}{4m^2}, \tag{7.4b}$$

$$:\tfrac{1}{2}\dot\phi^2+\tfrac{1}{2}m^2\phi^2:=\tfrac{1}{2}\dot\phi^2+\tfrac{1}{2}m^2\phi^2-\tfrac{1}{2}m. \tag{7.4c}$$

We now use Eq. (7.4) to rewrite the Wick-ordered Hamiltonian $:H:$ as a *new non-Wick-ordered* Hamiltonian:

$$:H:=\tfrac{1}{2}\dot\phi^2+\tfrac{1}{2}m^2\phi^2-\tfrac{1}{2}m+\lambda\phi^4-\left(\frac{6\lambda}{m^3}\right)\frac{m^2\phi^2}{2}+\frac{3\lambda}{4m^2}. \tag{7.5}$$

Comparing Eq. (7.5) with Eq. (1.4) shows that Wick-ordering is equivalent to the replacement

$$m^2\to m^2(1-6\lambda/m^3), \tag{7.6a}$$

$$E\to E-\tfrac{1}{2}m+\tfrac{3}{4}m\lambda/m^3. \tag{7.6b}$$

From Eqs. (7.6) and (1.7), it follows that we can immediately express the perturbation series for the Kth energy level of the Wick-ordered Hamiltonian in terms of the Rayleigh-Schrödinger coefficients for the non-Wick-ordered Hamiltonian:

$$E^K_{\rm Wick}\sim-\tfrac{1}{2}m+\tfrac{3}{4}m\Lambda+m(K+\tfrac{1}{2})(1-6\Lambda)^{1/2}+m\sum_{n=1}^{\infty}A_n^K\Lambda^n(1-6\Lambda)^{1/2-3n/2}, \tag{7.7}$$

where $\Lambda=\lambda m^{-3}$.

Using the binomial expansion,

$$(1-6\Lambda)^{1/2-3n/2}=\sum_{j=0}^{\infty}\frac{(6\Lambda)^j\Gamma(\frac{3}{2}n-\frac{1}{2}+j)}{j!\,\Gamma(\frac{3}{2}n-\frac{1}{2})}, \tag{7.8}$$

we simplify Eq. (7.7) to read[29]

$$E^K_{\rm Wick}\sim mK+\tfrac{3}{2}K(K-1)m\Lambda+m\sum_{n=2}^{\infty}\Lambda^nB_n, \tag{7.9}$$

where

$$B_n^K=\sum_{j=0}^{n}\frac{A^K_{n-j}6^j\Gamma(\frac{3}{2}n-\frac{1}{2}j-\frac{1}{2})}{j!\,\Gamma(\frac{3}{2}n-\frac{3}{2}j-\frac{1}{2})}. \tag{7.10}$$

[In Eq. (7.10), $A_0^K=K+\frac{1}{2}$.] Equations (7.9) and (7.10) are exact.

We proceed to compute the large-order behavior of B_n^K. To do this, we observe that for large n, the dominant contribution to the sum in Eq. (7.10) comes from the small-j terms. We thus approximate[30]

$$\frac{\Gamma(\frac{3}{2}n-\frac{1}{2}j-\frac{1}{2})}{\Gamma(\frac{3}{2}n-\frac{3}{2}j-\frac{1}{2})}\sim(\tfrac{3}{2}n)^j\left(1-\frac{2j(j+1)}{3n}+\frac{j(j-1)(12j+11)(j+1)}{54n^2}+O(1/n^3)\right). \tag{7.11}$$

As will be seen, it is most productive to compute the large-n behavior of the ratio A_n^K/B_n^K. Equations (7.10) and (7.11) give

$$\frac{B_n^K}{A_n^K} \sim \sum_{j=0}^{N} \frac{(9n)^j}{j!} \frac{A_{n-j}^K}{A_n^K} \left(1 - \frac{2j(j+1)}{3n} + \frac{j(j-1)(12j+11)(j+1)}{54n^2} + O(1/n^3)\right) . \tag{7.12}$$

Next, we refer to Eq. (5.23) and determine[30] that for large n

$$\frac{A_{n-j}^K}{A_n^K} \sim \frac{1}{(-3n)^j} \left(1 + \frac{j^2 - 2jK}{2n} + \frac{-j(\frac{95}{3} + 58K + 34K^2) + j(j+1)(12K^2 - 12Kj + 3j^2 + j - 1)}{24n^2} + O(1/n^3)\right) . \tag{7.13}$$

Note that even though we have only determined the large-n behavior of A_n^K up to terms of order $1/n^2$ we can still calculate the ratio in Eq. (7.13) up to terms of order $1/n^3$. This is the reason why we have chosen to approximate the ratio.

Finally, we combine Eqs. (7.12) and (7.13) and allow the summation index to run from zero to ∞ to obtain

$$\frac{B_n^K}{A_n^K} \sim \sum_{j=0}^{\infty} \frac{(-3)^j}{j!} \left(1 - \frac{j^2 + 4j + 6Kj}{6n} + j\,\frac{3j^3 + 8j^2 - 48j - 338 - 522K - 306K^2 + 36Kj(j+1) + 108K^2(j+1)}{216n^2} + O(1/n^3)\right) . \tag{7.14}$$

By repeatedly shifting the summation index, we do the indicated sums in Eq. (7.14) exactly. We obtain

$$\frac{B_n^K}{A_n^K} = e^{-3}\left(1 + \frac{1+3K}{n} + \frac{\frac{71}{6} + 31K + 23K^2}{4n^2} + O(1/n^3)\right) . \tag{7.15}$$

This is the desired result which was also given in Sec. I.

To compare this prediction with our numerical results, we let $K=0$ in Eq. (7.15), take the reciprocal, and get[31]

$$\frac{A_n^0}{B_n^0} = e^3\left(1 - \frac{1}{n} - \frac{47}{24n^2} + O(1/n^3)\right) . \tag{7.16}$$

We have calculated the ratio A_n^0/B_n^0 to 74th order in perturbation theory on a computer and find that

$$\left(\frac{A_{74}^0}{B_{74}^0}\right)_{\text{computer}} = 19.806\,55 . \tag{7.17}$$

The agreement between the theoretical result in Eq. (7.16) and the computer output in Eq. (7.17) is most impressive:

$$e^3 = 20.085\,537 , \tag{7.18a}$$

$$e^3(1 - 74^{-1}) = 19.814\,111 , \tag{7.18b}$$

$$e^3[1 - 74^{-1} - 47 \cdot 24^{-1} \cdot 74^{-2}] = 19.806\,928 . \tag{7.18c}$$

Despite the excellent results of Eq. (7.15) we point out that our derivation does *not* generalize to Wick-ordered $(\lambda\phi^{2N})$ field theories with $N>2$. For these theories there is no replacement equivalent to that in Eq. (7.6). However, the general problem of finding the large-n behavior of the ratio of the Rayleigh-Schrödinger coefficients in the perturbation series for the energy levels of the $(\lambda\phi^{2N})_1$ and $(:\lambda\phi^{2N}:)_1$ theories has now been solved and will be published elsewhere.[8]

APPENDIX

We give below a derivation of Eq. (3.36) which is less careful than that given in Sec. III, but which clarifies the physical ideas and minimizes the mathematical detail. In Sec. III we took pains to show how to deal with the subdominant contribution to the wave function [the exponentially decreasing $\Phi_2(x)$]. Now that $\Phi_2(x)$ is comfortably under control, we cavalierly rederive $\mathrm{Im}E(\lambda)$ without regard to subdominance. In a future paper, where we generalize to the much more complicated and difficult problem of many coupled oscillators, we will follow the techniques of this appendix rather than those of Sec. III.

First, we use a well-known relation[32] between the imaginary part of the energy of an unstable state of a real potential and the probability current $J(x)$:

$$\mathrm{Im}E = E_2 = J(x) \Big/ \int_0^x \Phi^*(x')\Phi(x')dx' , \tag{A1}$$

where

$$J(x) \equiv \frac{1}{2i}\left(-\Phi^*(x)\frac{d}{dx}\Phi(x) + \Phi(x)\frac{d}{dx}\Phi^*(x)\right) . \tag{A2}$$

Equation (A1) is trivially derived by multiplying Eq. (3.2) by $\Phi^*(x)$, subtracting the complex conjugate of this result, integrating from $-x$ to x, where $x > x_1$, and using the invariance of the potential under reflections $x \to -x$. (We integrate past x_1, the distant turning point, so that there is no point between x and ∞ where the current will be reflected back toward $x=0$. Thus the amount

of outward probability current flow is a measure of the decay rate of the unbound state.) Note that by conservation of probability current the right-hand side of Eq. (A1) does not depend on x.

Second, we approximate the denominator of Eq. (A1) as follows: For $x<x_1$, we can replace Φ in the integral with $\mathrm{Re}\Phi$ because $\mathrm{Im}\Phi$ is small, as was shown in Sec. III. Moreover, we can approximate $\mathrm{Re}\Phi$ by $\Phi_{1A}=D_K(x)$ [see Eq. (3.8)], because $\mathrm{Re}\Phi$ and Φ_{1A} differ only in the shape of their exponentially small tails. Finally, we extend the range of integration to all positive x. Thus,[33]

$$\int_0^x \Phi^*(x')\Phi(x')dx' \sim \int_0^\infty [D_K(x')]^2 dx' = (\tfrac{1}{2}\pi)^{1/2} K! \,. \tag{A3}$$

Third, we evaluate $J(x)$ in Eq. (A2). We will do this in two distinct ways.

Method 1

We follow the approach of Sec. III until Eqs. (3.21), (3.22), and (3.24) have been established. These equations together imply the following behavior for the wave function $\Phi(x)$ when $x>x_1$:

$$\Phi(x)\sim 2^{-1/4}\epsilon^{1/8}(x-x_1)^{-1/4}\exp[-\tfrac{1}{4}i\pi-(6\epsilon)^{-1}-\tfrac{1}{2}(K+\tfrac{1}{2})\ln\tfrac{1}{4}\epsilon-\tfrac{1}{3}i\sqrt{2}\epsilon^{-1/4}(x-x_1)^{3/2}]. \tag{A4}$$

The expression in Eq. (A4) is then inserted in Eq. (A2) giving

$$J(x)\sim \tfrac{1}{2}e^{-1/3\epsilon}\left(\frac{4}{\epsilon}\right)^{K+1/2}. \tag{A5}$$

Method 2

Here we use a trick to circumvent the asymptotic matching at the distant turning point x_1. We thus reduce the problem to just *one* asymptotic connection. We follow Sec. III until Eqs. (3.11), (3.12), and (3.14) have been established. Equation (3.11) is the WKB approximation to Φ in region B:

$$\Phi(x)\sim C_1(x^2-\epsilon x^4-4K-2)^{-1/4} \times\exp\left(-\tfrac{1}{2}\int_{x_0}^{x}(x'^2-\epsilon x'^4-4K-2)^{1/2}dx'\right). \tag{A6}$$

x_0 and C_1 are given in Eqs. (3.12) and (3.14). C_1 is determined by asymptotically matching $\Phi_{\mathrm{WKB}}(x)$ in Eq. (A6) to $D_K(x)$ at the boundary of regions A and B, as was done in Sec. III B. We would now like to allow x, the upper endpoint of the WKB integral, to be larger than x_1. But, of course, this expression for the WKB wave function is no longer valid as we pass the turning point at x_1. To avoid this difficulty we approach the point x along a path which goes around x_1: The path goes up the real axis, circles x_1 counterclockwise, and continues up the real axis until it reaches x. Along this contour, WKB gives a *good* approximation to Φ.

Fortunately, the *integral* in the WKB wave function depends only on the endpoint. Thus, for simplicity it may be taken entirely along the real axis. We then break the integral into two parts: (a) the portion below x_1 which is real and factors out of $J(x)$ as a constant, and (b) the portion above x_1 which is imaginary. To leading order [neglecting $O(x^{-2})<O(\epsilon)$ compared with $O(1)$], $J(x)$ is a real constant which we easily simplify to

$$J(x)=\tfrac{1}{2}C_1{}^2\exp\left(-\int_{x_0}^{x_1}(x'^2-\epsilon x'^4-4K-2)^{1/2}dx'\right). \tag{A7}$$

We evaluate the integral in Eq. (A7) (Ref. 17) to obtain the same result as in Eq. (A5).

Finally, we combine Eqs. (A3) and (A5) as indicated in Eq. (A 1) and get

$$\mathrm{Im}E=E_2 = \frac{4^{K+1/2}}{K!(2\pi)^{1/2}}e^{-1/3\epsilon-K-1/2}, \tag{A8}$$

which agrees with Eq. (3.36).

(Received 4 February 1969)

We consider the anharmonic oscillator defined by the differential equation $(-d^2/dx^2+\frac{1}{4}x^2+\frac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x)$ and the boundary condition $\lim_{x\to\pm\infty}\Phi(x)=0$. This model is interesting because the perturbation series for the ground-state energy diverges. To investigate the reason for this divergence, we analytically continue the energy levels of the Hamiltonian H into the complex λ plane. Using WKB techniques, we find that the energy levels as a function of λ, or more generally of λ^α, have an infinite number of branch points with a limit point at $\lambda=0$. Thus, the origin is not an isolated singularity. Level crossing occurs at each branch point. If we choose $\alpha=\frac{1}{3}$, the resolvent $(z-H)^{-1}$ has no branch cut. However, for all z it has an infinite sequence of poles which have a limit point at the origin. The anharmonic oscillator is of particular interest to field theoreticians because it is a model of $\lambda\varphi^4$ field theory in one-dimensional space-time. The unusual and unexpected properties exhibited by this model may give some indication of the analytic structure of a more realistic field theory.

I. INTRODUCTION

IN this paper, we discuss the familiar anharmonic oscillator.[1] We are concerned with the eigenvalue problem defined by the differential equation

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x) \quad (1.1)$$

and the associated boundary condition

$$\lim_{x\to\pm\infty}\Phi(x)=0. \quad (1.2)$$

We propose to answer the following questions within the context of the anharmonic oscillator:

(i) Is the perturbation series for the ground-state energy, which is a power series in the coupling constant λ, convergent for any $\lambda\neq 0$?

(ii) If not, does the ground-state energy, considered as a function of complex λ or more generally as a function of some fractional power α of λ, have an isolated singularity at $\lambda=0$?

(iii) Is the resolvent $(z-H)^{-1}$, considered as a function of λ^α for fixed z, analytic at $\lambda=0$? If not, is the point $\lambda=0$ an isolated singularity?

The answer to all these questions is *no*. More precisely, the energy levels, which are originally defined only for positive values of λ, can be analytically continued into the complex λ plane. This analytic continuation has an infinite number of branch points, which have a limit point at the origin $\lambda=0$. Moreover, level crossing occurs at each branch point. If α is chosen to be $\frac{1}{3}$, the resolvent has no branch cut. However, for all z, $(z-H)^{-1}$ has an infinite number of poles which have a limit point at the origin. These qualitative analytic properties of the energy levels and of the resolvent were totally unexpected and are, we feel, most unusual and exciting.

This paper will adhere to the following outline: In Sec. II (and Appendices A–E), we inspect in great detail the properties of the perturbation series for the ground-state energy in our model. However, this direct inspection gives no clue as to the nature of the singularities in the λ plane which cause this divergence. To

understand these singularities better, in Sec. III, we analytically continue the energy levels into the λ plane and derive some exact properties of this continuation. In particular, we derive an exact condition which gives the locations of the singularities in the λ plane.

To apply this condition we must know the wave function in coordinate space. To calculate the wave function approximately, in Sec. IV, we present a technique using zeroth-order WKB methods in the complex plane. (In Appendix F, we make the calculation of the wave function more precise by using first-order WKB techniques.)

In Sec. V, we use the results of Sec. IV to determine the singularities of the resolvent. In Sec. VI (and Appendix G), we combine the results of Secs. III and IV to find the approximate locations of the singularities in the analytic continuation of the energy levels. Section VI contains an exhaustive qualitative description of the analytic continuation of the energy levels $E(\lambda)$. The major result of this paper is that the energy levels of the anharmonic oscillator for a given positive real λ are the positive real values of $E(\lambda)$ on each of the infinite number of branches of a Riemann surface. Each energy level corresponds to a sheet of this Riemann surface.

Although it is not necessary to understand any field theory to read this paper (aside from Appendices A–C), it is important to point out that the anharmonic oscillator is a simple model field theory in one-dimensional space-time. This field theory is defined by the Hamiltonian

$$H=\tfrac{1}{2}\dot{\varphi}^2+\tfrac{1}{2}m^2\varphi^2+\lambda\varphi^4 \tag{1.3}$$

and the commutation relations

$$[\varphi,\dot{\varphi}]=i. \tag{1.4}$$

[In Appendix A, we prove rigorously that Eqs. (1.1) and (1.2) are consequences of Eqs. (1.3) and (1.4). In fact, Eqs. (1.1) and (1.2) are the coordinate representation of H.]

Since this field-theory model involves no space dimensions, there are no asymptotic states and therefore no particle scattering. Also, there is only one degree of freedom. In fact, all this theory describes is a universe which sits at one point and oscillates. Nevertheless, this model has value to the field theoretician. It enables one to conjecture with slight supporting evidence[2] that many of the fascinating properties we have observed are also present in a more realistic field theory. This model may give us some idea of the vast underlying complexity of such a theory.

The model was originally chosen for study because it had a well-defined but divergent perturbation series. We believe that the divergence of perturbation series in field theory was first discussed by Dyson.[3] Since then, many papers have been written on this topic. A particularly interesting investigation was carried out by Jaffe.[4] Jaffe proved that in two-dimensional space-time the perturbation series for Green's functions in self-interacting boson field theories diverge even though these series exist term by term. However, as far as we know, no techniques have been discovered to elucidate the singularities in field theories with divergent perturbation series. In this paper, we develop for the first time methods to describe the actual singularity structure of a particular field theory.

Having achieved the results of this paper, we hope in the future to apply the new analytical tools of Secs. III–VI to other models of increasing complexity in order to better understand how singularities depend upon the form of interaction. Additional zero-dimensional bose field theories which ought to be considered are self-interactions such as φ^6, φ^{2N}, and $\cos\varphi$ and couplings such as $\varphi_1^2\varphi_2^2$. Hopefully, these WKB techniques will be advanced to the point where they may be used to analyze higher-dimensional theories.

II. GROUND-STATE-ENERGY PERTURBATION SERIES

The perturbation series for the ground-state energy $E_0(\lambda)$ in this model is a power series in the coupling constant λ. This power series takes the form

$$E_0(\lambda)=\tfrac{1}{2}m+\sum_{n=1}^{\infty} mA_n(\lambda/m^3)^n. \tag{2.1}$$

Two methods for calculating the A_n in this equation are discussed below. Each method reveals some important properties of Eq. (2.1).

Method 1. In general, in a field theory the perturbation series for the ground-state energy is the sum of all connected Feynman diagrams having no external legs. Hence, Feynman diagrams can be used to calculate the A_n. (As an illustration of Feynman-diagram techniques, we calculate A_1, A_2, and A_3 in Appendix B.)

Moreover, an integral representation for these Feynman diagrams provides upper and lower bounds on the terms A_n in the perturbation series. We outline below the procedure for estimating these upper and lower bounds. (Detailed proofs for the following statements are given in Appendix C.)

(i) From the form of the Feynman integral representation, it follows that in the perturbation series all diagrams with the same number of vertices add in phase.

(ii) The integral representation places *uniform* bounds on the contribution of each diagram having n vertices.

[2] A. M. Jaffe, in his thesis [Princeton University, 1965 (unpublished)], was able to analytically continue the resolvent for $\lambda\varphi^4$ field theories of any space dimension into the cut λ plane. Jaffe did not predict the properties of the resolvent when $|\arg\lambda|\geq 180°$ (off the first sheet) but, as far as he did predict, his work agrees with ours.

[3] F. J. Dyson, Phys. Rev. **85**, 631 (1952).

[4] A. M. Jaffe, Commun. Math. Phys. **1**, 127 (1965). This paper contains a very complete list of references.

(iii) The maximum and minimum number of diagrams with n vertices is found to be $(2n-1)!!8^n$ and $(n-1)!3^{-n}$.

Combining the above three results implies that $A_n(-1)^{n+1}$ are positive numbers bounded below and above by

$$A\Gamma(n)B^n<A_n(-1)^{n+1}<C\Gamma(\tfrac{5}{2}n)D^n, \quad (2.2)$$

where A, B, C, and D are positive constants.[5] Equation (2.2) implies that, although the perturbation series [Eq. (2.1)] is finite in every order, the ground-state energy is not an analytic function of λ^α about $\lambda=0$ for any α.

Method 2. The A_n can also be calculated from a difference equation. To derive this difference equation we use the differential equation [Eq. (1.1)] which is

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x), \quad (2.3)$$

and the boundary conditions [Eq. (1.2)]

$$\lim_{x\to\pm\infty}\Phi(x)=0. \quad (2.4)$$

In Eq. (2.3), we substitute

$$\Phi(x)=\sum_{n=0}^{\infty}\lambda^n e^{-x^2/4}B_n(x), \quad (2.5)$$

where $B_0=1$ and $B_n(x)$ are the polynomials in x to be determined for $n=1, 2, 3, \cdots$.

We then combine Eqs. (2.1), (2.3), and (2.5) to get

$$\sum_{n=0}^{\infty}\lambda^n[xB_n'(x)-B_n''(x)+\tfrac{1}{4}x^4B_{n-1}(x)]$$
$$=(\sum_{n=1}^{\infty}\lambda^nA_n)(\sum_{m=0}^{\infty}\lambda^mB_m(x)). \quad (2.6)$$

Finally, we let $x=\sqrt{2}y$ and

$$B_i(y)=\sum_{j=1}^{2i}y^{2j}B_{i,j}(-1)^i. \quad (2.7)$$

The result is

$$2jB_{i,j}=(j+1)(2j+1)B_{i,j+1}+B_{i-1,j-2}$$
$$-\sum_{p=1}^{i-1}B_{i-p,1}B_{p,j}. \quad (2.8)$$

Equation (2.8) is the desired difference equation because the numbers $B_{i,j}$ are related to the A_n by the simple equation

$$A_n=-B_{n,1}. \quad (2.9)$$

[5] If the Hamiltonian were Wick-ordered, there would be fewer diagrams of order n because a line could not have both ends connected to the same vertex. Thus, the terms in the Wick-ordered perturbation series would be slightly smaller than those of our non-Wick-ordered series. However, the estimate [Eq. (2.2)] would hold for both perturbation series.

Equation (2.8) was used on a computer to calculate the first 75 terms in the ground-state-energy perturbation series [Eq. (2.1)].[6] From these results we have determined that their detailed asymptotic growth is

$$A_n\sim(-1)^{n+1}(6/\pi^3)^{1/2}\Gamma(n+\tfrac{1}{2})3^n. \quad (2.10)$$

[In Appendix D we discuss the details of this computer calculation and list the first 75 terms in the perturbation series to 12-place accuracy. In Appendix E, we present the calculation of Eq. (2.10).]

Numerical investigation of the difference equation [Eq. (2.8)] brings to light the following exact additional properties of the A_n which are not immediately evident from the Feynman-diagram treatment of the perturbation series:

(i) All A_n are rational fractions.

(ii) If we define

$$I_n\equiv(-1)^{n+1}4^nA_n, \quad (2.11)$$

then the I_n are all positive *integers*.

(iii) Every integer I_n is divisible by 3.

We list below the first nine terms in the perturbation series in exact fraction form to illustrate the above characteristics of the A_n.

$$A_1=\tfrac{3}{4}, \quad (2.12a)$$
$$A_2=-21/8, \quad (2.12b)$$
$$A_3=333/16, \quad (2.12c)$$
$$A_4=-30\,885/128, \quad (2.12d)$$
$$A_5=916\,731/256, \quad (2.12e)$$
$$A_6=-65\,518\,401/1024, \quad (2.12f)$$
$$A_7=2\,723\,294\,673/2048, \quad (2.12g)$$
$$A_8=-1\,030\,495\,099\,053/32\,768, \quad (2.12h)$$
$$A_9=54\,626\,982\,511\,455/65\,536. \quad (2.12i)$$

III. ANALYTIC CONTINUATION OF ENERGY LEVELS

In Sec. II and associated appendices, we studied the properties of the ground-state-energy perturbation series [Eq. (2.1)]. However, this study did not reveal the reason for the divergence of the series. In other words, the singularity structure of $E_0(\lambda)$ in the complex λ plane is as yet unknown. In this section, we define the analytic continuation of the energy levels, which are the eigenvalues of the differential equation [Eq. (1.1)], into the λ plane. Then we present some heuristic derivations of some properties of this continuation.

[6] One author (CMB) wishes to acknowledge partial financial support for this calculation from Dr. B. M. McCoy.

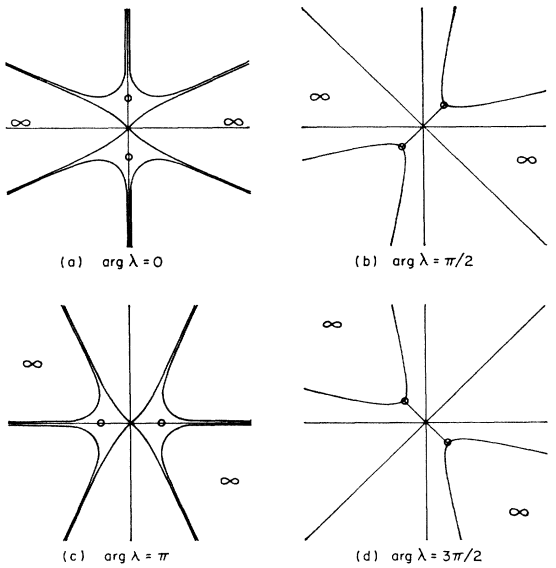

FIG. 1. Curves in the complex x plane where $\mathrm{Re}\lambda^{-1}[(1+\lambda x^2)^{1/2}-1]=0$ for various values of $\arg\lambda$. The circles denote the turning points at $x=\pm i\lambda^{-1/2}$. The symbol ∞ indicates the sectors in which the boundary condition [Eq. (3.4)] applies.

We shall need only Eqs. (1.1) and (1.2) which are

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x) \tag{3.1}$$

and

$$\lim_{x\to\pm\infty}\Phi(x)=0. \tag{3.2}$$

Equations (3.1) and (3.2) yield the asymptotic behavior of $\Phi(x)$ for large $|x|$ along the real axis:

$$\Phi(x)\sim\exp(-\tfrac{1}{6}\lambda^{1/2}|x|^3). \tag{3.3}$$

Equation (3.3) implies that Eq. (3.2), the boundary condition, holds not only on the real axis but also for complex x in the sector $|\arg x|<\frac{1}{6}\pi$.

Until now λ has been positive. When λ is complex, $\Phi(x)$ must satisfy the general boundary condition

$$\lim_{|x|\to\infty}\Phi(x)=0 \quad \text{when } |\arg(\pm x)+(\tfrac{1}{6}\arg\lambda)|<\tfrac{1}{6}\pi, \tag{3.4}$$

which follows from Eqs. (3.2) and (3.3).

We can now continue $E(\lambda)$ into the λ plane. We *define* the analytic continuation $E(\lambda)$ by the differential equation [Eq. (3.1)] in which $\Phi(x)$ satisfies the boundary condition in Eq. (3.4).

We shall use Eqs. (3.1) and (3.4) to find some exact properties of the analytic continuation of $E(\lambda)$:

Property (*i*). We may analytically continue $E(\lambda)$ to all points λ (except $\lambda=0$) where $\int_C\Phi^2(x,\lambda)dx\neq 0$. The integral is taken along an appropriate path C in the complex x plane.

Proof. Normalize $\Phi(x)$ by choosing

$$\Phi(0,\lambda)=1 \text{ for an even-parity wave function} \tag{3.5a}$$

and

$$(d/dx)\Phi(0,\lambda)=1 \text{ for an odd-parity wave function.} \tag{3.5b}$$

Vary λ by

$$\lambda\to\lambda+\delta\lambda. \tag{3.6}$$

Then,

$$E(\lambda)\to E(\lambda)+\delta E(\lambda) \tag{3.7}$$

and

$$\Phi(x,\lambda)\to\Phi(x,\lambda)+\delta\Phi(x,\lambda). \tag{3.8}$$

$\delta\Phi$ has the property that

$$\delta\Phi(0,\lambda)=0 \quad \text{or} \quad \delta\Phi'(0,\lambda)=0$$

for even or odd parity, respectively. $\delta\Phi(x,\lambda)$ obeys the same boundary conditions at ∞ as $\Phi(x,\lambda)$ does, namely, Eq. (3.4).

Substituting Eqs. (3.6), (3.7), and (3.8) into Eq. (3.1) gives

$$(d^2/dx^2-\tfrac{1}{4}x^2-\tfrac{1}{4}\lambda x^4)\delta\Phi(x,\lambda)-\tfrac{1}{4}\delta\lambda x^4\Phi(x,\lambda) =-E(\lambda)\delta\Phi(x,\lambda)+\delta E(\lambda)\Phi(x,\lambda). \tag{3.9}$$

Multiply Eq. (3.9) by $\Phi(x,\lambda)$. Then integrate by parts along a path C in the complex x plane such that each end of the path goes to ∞ in a sector in which the boundary condition [Eq. (3.4)] applies. [See Fig. 1 for the location of the sectors in which Eq. (3.4) applies for various choices of $\arg\lambda$.] The result of this manipulation is

$$0=\tfrac{1}{4}\delta\lambda\int_C x^4\Phi^2(x,\lambda)dx-\delta E(\lambda)\int_C\Phi^2(x,\lambda)dx. \tag{3.10}$$

Hence, $E(\lambda)$ is analytic (its derivative with respect to complex λ exists) at all points except those for which

$$\int_C\Phi^2(x,\lambda)dx=0. \tag{3.11}$$

Equation (3.11) will be used in Sec. VI as a condition for determining the location of the singularities of $E(\lambda)$.

Property (*ii*). At points where $E(\lambda)$ is analytic, there is no degeneracy in the energy.

Proof. Suppose $\Phi_1(x,\lambda)$ and $\Phi_2(x,\lambda)$ are two linearly-independent wave-function solutions to Eq. (3.1) each associated with energy E. We find that the derivative of the Wronskian $W'[\Phi_1(x),\Phi_2(x)]$ vanishes. Hence the Wronskian W is a constant. Because Φ_1 and Φ_2 obey the boundary condition [Eq. (3.4)], the constant must be 0. A vanishing Wronskian implies that Φ_1 and Φ_2 are not linearly-independent. Hence there is no degeneracy.

Property (*iii*). If there is a point λ_0 in the λ plane where $E_1(\lambda)\to E_2(\lambda)$ as $\lambda\to\lambda_0$, then $E_1(\lambda)$ is singular at $\lambda=\lambda_0$.

Proof. If $\Phi_i(x,\lambda)$ are the wave functions associated with $E_i(\lambda)$ for $i=1$ and 2, then because of property (ii)

$\Phi_1(x,\lambda) \to \Phi_2(x,\lambda)$ as $\lambda \to \lambda_0$. Consider the equation

$$\Phi_1(x,\lambda)(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi_2(x,\lambda) = E_2\Phi_1(x,\lambda)\Phi_2(x,\lambda). \quad (3.12)$$

Integrating Eq. (3.12) over the contour C in the complex x plane and integrating by parts gives

$$(E_1-E_2)\int_C \Phi_1(x,\lambda)\Phi_2(x,\lambda)dx=0. \quad (3.13)$$

Thus, when $\lambda \neq \lambda_0$,

$$\int_C \Phi_1(x,\lambda)\Phi_2(x,\lambda)dx=0. \quad (3.14)$$

Letting $\lambda \to \lambda_0$ in Eq. (3.14) gives

$$\int_C \Phi_2^2(x,\lambda)dx=0, \quad (3.15)$$

which is just Eq. (3.11). As a result of property (i), $E_1(\lambda)$ is singular at $\lambda=\lambda_0$. Thus, level crossing only occurs at singularity points of $E(\lambda)$.

Property (iv). The singularities of $E(\lambda)$ are of the square-root type for $\lambda \neq 0$.

Proof. Suppose $E(\lambda)$ has a singularity at $\lambda=\lambda_0\neq 0$. Let

$$\epsilon=(\lambda-\lambda_0)^{1/2}. \quad (3.16)$$

Then,

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda_0 x^4+\tfrac{1}{4}\epsilon^2 x^4)\Phi(x,\epsilon)=E(\epsilon)\Phi(x,\epsilon). \quad (3.17)$$

Expand

$$\Phi(x,\epsilon)=\Phi_0(x)+\epsilon\Phi_1(x)+\epsilon^2\Phi_2(x)+\cdots \quad (3.18)$$

and

$$E(\epsilon)=\alpha+\epsilon\beta+\epsilon^2\gamma+\cdots. \quad (3.19)$$

If we let $\Theta(x)=-d^2/dx^2+\frac{1}{4}x^2+\frac{1}{4}\lambda_0 x^4$, then

$$\Theta(x)\Phi_0(x)=\alpha\Phi_0(x), \quad (3.20a)$$

$$\Theta(x)\Phi_1(x)=\alpha\Phi_1(x)+\beta\Phi_0(x), \quad (3.20b)$$

and

$$\Theta(x)\Phi_2(x)+\tfrac{1}{4}x^4\Phi_0(x)=\alpha\Phi_2(x)+\beta\Phi_1(x)+\gamma\Phi_0(x). \quad (3.20c)$$

Equation (3.20b) gives no useful information, but multiplying Eq. (3.20c) by $\Phi_0(x)$ and integrating gives

$$\beta=\int_C \tfrac{1}{4}x^4\Phi_0^2(x)dx \Big/ \int_C \Phi_1(x)\Phi_0(x)dx. \quad (3.21)$$

β exists if the denominator in Eq. (3.21) does not vanish[7]; that is,

$$\int_C \Phi_1(x)\Phi_0(x)dx\neq 0. \quad (3.22)$$

[7] To zeroth order in the WKB expansion discussed in Secs. IV and VI, it can be shown that for those points which satisfy Eq. (3.11), Eq. (3.22) is indeed true. If Eq. (3.22) were not true, we would have to reexpand $E(\lambda)$ and $\Phi(x,\lambda)$ in terms of $(\lambda-\lambda_0)^{1/3}=\epsilon$. Physically, this would mean that three energy levels cross at λ_0 instead of two as is the case. One would expect intuitively that the chance of three levels crossing at the same point λ_0 is small.

An argument similar to the one given in the proof of property (i) implies that λ_0 is a square-root-type singularity point of $E(\lambda)$. Since a square-root singularity has associated with it a double Riemann sheet, energy-level crossing must take place at all points $\lambda_0\neq 0$ satisfying Eq. (3.11).

IV. WKB SOLUTION

In this section, we shall approximate the wave function $\Phi(x)$ using zeroth-order WKB techniques.[8] We only consider the case where $|\lambda|$ is small. We will need Eqs. (1.1) and (1.2) which are

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x) \quad (4.1)$$

and

$$\lim_{x\to\pm\infty}\Phi(x)=0. \quad (4.2)$$

The zeroth-order WKB solution to Eq. (4.1) is[8]

$$\Phi=\text{const}\times\mu^{-1/2}\exp\left(\pm\int^x \mu(x)dx\right), \quad (4.3)$$

where

$$\mu(x)=[-E(\lambda)+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4]^{1/2}. \quad (4.4)$$

For large $|x|$, Eq. (4.3), the zeroth-order WKB solution, becomes

$$\Phi(x)\sim\text{const}\times(x^2+\lambda x^4)^{-1/4}\times\exp\{(-6\lambda)^{-1}[(1+\lambda x^2)^{3/2}-1]\}. \quad (4.5)$$

Given $\arg\lambda$, we use Eq. (4.5) to locate in the complex x plane the turning points and the sectors in which the general boundary condition [Eq. (3.4)] applies. The turning points are at $\pm i\lambda^{-1/2}$. The boundaries of the above sectors are curves given by

$$\text{Re}\{\lambda^{-1}[(1+\lambda x^2)^{3/2}-1]\}=0.$$

The sectors and turning points are plotted in Fig. 1 for $\arg\lambda=0$, $\frac{1}{2}\pi$, π, and $\frac{3}{2}\pi$.

We now begin the WKB analysis. Near the origin $x=0$, the differential equation [Eq. (4.1)] becomes

$$(d^2/dx^2+E-\tfrac{1}{4}x^2)\Phi(x)=0, \quad (4.6)$$

which is the defining equation for the parabolic cylinder function $D_{E-\frac{1}{2}}(x)$.[9] The correct physical solution to Eq. (4.6) is

$$\Phi(x)=C[D_{E-\frac{1}{2}}(x)\pm D_{E-\frac{1}{2}}(-x)] \quad (4.7)$$

[8] For a review of zeroth-order WKB techniques, see A. Messiah, *Quantum Mechanics* (John Wiley & Sons, Inc., New York, 1961), Vol. 1, pp. 232–233. For a discussion of WKB techniques in the complex plane see T. T. Wu, Phys. Rev. **143**, 1110 (1966).

[9] A. Erdélyi, W. Magnus, F. Oberhettinger, and F. G. Tricomi, *Bateman Manuscript Project* (McGraw-Hill Book Co., New York, 1953), Vol. 2, pp. 116–123. In the future we will refer to this reference as BMP.

for even- or odd-parity wave functions. C is a multiplicative constant.

When the phase of λ is less than 270°, we can asymptotically connect the parabolic cylinder function in Eq. (4.7) to the WKB solution in Eq. (4.5). The connection restricts the possible values of E to

$$E=2n+\tfrac{1}{2} \quad \text{for even parity} \tag{4.8a}$$

and

$$E=2n+\tfrac{3}{2} \quad \text{for odd parity}, \tag{4.8b}$$

where $n=0, 1, 2, \cdots$.

However, Eq. (4.7) cannot be directly connected to Eq. (4.5) when the phase of λ is near 270° because a turning point lies in the path of the connection [see Fig. 1(d)]. Instead, we use the following procedure:

We define new variables $r\equiv xe^{i\pi/4}$, $\rho\equiv\lambda e^{-3\pi i/2}$, and $\epsilon\equiv 4iE$. In terms of these variables, Eq. (4.1) becomes

$$[d^2/dr^2+\tfrac{1}{4}(-\epsilon+r^2-\rho r^4)]\Phi(r)=0. \tag{4.9}$$

We assume that $|\lambda|$ is so small that $|\rho\epsilon|\ll 1$.

We define

$$r_0\equiv\{[1-(1-4\rho\epsilon)^{1/2}](2\rho)^{-1}\}^{1/2}\sim\epsilon^{1/2} \tag{4.10a}$$

and

$$r_1\equiv\{[1+(1-4\rho\epsilon)^{1/2}](2\rho)^{-1}\}^{1/2}\sim\rho^{-1/2}. \tag{4.10b}$$

r_1 is approximately the position of the turning point. $|\rho\epsilon|\ll 1$ implies that $|r_0|\ll|r_1|$.

Next, we identify four regions in the complex x plane: region A in which r is near the origin, $0<|r|\ll|r_0|\ll|r_1|$; region B in which $|r|\ll|r_1|$ but $|r|\gg|r_0|$; region C in which r is near the turning point, $|r|\lesssim|r_1|$ but $|r|\gg|r_0|$; and region D in which r is at the turning point, $|r|\sim|r_1|$.

In order to carry out the WKB procedure when $\arg\lambda$ is near 270°, approximate solutions to Eq. (4.9) must be found in regions A, B, C, and D. Then these solutions must be connected asymptotically at the boundaries of the regions.

Region A. In region A, Eq. (4.9) becomes approximately (that is, to zeroth order in λ)

$$(d^2/dr^2-\tfrac{1}{4}\epsilon-\tfrac{1}{4}r^2)\Phi_A(r)=0. \tag{4.11}$$

Equation (4.11) is the transformed defining equation for a parabolic cylinder function.[9] The even-parity solution to this equation is

$$\Phi_A(r)=C[D_{-\frac{1}{2}-i\epsilon/4}(re^{-i\pi/4})+D_{-\frac{1}{2}-i\epsilon/4}(-re^{-i\pi/4})]. \tag{4.12}$$

(In this section, we will treat even-parity wave functions in detail; only the final results will be given for odd-parity solutions.)

To compute the asymptotic expansion of Φ_A in region A, we need the leading term in the asymptotic expansion of $D_\nu(z)$,[9] which is

$$D_\nu(z)\sim z^\nu e^{-\frac{1}{4}z^2} \quad \text{for } -\tfrac{3}{4}\pi<\arg z<\tfrac{3}{4}\pi \tag{4.13a}$$

and

$$D_\nu(z)\sim z^\nu e^{-\frac{1}{4}z^2}-[(2\pi)^{1/2}/\Gamma(-\nu)]e^{\nu\pi i}z^{-\nu-1}e^{\frac{1}{4}z^2}$$

$$\text{for } \tfrac{1}{4}\pi<\arg z<(5/4)\pi. \tag{4.13b}$$

Equation (4.13) yields the asymptotic behavior of $\Phi_A(r)$ in region A for large $|r|$; that is, for r near region B. After much algebraic manipulation we have the desired asymptotic expansion:

$$\Phi_A(r)\sim\frac{C_1}{\sqrt{r}}\left\{\frac{1}{\Gamma(\frac{1}{4}-\frac{1}{8}i\epsilon)}\exp[\tfrac{1}{4}i(r^2-\epsilon\ln r+\tfrac{1}{2}\epsilon\ln 2-\tfrac{1}{2}\pi)]\right.$$

$$\left.+\frac{1}{\Gamma(\frac{1}{4}+\frac{1}{8}i\epsilon)}\exp[-\tfrac{1}{4}i(r^2-\epsilon\ln r+\tfrac{1}{2}\epsilon\ln 2-\tfrac{1}{2}\pi)]\right\}, \tag{4.14}$$

where

$$C_1=\frac{C2\pi e^{\pi\epsilon/16}2^{-i\epsilon/8}}{\Gamma(\frac{3}{4}+\frac{1}{8}i\epsilon)}. \tag{4.15}$$

Region B. In regions B and C, we need the zeroth-order WKB solution[8] to Eq. (4.9) which is

$$\Phi_{\mathrm{WKB}}(x)=(-\epsilon+r^2-\rho r^4)^{-1/4}$$

$$\times\left\{C_2\exp\left[\tfrac{1}{2}i\int_{r_0}^{r}(-\epsilon+r^2-\rho r^4)^{1/2}dr\right]\right.$$

$$\left.+C_3\exp\left[-\tfrac{1}{2}i\int_{r_0}^{r}(-\epsilon+r^2-\rho r^4)^{1/2}dr\right]\right\}. \tag{4.16}$$

In Eq. (4.16), we choose to integrate from the reference point r_0. We are free to choose the reference point, but this choice must be maintained for the WKB solution in region C as well as in region B.

For r in region B, the choice of r_0 and r_1 in Eq. (4.10) allows us to simplify Eq. (4.16). To zeroth order in ρ,

$$(-\epsilon+r^2-\rho r^4)\sim r^2-\epsilon. \tag{4.17}$$

Using Eq. (4.17), we easily evaluate the integrals and expand the expression in front of the curly brackets in Eq. (4.16). The result is

$$\Phi_B(x)\sim(1/\sqrt{r})\{C_2\exp[\tfrac{1}{4}i(r^2-\epsilon\ln r-\tfrac{1}{2}\epsilon+\epsilon\ln(\tfrac{1}{2}\sqrt{\epsilon}))]$$
$$+C_3\exp[-\tfrac{1}{4}i(r^2-\epsilon\ln r-\tfrac{1}{2}\epsilon+\epsilon\ln(\tfrac{1}{2}\sqrt{\epsilon}))]\}. \tag{4.18}$$

Region C. In region C, we need the zeroth-order WKB solution [Eq. (4.16)] to Eq. (4.9). The WKB solution in region C has the same constants C_2 and C_3 as the solution in region B. However, the integrals for region C are more difficult to perform than those for region B because of the approximations associated with region C which are $|r_0|\ll|r|\lesssim|r_1|$. We use the following

decomposition to evaluate the integrals:

$$\tfrac{1}{2}i\int_{r_0}^{r} dr(-\epsilon+r^2-\rho r^4)^{1/2} = -\tfrac{1}{2}i\rho^{1/2}\int_{r}^{r_1}[(r^2-r_0^2)(r_1^2-r^2)]^{1/2}dr + \tfrac{1}{2}i\rho^{1/2}\int_{r_0}^{r_1}[(r^2-r_0^2)(r_1^2-r^2)]^{1/2}dr. \quad (4.19)$$

To do the first integral, we introduce a change of variables

$$R=r_1-r. \quad (4.20)$$

Then, the integral becomes

$$-\tfrac{1}{2}i\rho^{1/2}(2r_1)^{1/2}(r_1^2-r_0^2)^{1/2}\int_0^R R^{1/2}dR \sim -i3^{-1}2^{1/2}\rho^{-1/4}R^{3/2}. \quad (4.21)$$

In the second integral (the definite integral), we let $K^2=1-r_0^2r_1^{-2}$. Then,

$$\tfrac{1}{2}i\rho^{1/2}\int_{r_0}^{r_1}[(r^2-r_0^2)(r_1^2-r^2)]^{1/2}dr = \tfrac{1}{6}ir_1^3[(1+r_0^2r_1^{-2})E(k)-2r_0^2r_1^{-2}K(k)]. \quad (4.22)$$

$E(k)$ and $K(k)$ are the standard elliptic integrals.[10] Expanding $E(k)$ and $K(k)$ for k near 1 gives[11]

$$E(k)\sim 1+\frac{r_0^2}{4r_1^2}\left(4\ln 2-1-2\ln\frac{r_0}{r_1}\right) \quad (4.23a)$$

and

$$K(k)\sim\ln(4r_1/r_0). \quad (4.23b)$$

Thus,

$$\tfrac{1}{2}i\rho^{1/2}\int_{r_0}^{r_1} dr[(r^2-r_0^2)(r_1^2-r^2)]^{1/2} \sim\frac{i}{6\rho}-\tfrac{1}{8}i\epsilon\left[\ln\frac{1}{\rho\epsilon}+4\ln 2+1\right]. \quad (4.24)$$

We also note that

$$(-\epsilon+r^2-\rho r^4)^{-1/4}\sim\rho^{-1/4}(r_1^2-r_0^2)^{-1/4}(2r_1)^{-1/4}R^{-1/4} \sim 2^{-1/4}\rho^{1/8}R^{-1/4}. \quad (4.25)$$

Equations (4.19)–(4.25) imply that near the turning point the WKB solution [Eq. (4.16)] in region C is asymptotically

$$\Phi_C(r)\sim 2^{-1/4}\rho^{1/8}R^{-1/4}\left\{C_2\exp\left[-\tfrac{1}{3}i\sqrt{2}\rho^{-1/4}R^{3/2}+\frac{i}{6\rho}-\tfrac{1}{8}i\epsilon\left(\ln\frac{1}{\rho\epsilon}+4\ln 2+1\right)\right] +C_3\exp\left[+\tfrac{1}{3}i\sqrt{2}\rho^{-1/4}R^{3/2}-\frac{i}{6\rho}+\tfrac{1}{8}i\epsilon\left(\ln\frac{1}{\rho\epsilon}+4\ln 2+1\right)\right]\right\}. \quad (4.26)$$

Region D. In region D, we use Eq. (4.20) to change variables from r to R in the differential equation [Eq. (4.9)] and find that to zeroth order in ρ

$$(d^2/dR^2+\tfrac{1}{2}R\rho^{-1/2})\Phi_D(R)=0. \quad (4.27)$$

Equation (4.27) is an Airy differential equation.[12] The solution to Eq. (4.27) is

$$\Phi_D(R)=D(\tfrac{1}{3}y)^{1/2}K_{1/3}(2y^{3/2}), \quad (4.28)$$

where

$$y=-(18\sqrt{\rho})^{-1/3}R. \quad (4.29)$$

There is only one undetermined constant D in Eq. (4.28) because only the $K_{1/3}$ function obeys the general boundary conditions at ∞ [Eq. (3.4)].

To determine the behavior of $K_{1/3}(2y^{3/2})$ near the turning point, we note that[13]

$$K_{1/3}(2e^{3\pi i/2}(-y)^{3/2})=-\tfrac{1}{2}i\pi\{e^{i\pi/6}H_{1/3}^{(1)}(2(-y)^{3/2}) +e^{-i\pi/6}H_{1/3}^{(2)}(2y^{3/2})\}. \quad (4.30)$$

Then we use the asymptotic expansions[14] for $H^{(1)}$ and $H^{(2)}$ and find that in region D near the turning point

$$\Phi_D\sim C_4R^{-1/4}[\exp(\tfrac{1}{3}i\sqrt{2}\rho^{-1/4}R^{3/2}-\tfrac{1}{4}i\pi) +\exp(-\tfrac{1}{3}i\sqrt{2}\rho^{-1/4}R^{3/2}+\tfrac{1}{4}i\pi)], \quad (4.31)$$

where

$$C_4=D\pi^{1/2}3^{-1/3}2^{-11/12}\rho^{1/24}. \quad (4.32)$$

We have thus completed the determination of the asymptotic behavior of Φ in regions A, B, C, and D. Next we must connect Φ across regions A and B and across C and D. (Φ in region B is already connected to Φ in region C because the same WKB solution is used in both regions.) Connecting Eq. (4.14) in region A to Eq. (4.18) in region B and Eq. (4.26) in region C to Eq. (4.31) in region D gives two independent determinations of the ratio C_2/C_3. These are, respectively,

$$\frac{C_2}{C_3}=\frac{\Gamma(\frac{1}{4}+\frac{1}{8}i\epsilon)}{\Gamma(\frac{1}{4}-\frac{1}{8}i\epsilon)}\exp\left[i\left(\frac{\epsilon}{2}+\frac{\epsilon}{2}\ln\frac{8}{\epsilon}-\frac{\pi}{2}\right)\right] \quad (4.33a)$$

and

$$\frac{C_2}{C_3}=\exp\left[i\left(\frac{\pi}{2}-\frac{1}{3\rho}+\frac{\epsilon}{4}\ln\frac{16}{\rho\epsilon}+\frac{\epsilon}{4}\right)\right]. \quad (4.33b)$$

[10] BMP, Vol. 2, pp. 317–318.

[11] To expand $E(k)$ and $K(k)$ near $k=1$, we use

$$E(k)=\tfrac{1}{2}\pi\,{}_2F_1(-\tfrac{1}{2},\tfrac{1}{2};1;k^2) \quad \text{and} \quad K(k)=\tfrac{1}{2}\pi\,{}_2F_1(\tfrac{1}{2},\tfrac{1}{2};1;k^2).$$

[See BMP, Vol. 2, p. 318, Eqs. (5) and (6).] Then we consult BMP, Vol. 1, p. 110, Eq. (12), where we find the appropriate expansion for the hypergeometric functions. These expansions may be simplified by using BMP, Vol. 1, pp. 1–20.

[12] BMP, Vol. 2, p. 22.

[13] BMP, Vol. 2, p. 5, Eq. (15) and p. 80, Eq. (43).

[14] BMP, Vol. 2, p. 85, Eqs. (1) and (2).

Combining Eqs. (4.33a) and (4.33b) gives a single transcendental equation which contains ρ and ϵ only.

$$\frac{\Gamma(\frac{1}{4}-\frac{1}{8}i\epsilon)}{\Gamma(\frac{1}{4}+\frac{1}{8}i\epsilon)}=\exp\left[\frac{5i\pi}{4}+\frac{i}{3\rho}+\frac{i\epsilon}{4}\ln\frac{\rho}{2}\right]. \quad (4.34)$$

Because Φ_D goes exponentially to 0 at ∞ as required by Eq. (4.5), we have connected the origin to ∞ via regions A, B, C, and D. We have found that Eq. (4.34) is the one requirement which must be obeyed for this connection to be valid. One should note that since Eq. (4.9) is a second-order differential equation, there are two undetermined constants in each region A, B, C, and D. An equation such as Eq. (4.34) is posible only because parity considerations restrict Φ_A to one constant C_1 and the boundary conditions [Eq. (3.4)] at ∞ limit Φ_D to one constant C_4.

If we rewrite Eq. (4.34) in terms of E instead of ϵ, we get

$$\frac{\Gamma(\frac{1}{4}+\frac{1}{2}E)}{\Gamma(\frac{1}{4}-\frac{1}{2}E)}=\exp\left(\frac{i}{3\rho}+\frac{5\pi i}{4}-E\ln\frac{\rho}{2}\right). \quad (4.35a)$$

For odd-parity wave functions the equivalent result is

$$\frac{\Gamma(\frac{3}{4}+\frac{1}{2}E)}{\Gamma(\frac{3}{4}-\frac{1}{2}E)}=\exp\left(\frac{i}{3\rho}-\frac{5\pi i}{4}-E\ln\frac{\rho}{2}\right). \quad (4.35b)$$

We may regard these results as approximate equations to zeroth order in λ relating the low-lying energy levels to complex λ near $\arg\lambda=270°$.

Appendix F contains a WKB calculation similar to the calculation in this section but to first order in λ. The result of Appendix F is more precise than Eq. (4.35), but it reduces to Eq. (4.35) when terms to first order in λ are neglected.

V. RESOLVENT

As a simple application of Eq. (4.35), we calculate in this section the locations of the singularities of the resolvent of the Hamiltonian H [Eq. (1.3)]. The resolventof the Hamiltonian is conventionally defined as $(z-H)^{-1}$. We will prove that $(z-H)^{-1}$ has poles when $\arg\lambda$ is near 270°.

It is clear that $(z-H)^{-1}$ has a pole in the λ plane whenever the following equations are satisfied:

$$\frac{\Gamma(\frac{1}{4}+\frac{1}{2}z)}{\Gamma(\frac{1}{4}-\frac{1}{2}z)}=e^{5\pi i/4}e^{i/3\rho}e^{-z\ln(\rho/2)} \quad (5.1a)$$

for even parity;

$$\frac{\Gamma(\frac{3}{4}+\frac{1}{2}z)}{\Gamma(\frac{3}{4}-\frac{1}{2}z)}=e^{-5\pi i/4}e^{i/3\rho}e^{-z\ln(\rho/2)} \quad (5.1b)$$

for odd parity.

We solve each of the above equations separately for ρ by taking the logarithm of both sides. Given z, it is always possible to choose a sufficiently small $|\rho|$ so that the $i/3\rho$ term dominates the $z\ln(2/\rho)$ term. Thus, the resolvent has poles at

$$\lambda=e^{3\pi i/2}\left[-3i\ln\frac{\Gamma(\frac{1}{4}+\frac{1}{2}z)}{\Gamma(\frac{1}{4}-\frac{1}{2}z)}+6\pi N+\tfrac{1}{4}\pi\right]^{-1}, \quad (5.2a)$$

provided that z is not an even integer $+\frac{1}{2}$, and at

$$\lambda=e^{3\pi i/2}\left[-3i\ln\frac{\Gamma(\frac{3}{4}+\frac{1}{2}z)}{\Gamma(\frac{3}{4}-\frac{1}{2}z)}+6\pi N-\tfrac{1}{4}\pi\right]^{-1}, \quad (5.2b)$$

provided that z is not an odd integer $+\frac{1}{2}$. In Eq. (5.2), N is any sufficiently large positive integer.

Equation (5.2) implies that for both parities $(z-H)^{-1}$ has an infinite sequence of poles approaching the origin. These correspond to an infinite sequence of choices for large positive N.

That the resolvent has poles was a surprise to us and, as far as we know, this had not even been conjectured. Jaffe[2] has proved that for negative z the resolvent is analytic in the cut λ plane, the cut extending from the origin to $-\infty$ along the negative real axis. This is entirely consistent with our results which maintain that no singularities appear in the resolvent until the phase of the coupling constant reaches nearly $\pm 270°$. Since the analytic continuation of the resolvent disappears through Jaffe's cut at $\arg\lambda=180°$, Jaffe observed no singularities.

VI. QUALITATIVE DESCRIPTION OF $E(\lambda)$

In this section, we use the results of Secs. III and IV to discover the properties of the analytic continuation of the energy levels $E(\lambda)$ as a function of complex λ. For purposes of clarity, this section is divided into three parts. Part A gives a calculation of the locations in the λ plane of the branch points of $E(\lambda)$. Part B describes in detail the paths traced out by the energy levels in the complex E plane as λ moves about the complex λ plane. Part C contains a discussion of level crossing.

A. Locations of Branch Points

We find the coordinates in the λ plane of the branch points of $E(\lambda)$ by solving a pair of simultaneous equations. The first of these is Eq. (4.35) which resulted from matching the zeroth-order WKB solution across the boundaries of regions A, B, C, and D, as was done in Sec. IV. We repeat Eq. (4.35) here:

$$\frac{\Gamma(\frac{1}{4}+\frac{1}{2}E)}{\Gamma(\frac{1}{4}-\frac{1}{2}E)}=\exp\left(\frac{i}{3\rho}+\frac{5\pi i}{4}-E\ln\frac{\rho}{2}\right)$$

for even parity, (6.1a)

$$\frac{\Gamma(\frac{3}{4}+\frac{1}{2}E)}{\Gamma(\frac{3}{4}-\frac{1}{2}E)}=\exp\left(\frac{i}{3\rho}-\frac{5\pi i}{4}-E\ln\frac{\rho}{2}\right)$$

for odd parity. (6.1b)

The second of the simultaneous equations is obtained by explicitly performing the integral in Eq. (3.11) which is

$$0=\int_C dx\,\Phi^2(x,\lambda). \tag{6.2}$$

Equation (6.2) is an exact condition which is satisfied by those λ and only those λ which are branch points of $E(\lambda)$. Now that the approximate WKB wave function is known from Sec. IV, it is possible to evaluate this integral and in turn to use the result to find the branch points. The evaluation is very lengthy and is done in Appendix G. The result of this calculation is

$$0=-\psi(E+\tfrac{1}{2})+\frac{\pi}{2}\cot\left(\frac{1}{4}-\frac{E}{2}\right)\pi+\ln\frac{4}{\rho}$$

for even parity (6.3a)

and

$$0=-\psi(E+\tfrac{1}{2})+\frac{\pi}{2}\cot\left(\frac{3}{4}-\frac{E}{2}\right)\pi+\ln\frac{4}{\rho}$$

for odd parity, (6.3b)

where ψ is the logarithmic derivative of the Γ function. Equation (6.3) now embodies the condition for λ to be a singularity of $E(\lambda)$. Because Eqs. (6.3) and (6.1) are both correct to zeroth order in λ and since these are the pair of simultaneous equations that will be solved to find the singularities of $E(\lambda)$, the positions of the singularities will be known to zeroth order in λ.

Equations (6.1) and (6.3) must be put into a form favorable for simultaneous solution. To do so we use the following procedure:

(i) In this calculation, we consider $|\rho|$ to be small and argρ to be near 0° (because argλ is near 270°). We may express this by

$$\mathrm{Re}(1/\rho)=O(\Lambda) \tag{6.4a}$$

and

$$\mathrm{Im}(1/\rho)=O(\ln\Lambda), \tag{6.4b}$$

where Λ is very large.

(ii) We also consider only low-lying energy levels (that is, levels near the ground state) because the derivation of Eq. (6.1) in Sec. IV is valid only for such levels. We may express this by

$$|E|=O(1). \tag{6.5}$$

(iii) Define η by

$$E=2n+\tfrac{1}{2}+\eta \quad \text{for even parity} \tag{6.6a}$$

and

$$E=2n+\tfrac{3}{2}+\eta \quad \text{for odd parity}, \tag{6.6b}$$

where $n=0, 1, 2, \cdots$.

(iv) Take the logarithm of both sides of Eq. (6.1), substitute Eq. (6.6), and apply the Legendre duplication formula[15] to get

$$\ln\Gamma(-n-\tfrac{1}{2}\eta)-\ln\Gamma(n+\tfrac{1}{2}\eta)+\ln\Gamma(2n+\eta)+\ln(2\sqrt{\pi})-(2n+\eta)\ln 2=\frac{i}{3\rho}+\frac{5\pi i}{4}-E\ln\frac{\rho}{2}-2\pi Ni \tag{6.7a}$$

and

$$\ln\Gamma(-n-\tfrac{1}{2}\eta)-\ln\Gamma(n+\tfrac{1}{2}\eta)+\ln\Gamma(2n+\eta)+\ln(2\sqrt{\pi})-(2n+\eta)\ln 2+\ln(\tfrac{1}{2}+n+\tfrac{1}{2}\eta)=\frac{i}{3\rho}-\frac{5\pi i}{4}-E\ln\frac{\rho}{2}-2\pi Ni. \tag{6.7b}$$

N in this equation is an integer referring to the multiple-valued logarithmic function.

(v) Expand the lnΓ functions using[16]

$$\ln\Gamma(1+z)=-\gamma z+\sum_{m=2}^{\infty}(-1)^m\xi(m)(z^m/m). \tag{6.8}$$

The result is

$$\ln(\tfrac{1}{2}\eta)+\ln(2n)!+\tfrac{1}{2}\ln(2\pi)+\eta\left(-\gamma+\sum_{k=1}^{2n}\frac{1}{k}\right)+\sum_{m=2}^{\infty}\frac{(-1)^m\eta^m}{m}\left\{\xi(m)-\xi(m)\left[\frac{1}{2^m}+\frac{1}{(-2)^m}\right]-\sum_{k=1}^{2n}\frac{1}{k^m}\right\}=\frac{i}{3\rho}+\frac{\pi i}{4}-(n\pi i)-2\pi Ni-(2n+\eta+\tfrac{1}{2})\ln\frac{\rho}{4} \tag{6.9a}$$

and

$$\ln(\tfrac{1}{2}\eta)+\ln(2n+1)!+\tfrac{1}{2}\ln(2\pi)+\eta\left(-\gamma+\sum_{k=1}^{2n+1}\frac{1}{k}\right)+\sum_{m=2}^{\infty}\frac{(-1)^m\eta^m}{m}\left\{\xi(m)-\xi(m)\left[\frac{1}{(2)^m}+\frac{1}{(-2)^m}\right]-\sum_{k=1}^{2n+1}\frac{1}{k^m}\right\}=\frac{i}{3\rho}+\frac{\pi i}{4}-(n\pi i)-2\pi(N+1)i-(2n+\eta+\tfrac{3}{2})\ln\frac{\rho}{4}. \tag{6.9b}$$

(vi) Substitute Eq. (6.6) into Eq. (6.3) and expand the function using[17]

$$\psi(1+z)=-\gamma+\sum_{m=2}^{\infty}(-1)^m\xi(m)z^{m-1}. \tag{6.10}$$

The result is

$$\frac{1}{\eta}+\left(-\gamma+\sum_{k=1}^{2n}\frac{1}{k}\right)+\sum_{m=2}^{\infty}(-1)^m\eta^{m-1}\left[-\sum_{k=1}^{2n}\frac{1}{k^m}+\xi(m)-\left(\frac{1}{2^m}+\frac{1}{(-2)^m}\right)\xi(m)\right]=-\ln(\tfrac{1}{4}\rho) \tag{6.11a}$$

[15] BMP, Vol. 1, p. 5, Eq. (15).
[16] BMP, Vol. 1, p. 45, Eq. (2). $\xi(m)$ is the Riemann zeta function.
[17] BMP, Vol. 1, p. 45, Eq. (5).

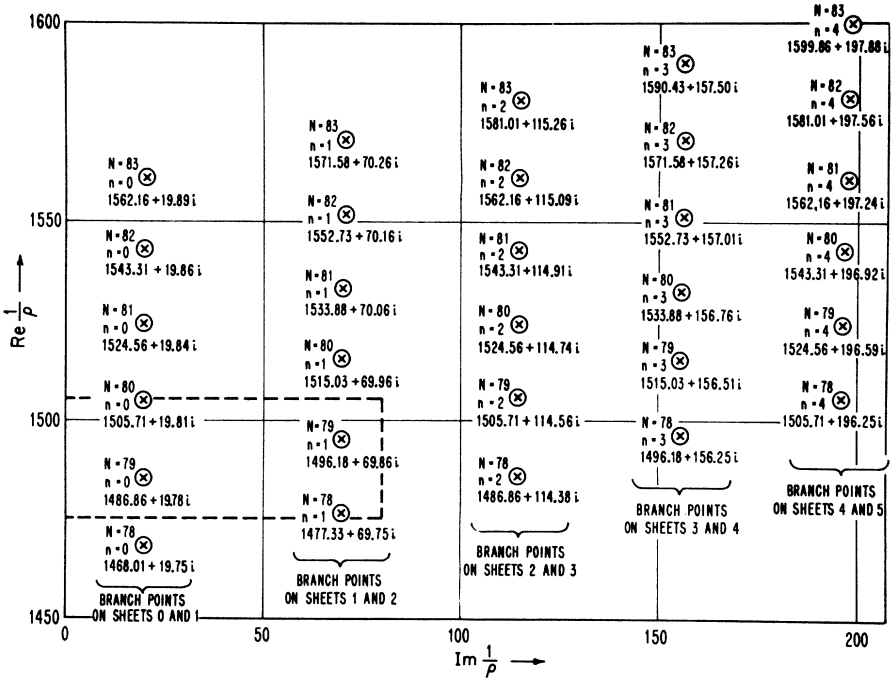

FIG. 2. A portion of the $1/\rho$ plane on which are plotted the even-parity branch points. The branch points are labeled by the integers n ranging from 0 through 4 and N ranging from 78 to 83. Next to each branch point are its coordinates correct to the nearest hundredth. The region of the graph surrounded by the dashed line is enlarged in Fig. 4 and will be discussed in connection with level crossing.

and

$$\frac{1}{\eta}+\left(-\gamma+\sum_{k=1}^{2n+1}\frac{1}{k}\right)+\sum_{m=2}^{\infty}(-1)^m\eta^{m-1}\left[-\sum_{k=1}^{2n+1}\frac{1}{k^m}+\xi(m)-\left(\frac{1}{2^m}+\frac{1}{(-2)^m}\right)\xi(m)\right]=-\ln(\tfrac{1}{4}\rho). \quad (6.11b)$$

Equations (6.9) and (6.11) are now in a form amenable to approximate simultaneous solution. The expansions in Eqs. (6.9) and (6.11) are power series in η and are most susceptible to techniques of approximation if $|\eta|\ll 1$. η is indeed small as will be seen. N is a large integer.

The simultaneous solution consists of using Eqs. (6.9) and (6.11) alternatively to provide successively more accurate approximations to $1/\rho$ and $1/\eta$. First, we use Eq. (6.9). To zeroth order in η, the locations of the singularities in the analytic continuation $E(\lambda)$ are approximately

$$1/\rho=6\pi N \quad (6.12a)$$

and

$$1/\rho=6\pi(n+1). \quad (6.12b)$$

Next we use Eqs. (6.12) and (6.11) to find $1/\eta$ to zeroth order in η:

$$\frac{1}{\eta}=\ln(24\pi N)+\gamma-\sum_{k=1}^{2n}\frac{1}{k} \quad (6.13a)$$

and

$$\frac{1}{\eta}=\ln[24\pi(N+1)]+\gamma-\sum_{k=1}^{2n+1}\frac{1}{k}. \quad (6.13b)$$

Remembering that N is large, we see that Eq. (6.13) verifies the earlier assumption that $|\eta|$ is small. We use Eqs. (6.13) and (6.9) and iterate once more to find the locations of the singularities of $E(\lambda)$ to first order in η:

$$1/\rho=6\pi N+3\pi n-3\pi/4-3i[\ln(2n)!+\tfrac{1}{2}\ln(\pi/2)-\ln\ln N-(2n+\tfrac{1}{2})\ln(24\pi N)-1] \quad (6.14a)$$

and

$$1/\rho=6\pi(N+1)+3\pi n+3\pi/4-3i\{\ln(2n+1)!+\tfrac{1}{2}\ln(\pi/2)-\ln\ln N-(2n+\tfrac{3}{2})\times\ln[24\pi(N+1)]-1\}. \quad (6.14b)$$

Equation (6.14) is the equation we have sought. It lists the coordinates of the branch points of $E(\lambda)$ parametrized by two integers N (large) and n (small).

Before discussing this equation, it is appropriate to make some observations here on the structure of Eqs. (6.9) and (6.11), the simultaneous equations that were used to derive Eq. (6.14). We note that Eq. (6.11) is the derivative of Eq. (6.9) with respect to η. This is true because Eq. (6.3) is the logarithmic derivative of Eq. (6.1) with respect to E. However, the significance of this relationship is not obvious.

An explanation for this relationship comes from a broader interpretation of Eqs. (4.35) than we have chosen to use. We might have assumed that Eqs. (4.35) were more than just equations relating E and λ for small λ. We might have treated them as approximate (to zeroth order in λ) analytic continuations of E as a function of λ. Based on this assumption, the condition for locating those points in the λ plane where the energy

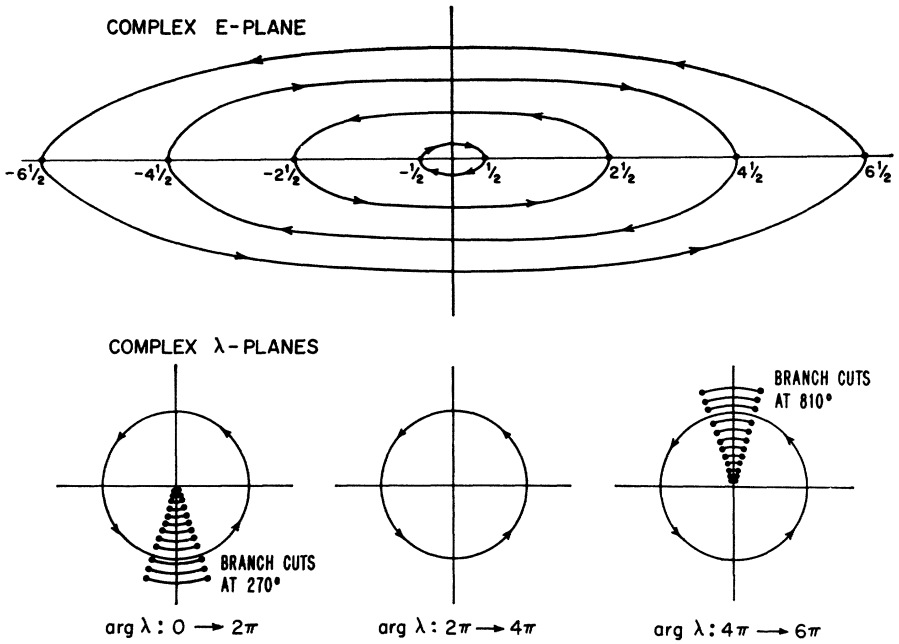

FIG. 3. A rough picture of a tour of the λ plane with the associated image of $E(\lambda)$ in the E plane. $|\lambda|$ is held fixed while $\arg\lambda$ ranges from 0 to 6π. The λ plane is drawn as three planes to show the full rotation of $\arg\lambda$. The branch points and arc-shaped branch lines are indicated schematically. The graph gives the paths of the even-parity energy levels only. The odd-parity levels behave similarly.

is twofold degenerate would be that the derivative of Eq. (6.9) with respect to E (or η) must be a valid equation. Because it gives the correct answer, this argument would have constituted a "derivation" of Eq. (6.11) and would have been a short cut past Appendix G.

We did not use the above argument on grounds of rigor. It is not clear what is meant by an "approximate zeroth-order analytic continuation." It is difficult to understand how one could approximate an exact concept like analyticity by zeroth-order techniques. The laborious method of getting Eq. (6.11) by deriving and evaluating $\int_C \Phi^2(x)dx$ in Sec. III and Appendix G was presented in this paper to avoid these mathematical imprecisions.

Having made this point we return to analyze Eq. (6.14). We note that as the integer N takes on a sequence of values approaching ∞, the associated sequence of branch points in the λ plane given by Eq. (6.14) begins at a finite distance from the origin and has a limit point at the origin. (Remember that $\rho=\lambda e^{-3\pi i/2}$.) That this sequence of branch points has a limit point at the origin explains the divergence of the perturbation series discussed earlier in Sec. II. Note that the origin in the λ plane is not an isolated singularity of $E(\lambda)$.

It is useful to plot the results of Eq. (6.14) on a graph. Figure 2 shows a portion of the $1/\rho$ plane on which are plotted the even-parity branch points labeled by the integer n ranging from 0 through 4 and N ranging from 78 to 83. Next to each branch point are its coordinates correct to two decimal places. The region of the graph surrounded by the dashed line is blown up in Fig. 4 and will be discussed in detail in Part C of this section in connection with level crossing.

It is clear from Fig. 2 that the branch points lie in a sequence of sequences. Each sequence of branch points is labeled by n and each sequence approaches the origin. A glance at Fig. 4 shows that the first ($n=0$) sequence of points lies at an angle of about $\frac{3}{4}°$ less than 270° in the λ plane. The next ($n=1$) sequence lies approximately $2\frac{1}{2}°$ less than 270°. Each successive sequence is rotated by a small angle toward the real axis in the λ plane.

However, we suspect that as n increases, these sequences bunch up before they reach 180° and that no branch points have a complex argument of less than 180°. If there were such branch points then, by the argument of Sec. V, the resolvent of the Hamiltonian would have poles in the cut λ plane. Jaffe[2] proved that this is not so. Unfortunately, Eq. (6.14) only holds for small n so this bunching phenomenon cannot be illustrated graphically.[18]

B. Paths in E Plane

Having found the branch points of $E(\lambda)$, we can give a qualitative picture of the complex function $E(\lambda)$. We will do this by tracing the paths of the energy levels in the complex E plane as λ moves about the complex λ plane.

We begin our analysis by observing that both differential equations [Eqs. (4.1) and (4.9)] are real in

[18] In Sec. VI C, it will be shown that the WKB solution [Eq. (6.1)] is valid in two semidisk-shaped regions of the λ plane bounded by $\arg\lambda=270°\pm90°$ and $\arg\lambda=810°\pm90°$. In the rest of the λ plane, the WKB solution is superseded by Eq. (4.8). Since the existence of branch points is a phenomenon associated only with Eq. (6.1), branch points must lie throughout the region in which Eq. (6.1) holds. Therefore, we expect that the bunching phenomenon occurs at the boundaries of the region; that is, at $\arg\lambda=180°$, 360°, 720°, and 900°.

their respective variables. From this arise some symmetry properties of $E(\lambda)$ which are

$$E(\lambda)=E^*(\lambda^*)=-E^*(e^{3\pi i}\lambda^*)=-E(e^{3\pi i}\lambda). \quad (6.15)$$

We also note that since the Hamiltonian [Eq. (1.3)] is Hermitian and positive definite, the energy levels lie along the positive real axis in the energy plane when λ is positive real. Similarly, when $\arg\lambda=270°$, Eq. (4.9) indicates that the energy levels are pure imaginary. At $\arg\lambda=270°$, the energy levels lie on both the positive and negative imaginary axes.

Equation (4.8) indicates that for fixed $|\lambda|$ the energy levels lie near the real axis in the energy plane as $\arg\lambda$ increases from 0 until nearly 270°. However, for $\arg\lambda$ in the neighborhood of 270° the full energy spectrum moves rapidly toward the imaginary axis.

Combining the symmetry properties [Eq. (6.1)] with the results of the previous two paragraphs enables us to predict the paths of the energy levels in the complex E plane when $|\lambda|$ is held fixed and $\arg\lambda$ is varied. (These paths are given in Fig. 3.) We predict that:

(i) When $\arg\lambda=0$, the energy spectrum lies along the positive real axis.

(ii) As $\arg\lambda$ increases toward $\frac{1}{4}(6\pi)$, each energy level traces out a path in the complex E plane which approaches the imaginary axis. The energy levels lie along the imaginary axis at $\arg\lambda=\frac{1}{4}(6\pi)$.

(iii) At $\arg\lambda=\frac{1}{2}(6\pi)$, the energy levels lie on the negative real axis at points equal to the negative of their original values for $\arg\lambda=0$.

(iv) As $\arg\lambda$ increases from $\frac{1}{2}(6\pi)$ to 6π, each energy level traces a path reflectionally symmetric about the origin to the path described above. At $\arg\lambda=6\pi$ the energy levels return to the values on the real axis that they had for $\arg\lambda=0$.

Thus, as λ goes in a circle three times about the origin in the λ plane, starting at the real axis, each energy level in the E plane traces a closed path starting and ending on the positive real axis. Moreover, it will be shown in Part C of this section that the paths in the complex E plane are concentric and that the directions of successive concentric paths alternate between clockwise and counterclockwise.

Because the energy levels return to their original values when $\arg\lambda$ is increased by 6π, in addition to the branch-point singularities discussed in Part A of this section there is also a $\lambda^{1/3}$ singularity at the origin. However, the divergence of perturbation theory discussed in Sec. II is in no way related to this singularity. If it were, we could then expand $E(\lambda)$ in powers of $\lambda^{1/3}$ and get a convergent power series. But there is no convergent power-series representation of $E(\lambda)$ about the origin in any fractional power of λ. Perturbation theory diverges because of the sequences of branch points discussed in Part A of this section.

How do these branch points affect the curves in the E plane in Fig. 3? Surprisingly, the answer to this question is "*not at all.*" To understand why this is we argue as follows:

(i) As proved in Sec. III, each of these singularities is a square-root type. (In the neighborhood of each branch point, there is a double-sheeted Riemann surface.) Level crossing (twofold degeneracy) must occur at each branch point. A branch line is connected to each singularity.

(ii) The symmetry properties listed in Eq. (6.15) imply that there is another set of branch points symmetrically reflected about 270° in the λ plane. Moreover, all these singularities (those in Fig. 2 and those reflected through 270°) also must occur at −270° (which is the same as 810° because of the cube-root singularity at the origin).

(iii) The branch lines join the branch points on either side of 270° and on either side of 810° pairwise; that is, each point is joined to its reflected image. These branch cuts are shaped like circular arcs and are very short because the branch points lie a short distance from either side of 270° or 810°. The cuts form two sequences of concentric arcs with each sequence of arcs approaching the origin. These cuts are schematically displayed on Fig. 3.

(iv) In the circular tour of the λ plane shown on Fig. 3 it is clear that none of the branch cuts was crossed because $|\lambda|$ was held fixed.

This reasoning explains why the branch points could not affect the curves in the E plane in Fig. 3. In addition, it shows that the presence of the branch points can never be detected as long as $|\lambda|$ is held fixed.

Therefore, to exhibit the delicate intricacy of this theory caused by the array of cuts in Fig. 3, we must make a new tour of the λ plane in which we cross the branch cuts. We still increase $\arg\lambda$ from 0 to 6π. However, when $\arg\lambda$ is near 270° (or 810°) we vary $|\lambda|$ so that the path in the λ plane crosses a branch line. If we follow an energy level as it traces a path in the complex E plane, we find that it returns to the positive real axis when $\arg\lambda=6\pi$ but as a different energy level from the original. This is what is meant by level crossing.

A complete description of level crossing is given in Part C of this section. Nevertheless, it should now be clear that the energy levels are completely interrelated by the structure of the branch cuts. That is, one can get to any given energy level from any other energy level by continuing around the appropriate branch points.

As a corollary of this, once one knows the ground-state energy of the anharmonic oscillator, one knows all the energy levels by analytic continuation. Or, in other words, *the physical energy levels of the anharmonic oscillator for a given positive real* λ *are the positive real values of* $E(\lambda)$ *on each of the infinite number of branches of a Riemann surface. Each energy level corresponds to a sheet of this Riemann surface.* This is the major result of our paper.

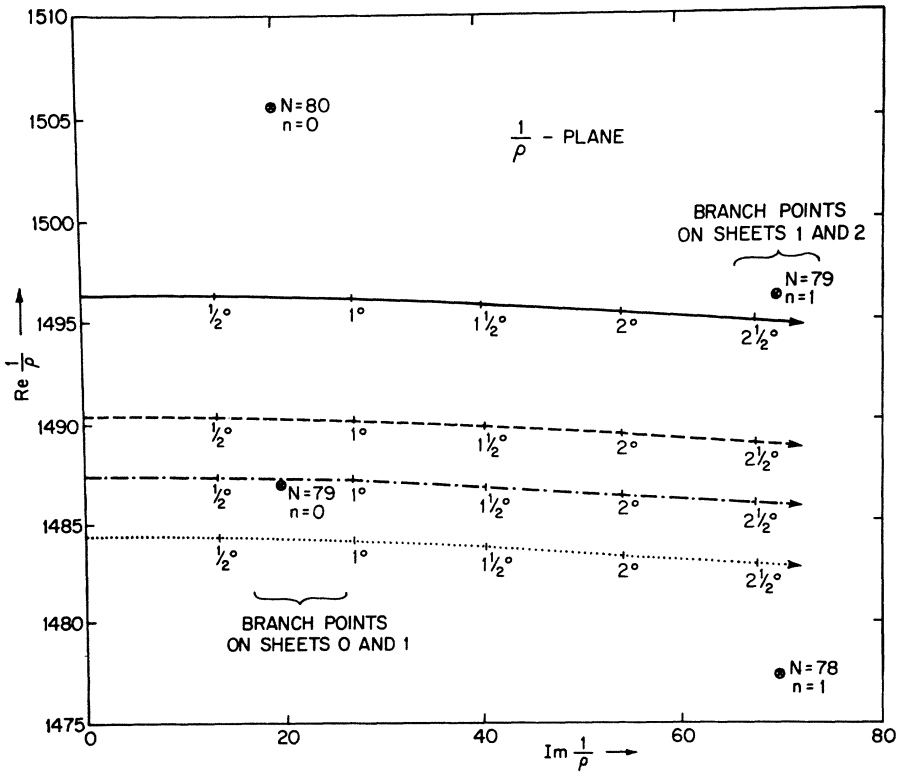

FIG. 4. An enlargement of a small portion of the $1/\rho$ plane of Fig. 2. The $(N=78, n=1)$, $(N=79, n=0)$, $(N=79, n=1)$, and $(N=78, n=1)$ branch points are precisely located. Four short circular arcs of unequal radii are drawn and the angular rotation along each arc is given in degrees. The arcs are indicated by a solid line, dashed line, dash-dotted line, and dotted line. The radii of these arcs to the nearest hundredth are 1496.50, 1490.50, 1487.50, and 1484.50, respectively. The images of these arcs in the E plane are plotted on Fig. 5 in connection with level crossing.

C. Level Crossing

We have shown that level crossing takes place at the branch points in the λ plane and we know the positions of these branch points. But the details of level crossing are not yet fully explained. In particular, in this part of Sec. VI we will answer these questions: (a) Which levels cross at which branch points? (b) What does level crossing look like graphically?

To give a precise answer to these questions, we carry out an intensive program of numerical calculation which enables us to construct Figs. 4 and 5. Figures 4 and 5 will give a beautiful pictorial answer to the questions we have posed. The numerical calculation involves the following procedure:

(i) We take a sequence of circular paths of varying radii in the $1/\rho$ plane. (This is equivalent to and easier to handle numerically than a sequence of circles in the λ plane.) The image of each of these circles in the E plane is a set of energy-level curves like those crudely drawn in Fig. 3. As in Fig. 3, we will consider the even-parity case only. (The odd-parity case is qualitatively similar.)

(ii) By symmetry [see Eq. (6.15) and the accompanying discussion] we need only to vary $\arg\lambda$ from 0° to 270°. Moreover, until $\arg\lambda$ is very nearly 270°, the energy levels stay extremely close to the values given in Eq. (4.8a). Therefore, we only need to consider the portions of the energy-level curves for λ near 270° (that is, where $1/\rho$ is approximately real).

(iii) We choose the sequence of radii in the $1/\rho$ plane so that a branch point is crossed. We then use Eq. (6.1a) to plot points accurately in the E plane and expect to observe the process of level crossing. We choose four values for the radii of the curves in the $1/\rho$ plane. To the nearest hundredth, these values of $|1/\rho|$ are 1496.50, 1490.50, 1487.50, and 1484.50. These curves are drawn on Fig. 4. (Figure 4 is an enlarged version of a part of Fig. 2. That portion which is enlarged is indicated on Fig. 2 by a dashed line.) The branch point that is crossed is the one labeled $N=79$, $n=0$.

(iv) We then choose points along the curves in Fig. 4 and solve the transcendental equation [Eq. (6.1)] numerically for complex E to the nearest hundredth. To solve Eq. (6.1a) numerically we take the logarithm of both sides. This gives

$$\ln\Gamma(\tfrac{1}{4}+\tfrac{1}{2}E)-\ln\Gamma(\tfrac{1}{4}-\tfrac{1}{2}E) = \frac{i}{3\rho}+\frac{5\pi i}{4}+E\ln\frac{2}{\rho}+2\pi iM. \quad (6.16)$$

M is an integer referring to the many-valued logarithmic function. M occurs for the same reason that N did in Eq. (6.7).

(v) We choose the branch line for the logarithmic function in Eq. (6.16) to lie along the negative real axis. We then break up Eq. (6.16) into its real and imaginary parts and, given $1/\rho$, solve the resulting

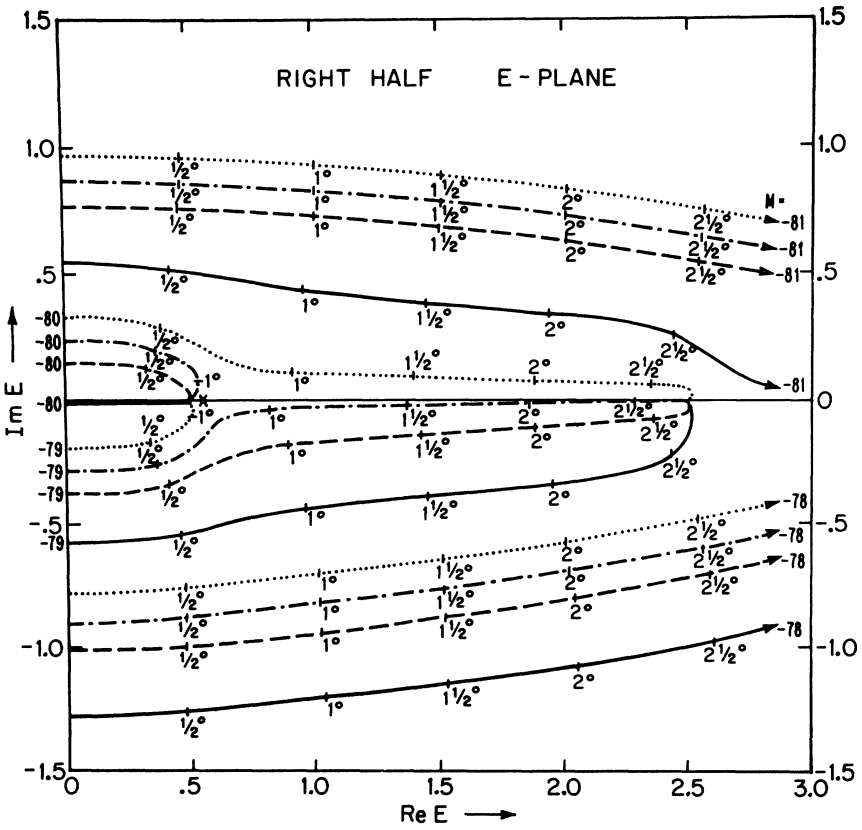

FIG. 5. The complex E plane, showing to the nearest hundredth the images of the circular arcs in the $1/\rho$ plane of Fig. 4. These curves exhibit level crossing. The precise point where this level crossing occurs is marked with an ×. × is the image of the branch point ($N=79$, $n=0$). The energy-level curves shown correspond with the four lowest energy levels. The curves are labeled by their M values [see Eq. (6.16)] and are represented by dotted, dot-dashed, dashed, and solid lines to correspond with the values of $|1/\rho|$ on Fig. 4 (1484.50, 1487.50, 1490.50, and 1496.50). The numbers in degrees along each curve indicate the rotation in the $1/\rho$ plane of the preimage points along the curves on Fig. 4.

pair of simultaneous transcendental equations for E. The solution is a painstaking trial-and-error process involving tables of $\ln\Gamma(z)$ functions. Fortunately, this mammoth task is tractable because $\arg(1/\rho)$ is small, ranging from 0 to approximately 3° (see Fig. 4). Several hundred values for E have been plotted on Fig. 5 and the energy-level curves have been drawn and labeled by their M values. We have plotted the energy-level curves connected to the four lowest energy levels.

This completes the description of the construction of Figs. 4 and 5. We list below our observations and conclusions with regard to these graphs.

As $|1/\rho|$ gets smaller, we observe that the points where the energy-level curves meet the imaginary axis in the E plane move upward. {This fact can be proved from the differential equation [Eq. (4.9)] independently of the numerical calculations involved in the graphing of Fig. 5.} Therefore, as $|1/\rho|$ decreases, either we will find that (a) level crossing occurs (that is, the curves associated with a given M value become associated with different energy values along the real E axis) or else that (b) the curves all remain attached to the same energy values on the real E axis and stretch higher and higher up the imaginary axis. The enormous distortion of the curves in the latter possibility (b) makes the former (a) a good probability.

Level crossing is indeed found on inspection of Fig. 5. (For each value of M the curves on Fig. 5 are represented in order of decreasing $|1/\rho|$ by solid lines, dashed lines, dash-dotted lines, and dotted lines.) We observe the following example of level crossing.

The solid $M=-79$ line is connected to $E=2\frac{1}{2}$ along the real axis. There is just a hint of inflection as this curve passes below $E=\frac{1}{2}$. Its companion, the solid $M=-80$ line, goes directly to $E=\frac{1}{2}$ and the dash-dotted line inflects strongly. Meanwhile, the companion $M=-80$ lines belly increasingly outward above $E=\frac{1}{2}$ to meet the inflecting $M=-79$ lines. As the curves in the $1/\rho$ plane pass through the $N=79$, $n=0$ branch point, the energy levels flip and the dotted $M=-79$ line is suddenly and discontinuously connected to $E=\frac{1}{2}$ and the companion $M=-80$ line to $E=2\frac{1}{2}$. *This is a precise pictorial description of level crossing.*

It is interesting to determine where the curves connecting $E=\frac{1}{2}$ and $E=2\frac{1}{2}$ cross. To determine this crossing point we have calculated the image of the branch point $N=79$, $n=0$ in the E plane. The crossing point is labeled on Fig. 5 by an ×.

In addition to the above level crossing we also observe an incipient level crossing at $E=2\frac{1}{2}$. As we look at the lines in the opposite order (dotted, dot-dashed, dashed, and solid), we see on Fig. 4 that a level crossing is about to take place at the $N=79$, $n=1$

branch point. The solid lines $M=-81$ and $M=-79$ are ready to cross near $E=2\frac{1}{2}$.

As $|\lambda|$ increases and the circle in the λ plane passes through the appropriate branch points, each pair of adjacent levels flips repeatedly. *Only adjacent levels can cross.* For example, the zeroth and first energy levels cross at $n=0$ branch points, the $n=1$ and $n=2$ energy levels cross at $n=1$ branch points, and so on. In general, *the nth sequence of branch points is common to and lies only on the nth and (n+1)st sheets of the Riemann surface of* $E(\lambda)$. (Remember that the nth sheet is the sheet which contains the nth energy level for real positive λ.) This is equivalent to saying that *the nth and (n+1)st energy levels can only cross at the nth sequence of branch points.*

Figure 5 evokes an additional, unexpected, and most welcome observation. Recall that near $\lambda=270°$ the WKB equation [Eq. (6.1a)] describes the paths of the energy levels in the E plane. Near $\arg\lambda=0$, Eq. (4.8a) describes these paths. Therefore, at some value of $\arg\lambda$ between 270° and 0°, Eq. (6.1a) is no longer accurate and is superseded by Eq. (4.8a). The angle at which this changeover occurs defines the angular opening about 270° (and 810°) in which the WKB solution is valid. The numerical investigations used to plot Fig. 5 give answers to two important questions: (a) At what angle does the changeover occur? (b) How accurate is the WKB result?

To answer these questions, we notice that the curves on Fig. 5 all approach the values predicted by Eq. (4.8a) which are $E=\frac{1}{2}, 2\frac{1}{2}, 4\frac{1}{2}, \cdots$. However, at some angle in the $1/\rho$ plane the WKB result [Eq. (6.1a)] no longer directs the energy-level curves toward these values. At that angle the curves begin to veer away. Therefore, the angle at which the curves are closest to the points $E=\frac{1}{2}, 2\frac{1}{2}, 4\frac{1}{2}, \cdots$ is the answer to question (a). Furthermore, the *distance* of closest approach of the WKB curves to these points is a useful measure of how accurate the WKB solution is and will answer question (b). The WKB result is accurate if the distance of closest approach is small.

It is easy to calculate the changeover angle and the distance of closest approach. We expand $\ln\Gamma(\frac{1}{4}-\frac{1}{2}E)$ in a Taylor series[16] about $E=\frac{1}{2}, 2\frac{1}{2}, 4\frac{1}{2}, \cdots$, and insert the series into Eq. (6.16). We determine from the resulting equation that $\arg(1/\rho)=90°$ is the condition for closest approach. That is, the WKB result applies in an angular opening of 90° on either side of $\arg\lambda=270°$ (and 810°). This answers question (a). This angular opening is much wider than originally anticipated and shows that the WKB solution is valid in a very large region of the λ plane.

Furthermore, the changeover angle at $\arg\lambda=180°$ ties in beautifully with three earlier results of this paper, First, Fig. 1(c) in Sec. IV shows that it is exactly at $\arg\lambda=180°$ that the WKB turning point enters the sector in which the general boundary condition [Eq. (3.4)] applies. This is just the point at which we would expect Eq. (6.1a), the WKB equation, to become valid. Second, a changeover angle of 180° indicates that the bunching phenomenon discussed in Part A of Sec. VI takes place at 180°.[18] Third, when combined with the arguments of Sec. V, a changeover angle of 180° implies that the poles of the resolvent occur when $\arg\lambda$ is larger than 180°. This is consistent with Jaffe's findings.[2]

A short numerical calculation reveals that the distance of closest approach to $E=\frac{1}{2}$ is the amazingly small number $\frac{1}{3}\times10^{-153}$. This distance is much smaller than originally anticipated. It is gratifying to observe that, in answer to question (b), the WKB solution is extremely accurate.

ACKNOWLEDGMENTS

We wish to thank Professor A. M. Jaffe for many interesting discussions. We are most grateful to Mrs. Carl M. Bender for her careful editorial reading of this paper.

APPENDIX A

In this appendix, we use field theory to derive the coordinate representation given by Eqs. (1.1) and (1.2) which are

$$(-d^2/dx^2+\tfrac{1}{4}x^2+\tfrac{1}{4}\lambda x^4)\Phi(x)=E(\lambda)\Phi(x) \tag{A1}$$

and

$$\lim_{x\to\pm\infty}\Phi(x)=0. \tag{A2}$$

A quick derivation follows from substituting

$$\varphi=2^{-1/2}x \quad \text{and} \quad \dot{\varphi}=-i2^{1/2}d/dx \tag{A3}$$

into the Hamiltonian H [Eq. (1.3)] which is

$$H=\tfrac{1}{2}\dot{\varphi}^2+\tfrac{1}{2}m^2\varphi^2+\lambda\varphi^4. \tag{A4}$$

We choose $m=1$ without loss of generality. Then the wave function $\Phi(x)$ satisfies the differential equation [Eq. (A1)]. Equation (A2) results from the requirement that $\Phi(x)$ be normalizable.

A more rigorous derivation follows from the assumption that in Fock space the energy eigenstates of H are normalizable.

In the interaction picture, the representation of the field φ in terms of creation and annihilation operators on Fock space is

$$\varphi=[1/(2m)^{1/2}](ae^{-imt}+a^\dagger e^{imt}), \tag{A5a}$$

$$\dot{\varphi}=(\tfrac{1}{2}m)^{1/2}(-iae^{-imt}+ia^\dagger e^{imt}), \tag{A5b}$$

$$[a,a^\dagger]=1. \tag{A5c}$$

In terms of the creation and annihilation operators, the Hamiltonian is

$$H=m(a^\dagger a+\tfrac{1}{2})+(g/4m^2)(a+a^\dagger)^4. \tag{A6}$$

Let $|E\rangle$ be an eigenstate of H of energy E. Then

$$H|E\rangle=E|E\rangle. \tag{A7}$$

The Fock representation consists of the states

$$|n\rangle=[1/\sqrt{(n!)}](a^\dagger)^n|0\rangle, \quad n=0, 1, 2, \cdots \tag{A8a}$$

where

$$\langle n|m\rangle=\delta_{nm}. \tag{A8b}$$

Assuming that $\{|n\rangle\}$ are a complete set of states,

$$|E\rangle=\sum_{n=0}^{\infty} a_n|n\rangle\sqrt{(n!)}. \tag{A9}$$

Equations (A6)-(A9) can be combined to give a difference equation that the $\{a_n\}$ satisfy:

$$\begin{aligned}Ea_n=m(n+\tfrac{1}{2})a_n+(g/4m^2)[&a_{n-4}+4(n-2)a_{n-2}\\&+6n(n-1)a_n+4n(n+1)(n+2)a_{n+2}\\&+(n+1)(n+2)(n+3)(n+4)a_{n+4}].\end{aligned} \tag{A10}$$

Furthermore, since $|E\rangle$ is assumed normalizable,

$$\sum_{n=0}^{\infty} |a_n|^2 n!<\infty. \tag{A11}$$

From Eq. (A11) it follows that as $n\to\infty$, $|a_n|\to 0$ faster than $1/\sqrt{(n!)}$. Thus, if we define the generating function $f(z)$ by

$$f(z)=\sum_{n=0}^{\infty} a_n z^n, \tag{A12}$$

then $f(z)$ is entire.

The difference equation [Eq. (A10)] becomes a differential equation satisfied by $f(z)$:

$$Ef(z)=\frac{g}{4m^2}\left(z+\frac{d}{dz}\right)^4 f(z)+mz\frac{d}{dz}f(z)+\tfrac{1}{2}mf(z). \tag{A13}$$

The differential equation [Eq. (A13)] and the side condition that $f(z)$ is entire embody the assumption that $|E\rangle$ is an eigenstate of H of finite norm and that $\{|n\rangle\}$ are a complete set of states.

Now let

$$f(z)=e^{-z^2/2}h(z). \tag{A14}$$

Then,

$$\begin{aligned}Eh(z)=&(g/4m^2)h''''(z)\\&+m[zh'(z)-z^2h(z)]+\tfrac{1}{2}mh(z).\end{aligned} \tag{A15}$$

Next we show that $h(z)$ must go to 0 rapidly along the imaginary axis. To do this, we apply the Cauchy formula to Eq. (A12):

$$a_n=\frac{1}{2\pi i}\oint\frac{f(z)}{z^{n+1}}dz=\frac{1}{2\pi i}\oint\frac{e^{-z^2/2}g(z)}{z^{n+1}}. \tag{A16}$$

Suppose that $g(z)$ did not go to 0 along the imaginary axis. In fact, suppose for simplicity that $g(z)$ were constant. Then, since the major contribution to this integral would come from the region where the path of integration crosses the imaginary axis, we calculate (using the method of steepest descent) that $a_n\sim A/\sqrt{n}$ for large n. This contradicts Eq. (A11) and the entirety of $f(z)$. Hence, $h(z)$ must go to 0 along the imaginary axis.

To see how fast $h(z)\to 0$, we consider the differential equation for $h(z)$ [Eq. (A15)]. By systematically investigating pairs of terms, we find that the dominant behavior at large z is given by

$$(g/4m^2)h''''(z)-mz^2h(z)=0. \tag{A17}$$

Thus,

$$h(z)\sim\exp[C\tfrac{2}{3}(4m^2/g)^{1/4}z^{3/2}], \tag{A18}$$

where $C=1, -1, i, -i$. Since there are four solutions to the fourth-order differential equation [Eq. (A17)], we have them all. Combining Eq. (A18) with our knowledge that $h(z)$ goes to 0 along the imaginary axis, we learn that $h(z)$ goes to 0 along the imaginary axis extremely rapidly. Hence, $h(z)$ may be Fourier-transformed along the imaginary axis. We thus define (for real x)

$$h(z)=\int_{-\infty}^{\infty} H(x)e^{zx}dx. \tag{A19}$$

Fourier-transforming Eq. (A15) according to Eq. (A19) gives

$$\begin{aligned}&mH''(x)+mxH'(x)+(E+\tfrac{1}{2}m)H(x)\\&\qquad-(g/4m^2)x^4H(x)=0.\end{aligned} \tag{A20}$$

Finally, we let

$$H(x)=e^{-x^2/4}\Phi(x). \tag{A21}$$

This substitution [Eq. (A21)] simplifies (A20) to

$$m\Phi''(x)+E\Phi(x)-\tfrac{1}{4}mx^2\Phi(x)-(g/4m^2)x^4\Phi(x)=0. \tag{A22}$$

Equation (A22) implies that the dominant behavior of Φ for large x is $e^{|x|^3}$ or $e^{-|x|^3}$. The former is not possible because the inverse transform would not exist and $h(z)$ would be undefined. Hence, $\Phi(x)\to 0$ as $|x|\to\infty$.

We set $m=1$ as we did earlier in this appendix and Eq. (A22) becomes

$$-\Phi''(x)+\tfrac{1}{4}x^2\Phi(x)+\tfrac{1}{4}\lambda x^4\Phi(x)=E\Phi(x), \tag{A23}$$

and

$$\lim_{|x|\to\infty}\Phi(x)=0. \tag{A24}$$

Equations (A23) and (A24) are precisely Eqs. (A1) and (A2). We have thus rigorously derived the coordinate representation and the boundary condition satisfied by the wave function Φ.

This connection between field theory and the wave function in coordinate space will be used in Sec. II and Appendices B and C.

APPENDIX B

In this appendix, we use Feynman rules to calculate A_1, A_2, and A_3. These are the first three terms beyond the constant zero-point energy term in the perturbation series for the ground-state energy [Eq. (2.1)]. The Feynman rules for the anharmonic oscillator considered as a field theory are

$$(E^2-m^2+i\epsilon)^{-1} \quad \text{for a propagator,} \tag{B1a}$$

$$24\lambda \quad \text{for a vertex,} \tag{B1b}$$

$$i(2\pi)^{-1}\int_{-\infty}^{\infty} dE \quad \text{for a loop integration.} \tag{B1c}$$

The symmetry numbers are the same as in the (3+1)-dimensional theory.[19]

The nth term in the perturbation series for the ground-state energy is the sum of all connected n-vertex Feynman diagrams with no external legs. (Each diagram is of course multiplied by its appropriate symmetry number.) Figure 6 shows all such diagrams of order $n=1$, 2, and 3 with their symmetry numbers.[20]

We find the contribution of each of the diagrams by applying the Feynman rules [Eq. (B1)] and by evaluating the resulting simple contour integrals. This calculation yields

$$\begin{aligned}
&(1a)=(24)\tfrac{1}{4}(\lambda/m^3)m,\\
&(2a)=(24)^2(-1/16)(\lambda/m^3)^2m,\\
&(2b)=(24)^2(-1/32)(\lambda/m^3)^2m,\\
&(3a)=(24)^3(3/128)(\lambda/m^3)^3m,\\
&(3b)=(24)^3(5/512)(\lambda/m^3)^3m,\\
&(3c)=(24)^3(3/512)(\lambda/m^3)^3m,\\
&(3d)=(24)^3(1/64)(\lambda/m^3)^3m.
\end{aligned} \tag{B2}$$

Next, we combine the symmetry numbers listed on Fig. 6 with Eq. (B2) and find that[21]

$$A_1=(24/4)\times\tfrac{1}{8}=\tfrac{3}{4}, \tag{B3a}$$

$$A_2=-\frac{(24)^2}{16\times16}-\frac{(24)^2}{32\times48}=-\frac{21}{8}, \tag{B3b}$$

[19] T. T. Wu, Phys. Rev. **125**, 1436 (1962).

[20] The interaction we are discussing is not Wick-ordered. If it were Wick-ordered, only diagrams (2b) and (3c) would contribute to the ground-state-energy perturbation series. All other diagrams would be excluded because they have at least one line emerging from and returning to the same vertex.

[21] In the definition of the ground-state-energy perturbation series [Eq. (2.1)], which is

$$E_0(\lambda)=\tfrac{1}{2}m+\sum_{n=1}^{\infty}(\lambda/m^3)^n mA_n,$$

the factors of m and $(\lambda/m^3)^n$ have been isolated from the A_n.

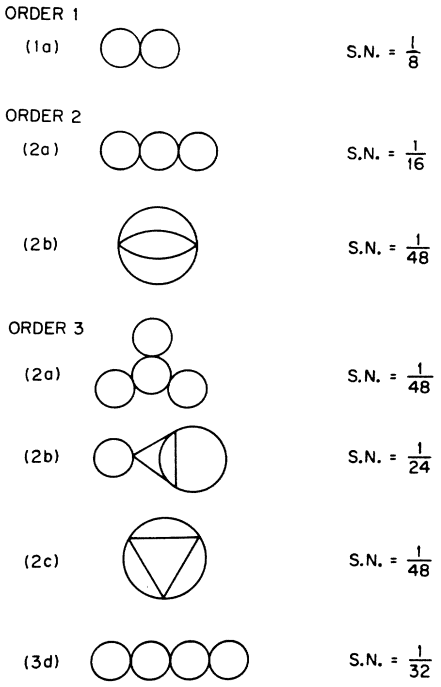

FIG. 6. All connected Feynman diagrams of order $n=1$, 2, and 3 with no external legs. To the right of each diagram is its symmetry number (S.N.).

$$A_3=\frac{(24)^3\times3}{128\times48}+\frac{(24)^3\times5}{512\times24}+\frac{(24)^3\times3}{512\times48}+\frac{(24)^3}{64\times32}=\frac{333}{16}. \tag{B3c}$$

The results in Eqs. (B3a)–(B3c) agree with Eqs. (2.12a)–(2.12c). This agreement illustrates the equivalence of the Feynman-diagram and difference-equation techniques for computing the numbers A_n.

APPENDIX C

Equation (2.2) gave without proof upper and lower bounds on $(-1)^{n+1}A_n$,[22] the terms in the perturbation series for the ground-state energy [Eq. (2.1)]. In this appendix, we rigorously derive these bounds using a Feynman-integral representation.

To develop the notation of the Feynman-integral representation, we restate here the ground-state-energy perturbation series [Eq. (2.1)]:

$$E_0(\lambda)=\tfrac{1}{2}m+\sum_{n=1}^{\infty} m(\lambda/m^3)^n A_n. \tag{C1}$$

A_n is the sum of all connected diagrams of order n (diagrams with n vertices) with no external legs.

[22] We find upper and lower bounds on $(-1)^{n+1}A_n$ because $(-1)^{n+1}A_n$ are positive quantities. This is evident from Eq. (C3).

Rewriting the perturbation series [Eq. (C1)] in terms of individual diagrams gives

$$E_0(\lambda)=\tfrac{1}{2}m+\sum_{n=1}^{\infty} m(\lambda/m^3)^n\sum I, \tag{C2}$$

where the summation $\sum I$ is over all connected diagrams of order n with no external legs.

I is the numerical value of each diagram. In terms of a Feynman-integral representation for non-Wick-ordered connected diagrams with no external legs, I is given by

$$I=(\text{symmetry number})(\tfrac{1}{2})^w(24)^n(-1)^{n+1}\times(1/4\pi)^{(n+1-w)/2}\Gamma(\tfrac{3}{2}n-\tfrac{1}{2}w-\tfrac{1}{2})\times\int_0^\infty\prod_{i=1}^{N}\frac{dx_i}{\sqrt{x_i}}\{\delta(1-\sum_{i=1}^{N}x_i)/[D(1/x_i)]^{1/2}\}. \tag{C3}$$

In Eq. (C3), (i) n=order of diagram=number of vertices. In Eq. (C3), $n\geq 2$. For $n=1$, A_1 is calculated in Appendix B. (ii) w=number of lines returning to the same vertex from which they emerged (w would be zero if the interaction were Wick ordered). (iii) N=number of lines$=2n$. (iv) x_i=the Feynman parameters. (v) A skeleton of a diagram is a simply connected subdiagram. $D(1/x_i)$=the sum over all skeletons of a diagram of

$$\left(\prod_{i=1}^{N}\frac{1}{x_i}\right)^{-1}.$$

The product is taken over all lines in the skeleton.[23]

We use Eq. (C3) to establish bounds on $(-1)^{n+1}A_n$ by proving a sequence of theorems.

Theorem 1. Let

$$L\equiv\int_0^\infty\prod_{i=1}^{N}\frac{dx_i}{\sqrt{x_i}}\{\delta(1-\sum_{i=1}^{N}x_i)/[D(1/x_i)]^{1/2}\}. \tag{C4}$$

Then, (i) L is uniformly bounded above and (ii) L is uniformly bounded below. (A uniform bound on diagrams means that the bound depends only on the number of vertices and not on the individual diagrams.)

Proof of part (i). We substitute $y=\sqrt{x_i}$ into the definition of L [Eq. (C4)] and get

$$L=\int_0^\infty\prod_{i=1}^{N}2dy_i\frac{\delta(1-\sum y_i^2)}{[D(1/y_i^2)]^{1/2}}. \tag{C5}$$

Let K_N be the surface area of a unit sphere in N dimensions. Then,

$$L\leq K_N\sup\frac{1}{[D(1/y_i^2)]^{1/2}}\Big|_{\Sigma y_i^2=1}. \tag{C6}$$

We evaluate the factors in Eq. (C6) separately.

[23] Precise definitions of "skeleton" and "$D(1/x_i)$" are given in Jaffe's paper. See Ref. 4.

By a straightforward evaluation of the surface-area integral, we get for the first factor

$$K_N=2\pi^{\frac{1}{2}N}/\Gamma(\tfrac{1}{2}N). \tag{C7}$$

In order to find the maximum of $[D(1/y_i^2)]^{-1/2}|_{\Sigma y_i^2=1}$, we note that $0\leq y_i^2\leq 1$ for each $1\leq i\leq N$. We can overestimate a maximum by letting every $y_i=1$. Then

$$\frac{1}{[D(1/y_i^2)]^{1/2}}\Big|_{\Sigma y_i^2=1}\leq\frac{1}{\sqrt{D(1)}}\leq\frac{1}{\sqrt{(\text{number of skeletons})}}. \tag{C8}$$

Clearly, the smallest number of skeletons a graph could have is 1. Hence,

$$\sup\frac{1}{[D(1/y_i^2)]^{1/2}}\Big|_{\Sigma y_i^2=1}=1. \tag{C9}$$

Combining Eqs. (C6), (C7), and (C9) and using $N=2n$ yields

$$L\leq 2\pi^n/\Gamma(n). \tag{C10}$$

This is the desired estimate for Theorem 1, part (i).

Proof of part (ii).[24] We make the substitution $\alpha_i=1/x_i$ in Eq. (C4) and integrate over the δ function. The result is that

$$L=\int_0^\infty\cdots\int_0^\infty\prod_{i=2}^{N}\frac{d\alpha_i}{\alpha_i^{3/2}}\alpha_1^{1/2}\frac{1}{[D(\alpha_i)]^{1/2}}\Big|_{\Sigma(1/\alpha_i)=1}. \tag{C11}$$

Hence,

$$L\geq\int_{2N}^{3N}\cdots\int_{2N}^{3N}\prod_{i=2}^{N}\frac{d\alpha_i}{\alpha_i^{3/2}}\alpha_1^{1/2}\frac{1}{[D(\alpha_i)]^{1/2}}\Big|_{\Sigma(1/\alpha_i)=1}. \tag{C12}$$

So

$$L\geq\left\{\int_{2N}^{3N}\prod_{i=2}^{N}\frac{d\alpha_i}{\alpha_i^{3/2}}\right\}\{\inf(\sqrt{\alpha_1})\,|\,{}_{2N\leq\alpha_i\leq 3N}\}\times\left\{\inf\frac{1}{[D(\alpha_i)]^{1/2}}\Big|_{\Sigma(1/\alpha_i)=1,\ 2N\leq\alpha_i\leq 3N}\right\}. \tag{C13}$$

We treat each of the factors in (C13) separately.

We evaluate the first factor exactly:

$$\int_{2N}^{3N}\prod_{i=2}^{N}\frac{d\alpha_i}{\alpha_i^{3/2}}=\left(\frac{2\sqrt{3}-2\sqrt{2}}{(6N)^{1/2}}\right)^{N-1}\geq N^{(1-N)/2}(\tfrac{1}{10})^{N-1}. \tag{C14}$$

The smallest possible value for the second factor is obtained when $\alpha_i=3N$. Then,

$$\inf(\sqrt{\alpha_1})=\left(\frac{3}{2+1/N}\right)^{1/2}\geq 1. \tag{C15}$$

[24] The proof of Theorem 2, part (ii) closely follows the proof given by Jaffe. See Ref. 4. However, Jaffe's other arguments do not apply here because of counting and duplication problems associated with diagrams having no external legs.

The minimum value for the third term in Eq. (C13) is found by computing the maximum value for $D(\alpha_i)\,|_{\Sigma\alpha_i=1,\ 2N\le\alpha_i\le 3N}$. But

$$\sup D(\alpha_i) = (\text{max number of skeletons}) \times (\text{max value for each skeleton}). \quad \text{(C16)}$$

An overestimation of the maximum number of skeletons a graph of n vertices has is 4^{n-1}. Also, the maximum value for each skeleton is achieved when all the $\alpha_i = 3N$. Putting this into Eq. (C16) yields

$$\sup D(\alpha_i) = 4^{n-1}(3N)^{n-1}. \quad \text{(C17)}$$

Hence,

$$\inf\left\{\frac{1}{[D(\alpha_i)]^{1/2}}\bigg|_{\Sigma(1/\alpha_i)=1,\ 2N\le\alpha_i\le 3N}\right\} = (12N)^{(1-n)/2}. \quad \text{(C18)}$$

We combine Eqs. (C14), (C15), and (C18) with Eq. (C13) to get

$$L \ge (N^{(1-N)/2})(\tfrac{1}{10})^{N-1}(12N)^{(1-n)/2}. \quad \text{(C19)}$$

Substituting $N = 2n$,

$$L \ge (2n)^{(1-2n)/2}(10)^{1-2n}(24n)^{(1-n)/2}. \quad \text{(C20)}$$

This is the desired estimate for Theorem 1, part (ii). Note that the bounds given in Eq. (C10) and in Eq. (C20) are uniform. That is, they depend on n but not on the individual diagrams.

Theorem 2. The symmetry number for diagrams is uniformly bounded (i) above and (ii) below.

Proof of part (i). Since all symmetry numbers are less than 1, an upper bound on symmetry numbers for all diagrams is 1.

Proof of part (ii). A small symmetry number corresponds to a diagram having much symmetry. The class of connected diagrams having the greatest degree of symmetry per number of vertices is shown in Fig. 7. If n is the number of vertices, the symmetry numbers for diagrams belonging to this infinite class is exactly

$$\text{S.N.} = 1/(8\times 6^{n/2}). \quad \text{(C21)}$$

Equation (C21) serves as a lower bound on all symmetry numbers. This completes Theorem 2.

Combining the results of Theorems 1 and 2 places upper and lower bounds on $(-1)^{n+1}I$. Those bounds are

$$(-1)^{n+1}I \le (\tfrac{1}{2})^w(24)^n\left(\frac{1}{(4\pi)^{1/2}}\right)^{n+1-w} \times\Gamma(\tfrac{3}{2}n-\tfrac{1}{2}w-\tfrac{1}{2})\frac{2\pi^n}{\Gamma(n)} \quad \text{(C22)}$$

and

$$(-1)^{n+1}I \ge \frac{1}{8}\frac{1}{6^{n/2}}(\tfrac{1}{2})^w(24)^n\left(\frac{1}{(4\pi)^{1/2}}\right)^{n+1-w} \times\Gamma(\tfrac{3}{2}n-\tfrac{1}{2}w-\tfrac{1}{2})(2n)^{(1-2n)/2}\times 10^{1-2n}(24n)^{(1-n)/2}. \quad \text{(C23)}$$

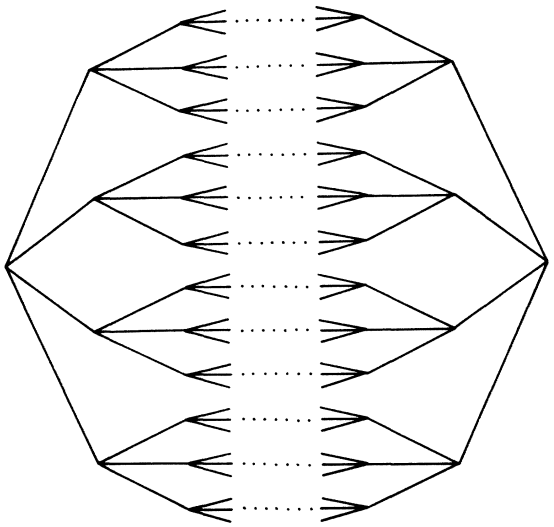

FIG. 7. The infinite class of diagrams having maximum symmetry per number of vertices. These diagrams have the smallest symmetry numbers for diagrams with a comparable number of vertices. All diagrams in this class start from a single vertex, each of whose four lines branches repeatedly and symmetrically into three new lines; after an arbitrary number of branchings, the lines symmetrically recombine into a single vertex.

To find bounds on $(-1)^{n+1}A_n$, we must make the estimates for $(-1)^{n+1}I$ independent of w. Clearly, for a connected diagram of n vertices, w can range from 0 to n. Therefore, in Eq. (C22) we take $w=0$ and in Eq. (C23) we take $w=n$. After simplification, the estimates [Eqs. (C22) and (C23)] become

$$(-1)^{n+1}I \le \frac{1}{\sqrt{\pi}}(12\sqrt{\pi})^n\frac{\Gamma(\frac{3}{2}n-\frac{1}{2})}{\Gamma(n)} \quad \text{(C24)}$$

and

$$(-1)^{n+1}I \ge \frac{5}{2}\left(\frac{3}{\pi}\right)^{1/2}\left(\frac{1}{200}\right)^n\Gamma(n-\tfrac{1}{2})n^{(2-3n)/2}. \quad \text{(C25)}$$

We now return to the integral representation [Eq. (C3)] and observe that for a given order n the contributions from all diagrams add in phase. Therefore, upper and lower bounds on $(-1)^{n+1}A_n$, the terms in the perturbation series, may be obtained once we place bounds on the number of diagrams in each order.

Theorem 3. The number of diagrams of order n is (i) bounded above by $(4n-1)!!$ and (ii) bounded below by $n!/3^n$.

Proof of part (i). We establish an upper bound on the number of diagrams by constructing them as follows.

We begin with n vertices. None of the vertices are connected, so each has four free lines emerging from it. There are $4n$ free lines.

We pick any line and connect it to one of the other $4n-1$ lines. There are now $4n-2$ lines. We pick and connect another line in one of $4n-3$ ways. We continue until there are no free lines. Therefore, there are at most $(4n-1)!!$ diagrams.

Proof of part (ii). In order to establish a lower bound on the number of diagrams, we establish a lower bound on the number of diagrams belonging to a particular class. We consider only those diagrams in which all the vertices lie on a continuous closed line (a circular path). We construct such a class of diagrams as follows.

Draw a circle and place all the n vertices on it. The circle uses up two of the four lines at each vertex. This leaves two free (unconnected) lines extending from every vertex. Now start with any vertex and pick one of the two free lines emerging from it. Join this line to a line coming from any of the n vertices (including itself). Connect the last free line coming from this new vertex to one of the remaining $n-1$ vertices. Continue this process, going sequentially from vertex to vertex until all pairs of free lines are used up. Since we use both lines at each vertex one right after the other, the number of available vertices keeps decreasing by one. Of course, at any time the process may close on itself if the free line is connected to the last line available at the original vertex. If this happens, we simply start over at any other free vertex, which will have two available lines, and continue.

Clearly, there are $n!$ ways to carry out the above process, but there will be many duplications. To avoid these duplications, we divide by three at each vertex.

We conclude that there are at least $n!/3^n$ diagrams. This establishes Theorem 3.

Combining the results of Theorem 3 with Eqs. (C24) and (C25) places upper and lower bounds on $(-1)^{n+1}A_n$:

$$(-1)^{n+1}A_n \leq \frac{(4n-1)!!\Gamma(\frac{3}{2}n-\frac{1}{2})}{\Gamma(n)} \frac{(12\sqrt{\pi})^n}{\sqrt{\pi}} \quad \text{(C26)}$$

and

$$(-1)^{n+1}A_n \geq \frac{n!\Gamma(n-\frac{1}{2})}{n^{(3n-2)/2}}(600)^{-n}\frac{5}{2}\left(\frac{3}{\pi}\right)^{1/2}. \quad \text{(C27)}$$

Simplifying Eqs. (C26) and (C27) yields

$$AB^n\Gamma(\tfrac{1}{2}n) \leq (-1)^{n+1}A_n \leq CD^n\Gamma(\tfrac{5}{2}n). \quad \text{(C28)}$$

Equation (C28) is the final result. Note that it agrees with the bounds in Eq. (2.2).

APPENDIX D

In this appendix, we discuss the details of the computer calculation of the first 75 terms in the ground-state-energy perturbation series [Eq. (2.1)] which is

$$E_0(\lambda) = \tfrac{1}{2}m + \sum_{n=1}^{\infty} mA_n(\lambda/m^3)^n. \quad \text{(D1)}$$

In the calculation, the difference equation [Eq. (2.8)] which is

$$2jB_{i,j} = (j+1)(2j+1)B_{i,j+1} + B_{i-1,j-2} - \sum_{p=1}^{i-1}(B_{i-p,1})(B_{p,j}) \quad \text{(D2)}$$

and Eq. (2.9) which is

$$A_i = -B_{i,1} \quad \text{(D3)}$$

were used on an IBM 7094 in double-precision mode. (The results of this computer calculation are listed in Table I. The absolute value of A_n is listed to the right of the order n. The number following the comma is the power of 10 multiplying the decimal.)

The computer program had three interesting features.

(i) To calculate A_n it was necessary to know all $B_{i,j}$ for $j=1, 2, \cdots, 2n$ and $i=1, \cdots, n$. Because $B_{i,j}$ has two indices, the limiting factor in this calculation was not time but memory capacity. Seventy-five was the maximum number of terms in the perturbation series

TABLE I. The absolute values of the first 75 terms A_n in the perturbation series for the ground-state energy [Eq. (2.1)]. The number following the comma is the power of 10 multiplying the decimal. The signs of A_n alternate beginning with plus, i.e., $A_n = (-)^{n-1}|A_n|$.

which could be computed without using additional memory space on disks or tapes.

(ii) The numbers $B_{i,j}$ grow exponentially large or small with i for j near 1 or near $2i$. As a result, the capacity of the 7094 to manipulate these large and small exponents in floating point would be exceeded before $i=20$. Therefore, it was necessary to scale the $B_{i,j}$. One particularly useful scaling is

$$C_{i,j}=(1/100^{i-j})B_{i,j}. \tag{D4}$$

Equation (D4) is adequate for $n\lesssim 100$.

(iii) The structure of the difference equation [Eq. (D2)] indicated that a huge number of manipulations would have to be performed in which numbers with greatly differing exponents would be added together. This would cause round-off errors which on a computer are cumulative. Therefore, although the calculation was done to 16 decimal places (double-precision mode), one must take care to determine the number of decimal places which are really significant.

If we assume that the round-off errors are purely random (not systematic), then the cumulative error grows as the square root of the number of operations. Because there are approximately 10^8 operations performed in the calculation of A_{75}, we expect that the error is about 10^4 in 10^{16}. That is, the last four decimal places (of the sixteen) are random.

We can check that there are indeed 12 significant figures in the table of A_n as follows: Divide out the dominant asymptotic behavior of the A_n [see Eq. (2.10)] and make a table of the resulting numbers Q_n:

$$Q_n\equiv\frac{A_n}{(\sqrt{6})\pi^{-3/2}\Gamma(n+\frac{1}{2})3^n}. \tag{D5}$$

Then compute a table of the successive differences:

$$Q_n{}^{(1)}\equiv Q_n-Q_{n-1}, \tag{D6a}$$

$$Q_n{}^{(2)}\equiv Q_n{}^{(1)}-Q_{n-1}{}^{(1)}, \tag{D6b}$$

and so on.

The $Q_n{}^{(i)}$ are regularly monotonic as i increases until they become random. By inspection we find that $Q^{(9)}$ is random and, as expected, it is nonzero in the last four decimal places (of the sixteen). This verifies that the Q_n and hence the A_n are correct to 12 places.

APPENDIX E

There is no known mathematically rigorous proof of the detailed asymptotic growth of the A_n as given in Eq. (2.10). However, in this appendix, we justify this equation using numerical methods. The raw data used in this appendix are contained in Table I.

We approach the problem by finding the rough growth of A_n. To do this, we construct a table of the ratios

$$R_n=A_{n+1}/A_n \tag{E1}$$

from the values of A_n listed in Table I. As $n\to 75$, we observe that to a good approximation $R_n\to 3(n+\frac{1}{2})$. This indicates that A_n grows as $3^n\Gamma(n+\frac{1}{2})$.

Next we try to fit A_n very accurately by

$$A_n\sim 3^n\Gamma(n+\tfrac{1}{2})\left(a_0+\frac{a_1}{n}+\frac{a_2}{n^2}+\frac{a_3}{n^3}+\cdots\right). \tag{E2}$$

[The $\sim$ notation in Eq. (E2) is justified because the term in square brackets is an asymptotic (nonconvergent) series.] Note that it would not be possible to fit A_n by a series such as that in Eq. (E2) if A_n did not grow as $3^n\Gamma(n+\frac{1}{2})$; that is, if the rough growth of A_n were, say, $(2.9)^n\Gamma(n+\frac{1}{2})$ or $3^n\Gamma(n+0.6)$.

To evaluate the a_i in Eq. (E2), we use Table I to calculate

$$P_n=A_n/3^n\Gamma(n+\tfrac{1}{2}). \tag{E3}$$

Then we terminate the series in Eq. (E2) at a_k and solve for a_i, $i=0, 1, \cdots, k$, in the resulting set of simultaneous equations:

$$P_n=a_0+\frac{a_1}{n}+\frac{a_2}{n^2}+\cdots+\frac{a_k}{n^k}, \tag{E4}$$

where $n=75-k, 75-k+1, \cdots, 75$.

We solve for a_0 in Eq. (E4) by multiplying each equation by n^k, taking successive differences, and using the beautiful identity:

$$\sum_{i=0}^{k}(n-i)^k\binom{k}{i}(-1)^i=k!. \tag{E5}$$

a_0 may thus be given exactly in closed form by

$$a_0=\sum_{i=0}^{k}(-1)^iP_{75-i}\binom{k}{i}(75-i)^k\Big/k!. \tag{E6}$$

Once a_0 is known, we can reduce Eq. (E4) to a new set of equations in which P_n is replaced by $(P_n-a_0)n$ and k by $k-1$. We solve as before for the new a_0 which is the old a_1. Repeating this process k times gives all a_i.

If we terminate the series at a_5, we find that to four parts in 10^9

$$a_0=(\sqrt{6})/\pi^{3/2}. \tag{E7}$$

We also find that

$$a_1/a_0=1.3194528, \tag{E8a}$$

$$a_2/a_0=1.9366649, \tag{E8b}$$

$$a_3/a_0=7.1004516, \tag{E8c}$$

$$a_4/a_0=27.445970, \tag{E8d}$$

$$a_5/a_0=665.57303. \tag{E8e}$$

Apparently, as i increases, the growth of the numbers a_i is so rapid that when $n\sim 75$, the term a_6/n^6 is larger than a_5/n^5. This suggests that the asymptotic series

in Eq. (E4) is an optimal approximation of P_n when it is terminated at a_5/n^5. (More terms could be included, giving a more accurate approximation to P_n, only if n were larger.)

Since we keep six terms in the asymptotic series, we expect that P_n should be represented accurately and uniformly to a few parts in 10^9. This turns out to be the case for n near 75 down to well below 50. Because a_0 is $(\sqrt{6})\pi^{-3/2}$ to four parts in a billion and since the magnitude of this error is exactly what we would expect, we assert that a_0 *is* $(\sqrt{6})\pi^{-3/2}$.

Combining this value for a_0 with Eq. (E2) gives Eq. (2.10) which is the result we had set out to derive in this appendix, namely,

$$A_n \sim 3^n \Gamma(n+\tfrac{1}{2})(\sqrt{6})\pi^{-3/2}. \tag{E9}$$

One might note that although a_0 is known to four parts in 10^9, a_i/a_0 in Eq. (E8) is known less and less accurately as i increases. a_1/a_0 is accurate to seven or eight places; a_2/a_0 is accurate to five or six places; and a_5/a_0 is accurate to one place at most.

To increase the accuracy of a_i, A_n would have to be calculated for n much larger than 75. As is always the case with asymptotic series, nothing is gained by calculating A_n more precisely for n near 75.

Aside from simplicity, there is no compelling reason why P_n should be expanded into an asymptotic series of the form in Eq. (E2). One might prefer to use the more general series

$$P_n \sim \alpha_0 + \frac{\alpha_1}{(n+\epsilon)} + \frac{\alpha_2}{(n+\epsilon)^2} + \frac{\alpha_3}{(n+\epsilon)^3} + \cdots, \tag{E10}$$

where ϵ is any number which is small compared to n. Then a simple formula relates the a_i to the α_i:

$$\alpha_0 = a_0, \tag{E11a}$$

$$\alpha_1 = a_1, \tag{E11b}$$

$$\alpha_2 = a_2 + \epsilon a_1, \tag{E11c}$$

$$\alpha_3 = a_3 + 2\epsilon a_2 + \epsilon^2 a_1, \tag{E11d}$$

$$\alpha_4 = a_4 + 3\epsilon a_3 + 3\epsilon^2 a_2 + \epsilon^3 a_1, \tag{E11e}$$

and, in general,

$$\alpha_n = \sum_{i=1}^{n} a_i \epsilon^{n-i} \binom{n-1}{i-1}. \tag{E11f}$$

This completes our remarks on these numerical calculations. However, before concluding this appendix, we will discuss an example of how investigations of this sort might lead to a better understanding of the singularity structure of the ground-state energy $E_0(\lambda)$ in the complex plane.

Example. As a crude illustration of how one might recover the analytic properties of $E_0(\lambda)$ from Eq. (E2), we neglect a_i for $i \geq 1$. Then Eqs. (E2) and (2.1) give

$$E_0(\lambda) \sim \sum_{n=0}^{\infty} \lambda^n (-1)^n (\sqrt{6})\pi^{-3/2}\Gamma(n+\tfrac{1}{2})3^n. \tag{E12}$$

Then, ignoring the possibility that two unequal functions can have the same asymptotic expansion, we substitute the expression

$$\Gamma(n+\tfrac{1}{2}) = \int_0^\infty e^{-t} t^{n-\frac{1}{2}} dt \tag{E13}$$

into Eq. (E12). Interchanging summation and integration, summing the series, and letting $s=\sqrt{t}$ gives a convergent integral representation for E_0:

$$E_0(\lambda) \cong \frac{2\sqrt{6}}{\pi^{3/2}} \int_0^\infty \frac{e^{-s^2}}{1+3\lambda s^2} ds. \tag{E14}$$

For λ real and positive, this integral can be evaluated explicitly with the result that

$$E_0(\lambda) \cong (2/\pi\lambda)^{1/2} \exp(1/3\lambda)\ \mathrm{Erfc}[(3\lambda)^{-1/2}], \tag{E15}$$

where

$$\mathrm{Erfc}(x) = \frac{2}{\sqrt{\pi}} \int_0^\infty e^{-t^2} dt. \tag{E16}$$

More importantly, the dispersion-type integral in Eq. (E14) defines a nontrivial singularity structure in the λ plane—a cut along the negative real λ axis. The jump across the cut is easily calculated. Unfortunately, this result does not come close to giving the true singularity structure of $E_0(\lambda)$ as derived in Secs. III, IV, and VI of this paper. Nevertheless, it is hoped that future calculations of this sort will lead to positive results.

APPENDIX F

In this appendix, we present the WKB calculation of Eq. (4.35) to first order in λ. A successful calculation would be a significant result because:

(i) Our continued ability to match the asymptotic expansions across the boundaries in regions A, B, C, and D would give added assurance that the application of WKB techniques to the problem of locating singularities in $E(\lambda)$ is valid.

(ii) It is most important to make sure that the first-order result we obtain here differs from the zeroth-order result only by terms of order λ. This would imply that the error in Eq. (4.35) is indeed small, as is tacitly assumed in Secs. IV, V, and VI.

(iii) As a byproduct, this calculation would define the boundaries of regions A, B, C, and D more precisely than the zeroth-order calculation does. This added precision would result from the greater number of terms that would be matched across the boundaries.

In this appendix, we will follow the same procedure as in the zeroth-order calculation in Sec. IV. However, we keep terms of order λ as well as of order 1. We neglect terms of order λ^2 or smaller. We again use the differential equation [Eq. (4.9)] which is

$$[d^2/dr^2+\tfrac{1}{4}(-\epsilon+r^2-\rho r^4)]\Phi(r)=0, \tag{F1}$$

and recall the definitions $\rho=\lambda e^{-3\pi i/2}$, $\epsilon=4iE$, and $r=xe^{i\pi/4}$.

We define the four regions A, B, C, and D as in Sec. IV. That is, in region A, $0<|r|\ll|r_0|$; in region B, $|r_0|\ll|r|\ll|r_1|$; in region C, $|r_0|\ll|r|\lesssim|r_1|$; and in region D, $|r|\sim|r_1|$.

Also, for the first-order calculation r_0 and r_1 must be given more exactly than for the zeroth-order calculation. From Eq. (4.10), we have

$$r_0=\{[1-(1-4\rho\epsilon)^{1/2}](2\rho)^{-1}\}^{1/2}\sim(\sqrt{\epsilon})(1+\tfrac{1}{2}\rho\epsilon) \tag{F2a}$$

and

$$r_1=\{[1+(1-4\rho\epsilon)^{1/2}](2\rho)^{-1}\}^{1/2}\sim(1/\sqrt{\rho})(1-\tfrac{1}{2}\rho\epsilon). \tag{F2b}$$

As in Sec. IV, we consider separately the regions A, B, C, and D.

Region A. We solve Eq. (F1) to first order in λ. To do this for region A, we find a transformation which to first order in λ turns Eq. (F1) into a parabolic cylinder function differential equation.[25] The transformation which works is

$$w=x+\lambda(\tfrac{1}{8}x^3+\tfrac{3}{4}Ex). \tag{F3}$$

Then, the even-parity solution to (D1) is

$$\Phi_A=C(1-\tfrac{3}{16}\lambda x^2)[D_\nu(w)+D_\nu(-w)], \tag{F4}$$

where

$$\nu=E-\tfrac{1}{2}-\tfrac{3}{2}\lambda(E^2+\tfrac{1}{4}). \tag{F5}$$

[In this appendix, we do the WKB calculation for even-parity wave functions only. The differences for odd parity involve the algebraic manipulations in region A.]

We compute the asymptotic expansion of Φ_A in region A for r near region B. The first two terms in the asymptotic expansion[26] for $D_\nu(w)$ are

$$D_\nu(w)\sim w^\nu e^{-\frac{1}{4}w^2}\left[1+\frac{\nu(1-\nu)}{2w^2}\right] \quad \text{for } -\tfrac{3}{4}\pi<\arg w<\tfrac{3}{4}\pi \tag{F6a}$$

and

$$D_\nu(w)\sim w^\nu e^{-\frac{1}{4}w^2}\left[1+\frac{\nu(1-\nu)}{2w^2}\right]-\frac{(2\pi)^{1/2}}{\Gamma(-\nu)}\times e^{\nu\pi i}w^{-\nu-1}e^{\frac{1}{4}w^2}\left[1+\frac{(1+\nu)(2+\nu)}{2w^2}\right] \quad \text{for } \tfrac{1}{4}\pi<\arg w<(5/4)\pi. \tag{F6b}$$

Equations (F2)–(F6) are used to expand Φ_A into its asymptotic form. We expand to first order in powers of ρ and r_0^2/r^2. We keep terms of the form ρ and r_0^2/r^2 and neglect terms of the form ρ^2, $\rho r_0^2/r^2$, and r_0^4/r^4. These approximations are justified because they give the correct asymptotic connection with Φ_B. As we had expected, these approximations define the extent of region A more clearly than the zeroth-order calculation did.

After considerable simplification,[27] the asymptotic expansion for Φ_A is

$$\Phi_A\sim C2\pi 2^{\frac{1}{2}\nu+\frac{1}{4}}e^{\pi i/8}e^{\pi i\nu/4}\left(1+\frac{3\rho r^2}{16}\right)\left(1+\frac{\epsilon}{4r^2}+\frac{\rho r^2}{16}+\frac{17\rho\epsilon}{64}\right)\left[1-\frac{\rho\epsilon}{32}\left(\frac{37}{8}+\frac{\epsilon^2}{32}\right)\right]$$
$$\times\left\{\frac{r^\nu}{\Gamma(\frac{1}{2}+\frac{1}{2}\nu)}\exp\left[\frac{ir^2}{4}\left(1-\frac{3\rho\epsilon}{8}-\frac{\rho r^2}{4}\right)-\frac{i\pi}{8}\right]\exp\left[\frac{i}{4}\left(\frac{3\rho\epsilon^2}{16}+\frac{\rho\epsilon r^2}{8}+\frac{\epsilon^2}{8r^2}-\frac{2}{2r^2}\right)\right]2^{-\frac{1}{2}\nu-\frac{1}{4}}\right.$$
$$\left.+\frac{r^{-\nu-1}}{\Gamma(-\frac{1}{2}\nu)}\exp\left[\frac{-ir^2}{4}\left(1-\frac{3\rho\epsilon}{8}-\frac{\rho r^2}{4}\right)+\frac{i\pi}{8}\right]\exp\left[-\frac{i}{4}\left(\frac{3\rho\epsilon^2}{16}+\frac{\rho\epsilon r^2}{8}+\frac{\epsilon^2}{8r^2}-\frac{3}{2r^2}\right)\right]2^{\frac{1}{2}\nu+\frac{1}{4}}\right\}. \tag{F7}$$

This is the desired result for region A.

Region B. The first-order WKB solution[28] to the differential equation [Eq. (F1)] is

$$\Phi_{\mathrm{WKB}}=\frac{\sqrt{\mu}}{(1-\frac{1}{8}\mu'^2+\frac{1}{4}\mu''\mu)^{1/2}}\left(C_2\exp\left\{i\left[\int^r\left(\frac{1}{\mu}-\frac{\mu'^2}{8\mu}\right)dr+\frac{\mu'}{4}\right]\right\}C_3\exp\left\{-i\left[\int^r\left(\frac{1}{\mu}-\frac{\mu'^2}{8\mu}\right)dr+\frac{\mu'}{4}\right]\right\}\right), \tag{F8}$$

[25] BMP, Vol. 2, p. 116, Eq. (1).

[25] BMP, Vol. 2, pp. 116–123. There is a serious misprint not on the errata sheet which must be corrected before one can do the first-order WKB calculation. Equation (2), p. 123, should read

$$D_\nu(z)=z^\nu e^{-z^2/4}\left[\sum_{n=0}^{N}\frac{(-\frac{1}{2}\nu)_n(\frac{1}{2}-\frac{1}{2}\nu)_n}{n!(-z^2/2)^n}+O|z^2|^{-N-1}\right]-\frac{(2\pi)^{1/2}}{\Gamma(-z)}e^{\nu\pi i}z^{-\nu-1}e^{z^2/4}\left[\sum_{n=0}^{N}\frac{(1+\frac{1}{2}\nu)_n(\frac{1}{2}+\frac{1}{2}\nu)_n}{n!(z^2/2)^n}+O|z^2|^{-N-1}\right] \text{ for } \pi/4<\arg z<5\pi/4.$$

Equation (3), p. 123, has a similar misprint but it is not needed in this paper. The equation is derived correctly in E. T. Whittaker and G. N. Watson, *A Course of Modern Analysis* (Cambridge University Press, Cambridge, 1952).

[27] BMP, Vol. 1, pp. 1–5.

[28] See Ref. 8. For first-order WKB techniques, see A. Messiah, pp. 233–234.

where

$$\mu=2(-\epsilon+r^2-\rho r^4)^{-1/2}. \tag{F9}$$

We would encounter a serious difficulty with this first-order calculation if we were to proceed as we did in Sec. IV. If we fixed the constants C_2 and C_3 in Eq. (F8) by defining the lower endpoint (the reference point) in the integrals to be r_0, we would find that the integrals become divergent regardless of the upper endpoint. The same would be true if we picked r_1 to be the reference point. In order to avoid this difficulty, we carry out the following procedure.

We treat $-\frac{1}{8}\int dr\,\mu'^2/\mu$ as an indefinite integral and integrate by parts repeatedly. This isolates the divergences at $r=r_0$ and r_1. After some tedious algebra, the result is

$$\begin{aligned}-\frac{1}{8}\int^r dr\frac{\mu'^2}{\mu}=&-\frac{1}{6}\left(\rho r^3-\frac{r}{2}\right)(-\epsilon+r^2-\rho r^4)^{-3/2}\\&-\frac{1}{12\epsilon(1-4\rho\epsilon)}(-\epsilon+r^2-\rho r^4)^{-1/2}\\&\times[\rho r^3(1-12\rho\epsilon)-r(1-8\rho\epsilon)]\\&+\frac{\rho}{12\epsilon(1-4\rho\epsilon)}\int_{r_0}^r\frac{4\epsilon+(1-12\rho\epsilon)r^2}{(-\epsilon+r^2-\rho r^4)^{1/2}}dr+\text{const}.\end{aligned} \tag{F10}$$

In Eq. (F10),

$$\epsilon=r_1^2r_0^2/(r_1^2+r_0^2), \tag{F11}$$

$$\rho=(r_1^2+r_0^2)^{-1}. \tag{F12}$$

Equation (F10) is an exact equation. Equations (F11) and (F12) are also exact and follow from the definitions of r_0 and r_1 [Eq. (4.10)].

We determine the constant in Eq. (F10) to first order by evaluating the integral $-\frac{1}{8}\int^r dr\,\mu'^2/\mu$ using a second method. Using Eq. (F9), we have

$$\begin{aligned}\int^r-\frac{1}{8}\frac{\mu'^2}{\mu}dr&\\=-\int^r dr(-\epsilon+r^2-\rho r^4)^{-5/2}(\rho r^3-\tfrac{1}{2}r)^2.&\end{aligned} \tag{F13}$$

Expanding the right-hand side of Eq. (F13) in region B to first order, we find that

$$\begin{aligned}\int^r-\frac{1}{8}\frac{\mu'^2}{\mu}dr\sim-\frac{1}{4}\int^r dr\left(r^{-3}+\frac{5}{2}\epsilon r^{-5}-\frac{3}{2}\rho r^{-1}-\frac{5}{4}r^{-3}\rho\epsilon\right)&\\\sim\frac{1}{8r^2}+\frac{3\rho}{8}\ln\frac{2r}{r_0}.&\end{aligned} \tag{F14}$$

As in region A, the first-order asymptotic expansion in region B means that we expand in powers of ρ and and r_0^2/r^2. We keep terms of the form ρ and r_0^2/r^2 and neglect terms of the form r_0^4/r^4, ρ/r^2, and ρ^2.

Finally, we return to Eq. (F10) and approximate that equation to first order in region B with the result that

$$\int^r-\frac{1}{8}\frac{\mu'^2}{\mu}dr\sim\text{const}+\frac{1}{8r^2}+\frac{3\rho}{8}\ln\frac{2r}{r_0}+\frac{1}{12\epsilon}-\frac{3\rho}{8}. \tag{F15}$$

Comparing Eqs. (F14) and (F15) determines that the constant in Eq. (F13) gives

$$\text{const}=3\rho/8-1/12\epsilon. \tag{F16}$$

We have thus avoided the divergences which come from the endpoints in the evaluation of $-\frac{1}{8}\int dr\,\mu'^2/\mu$. As a result, Eq. (F10) with the constant of integration given in Eq. (F16) is a well-defined and consistent integral evaluation valid in both regions B and C. Hence, the constants C_2 and C_3 are fixed.

We now calculate to first order the asymptotic expansion of Φ_{WKB} [Eq. (F8)] in region B.

First, we expand $\frac{1}{4}\mu'$.

$$\tfrac{1}{4}\mu'=(-\epsilon+r^2-\rho r^4)^{-3/2}(\rho r^3-\tfrac{1}{2}r) \tag{F17}$$

$$\sim-\frac{1}{2r^2}+\frac{\rho}{4}. \tag{F18}$$

Second, we expand $(1-\frac{1}{8}\mu'^2+\frac{1}{4}\mu\mu'')^{-1/2}$ to first order and get simply

$$(1-\tfrac{1}{8}\mu'^2+\tfrac{1}{4}\mu\mu'')^{-1/2}\sim1. \tag{F19}$$

Third, we expand $\sqrt{\mu}$. To first order,

$$\sqrt{\mu}\sim\left(\frac{2}{r}\right)^{1/2}\left(1+\frac{3}{16}\rho r^2\right)\left(1+\frac{\epsilon}{4r^2}+\frac{\rho r^2}{16}+\frac{17\rho\epsilon}{64}\right). \tag{F20}$$

Fourth, we must evaluate $\int_{r_0}^r(1/\mu)dr$. Note that there is no difficulty with endpoint divergences in this integral. Therefore, we treat it just as we did in Sec. IV except that we retain first-order terms. From Eq. (F9), we have

$$\int_{r_0}^r\frac{1}{\mu}dr=\frac{1}{2}\int_{r_0}^r(-\epsilon+r^2-\rho r^4)^{1/2}dr. \tag{F21}$$

We expand the integral in Eq. (F21) and get

$$\int_{r_0}^r\frac{1}{\mu}dr\sim\frac{\sqrt{\rho}}{2}\int_{r_0}^r dr(r^2-r_0^2)^{1/2}r_1-\left(\frac{r^2}{2r_1}\right). \tag{F22}$$

Substituting $r=r_0\cosh\Theta$ into Eq. (F22) and integrating gives

$$\begin{aligned}\int_{r_0}^r\frac{1}{\mu}dr\sim\frac{1}{4}\Big\{&-\epsilon\left(1+\frac{3}{8}\rho\epsilon\right)\ln\frac{2r}{r_0}+r^2\left(1-\frac{1}{4}\rho\epsilon\right)\\&-\frac{r^4\rho}{4}-\frac{1}{2}\epsilon\left(1+\frac{9}{16}\rho\epsilon\right)+\frac{\epsilon^2}{8r^2}\Big\}.\end{aligned} \tag{F23}$$

We combine Eqs. (F14), (F18)–(F20), and (F23). These five results are needed to give us the asymptotic expansion of Φ_{WKB} (F8) in region B:

$$\Phi_B\sim\left(\frac{2}{r}\right)^{1/2}\left(1+\frac{3}{16}\rho r^2\right)\left(1+\frac{\epsilon}{4r^2}+\frac{\rho r^2}{16}+\frac{17\rho\epsilon}{64}\right)$$
$$\times\Bigg(C_2\exp\Bigg\{i\Bigg[\frac{1}{4}\Bigg(-\epsilon(1+\tfrac{3}{8}\rho\epsilon)\ln\frac{2r}{r_0}+r^2(1-\tfrac{1}{4}\rho\epsilon)-\tfrac{1}{4}r^4\rho$$
$$-\tfrac{1}{2}\epsilon\left(1+\frac{9}{16}\rho\epsilon\right)+\frac{\epsilon^2}{8r^2}\Bigg)-\frac{1}{2r^2}+\frac{\rho}{4}+\frac{1}{8r^2}+\frac{3\rho}{8}\ln\frac{2r}{r_0}\Bigg]\Bigg\}$$
$$+C_3\exp\{-i[\cdots]\}\Bigg). \quad \text{(F24)}$$

Region C. We calculate to first order the asymptotic expansion of Φ_{WKB} [Eq. (F8)] in region C. For this purpose it is convenient to use a new variable R:

$$R\equiv r_1-r_0. \quad \text{(F25)}$$

Expansions in region C are done in powers of ρ and R/r_1. For first order we keep terms of the form ρ and R/r_1 and neglect terms of the form R^2/r_1^2, $R\rho/r_1$, and ρ^2.

The components of the asymptotic expansion of Φ_{WKB} [Eq. (F8)] are computed in turn:

First,

$$\mu^{1/2}\sim\frac{2^{1/4}\rho^{1/8}}{R^{1/4}}\left[1+\frac{\rho}{4}\left(\frac{5}{2}\epsilon+\frac{5}{2}\frac{R}{\rho^{1/2}}\right)\right]. \quad \text{(F26)}$$

Second, as in region B,

$$(1-\tfrac{1}{8}\mu'^2+\tfrac{1}{4}\mu''\mu)^{-1/2}\sim 1. \quad \text{(F27)}$$

Third,

$$\tfrac{1}{4}\mu'\sim\frac{R^{-3/2}\rho^{1/4}}{24\sqrt{2}}\left(6+\frac{15}{2}\rho\epsilon-\frac{15}{2}R\sqrt{\rho}\right). \quad \text{(F28)}$$

Fourth, we decompose the integral $\int_{r_0}^{r}(1/\mu)dr$ as follows:

$$\int_{r_0}^{r}\frac{1}{\mu}dr=\int_{r_0}^{r_1}\frac{1}{\mu}dr-\int_{r}^{r_1}\frac{1}{\mu}dr. \quad \text{(F29)}$$

The first integral in Eq. (F29) will be expressed later in terms of elliptic integrals [see Eq. (F47)]. For now we label it P:

$$P=\int_{r_0}^{r_1}\frac{1}{\mu}dr. \quad \text{(F30)}$$

The second integral in Eq. (F29) may be approximated easily, with the result that

$$-\int_{r}^{r_1}\frac{1}{\mu}dr\sim-\tfrac{1}{2}\sqrt{3}\rho^{-1/4}R^{3/2}\left(1-\frac{5}{4}\rho\epsilon-\frac{3}{4}(\sqrt{\rho})R\right). \quad \text{(F31)}$$

Fifth, we use Eq. (F10) to approximate $\int-\frac{1}{8}(\mu'^2/\mu)dr$. We decompose the integral in Eq. (F10) using the same method as in Eq. (F29) and define the definite integral as Q:

$$Q=\int_{r_0}^{r_1}\frac{\rho dr}{12\epsilon(1-4\rho\epsilon)}\frac{4\epsilon+(1-12\rho\epsilon)r^2}{(-\epsilon+r^2-\rho r^4)^{1/2}}. \quad \text{(F32)}$$

Then, after some heavy algebra,

$$\int^{r}-\frac{1}{8}\frac{\mu'^2}{\mu}dr=\frac{3\rho}{8}-\frac{1}{12\epsilon}+\frac{10R^{-3/2}\rho^{1/4}R\sqrt{\rho}}{24\sqrt{2}}$$
$$-\frac{\rho^{1/4}R^{-3/2}}{24\sqrt{2}}\left(1+\frac{5}{4}\rho\epsilon-\frac{5}{4}(\sqrt{\rho})R\right)+Q. \quad \text{(F33)}$$

We have now determined Φ_C, the asymptotic expansion of Φ_{WKB} in region C:

$$\Phi_C\sim\frac{2^{1/4}\rho^{1/8}}{R^{1/4}}\left(1+\frac{5}{8}\rho\epsilon\right)\left[1+\frac{5}{8}(\sqrt{\rho})R\right]$$
$$\times\Bigg(C_2\exp\Bigg\{i\Bigg[\frac{R^{-3/2}\rho^{1/4}}{24\sqrt{2}}\left(5+\frac{25}{4}\rho\epsilon+\frac{15}{4}R\sqrt{\rho}\right)+P$$
$$+Q+\tfrac{3}{8}\rho-\frac{1}{12\epsilon}-\tfrac{1}{3}\sqrt{2}\rho^{-1/4}R^{3/2}[1-\tfrac{3}{2}(\tfrac{5}{6}\rho\epsilon+\tfrac{1}{2}\rho^{1/2}R)]\Bigg]\Bigg\}$$
$$+C_3\exp\{-i[\cdots]\}\Bigg), \quad \text{(F34)}$$

where P and Q are defined in Eqs. (F30) and (F32), respectively.

Region D. In region D, we substitute Eq. (F25) into the differential equation (F1) and transform the equation to

$$0=\left\{\frac{d^2}{dR^2}+\tfrac{1}{2}\rho^{-1/2}R\left[1-\rho\left(\frac{5}{2}\epsilon+\frac{5}{2}\frac{R}{\rho^{1/2}}\right)\right]\right\}\Phi(R). \quad \text{(F35)}$$

Equation (F35) must be solved to first order and Φ_D is its solution. We solve Eq. (F35) by finding a transformation of variable which to first order changes Eq. (F35) into an Airy equation.[29] The correct change of variables is

$$R=\rho^{1/2}[z+\rho(\tfrac{3}{2}+\tfrac{5}{6}\epsilon z+\tfrac{1}{2}z^2)]. \quad \text{(F36)}$$

Then,

$$\Phi_D=\{\exp\tfrac{1}{2}\rho[z-\rho(\tfrac{5}{6}\epsilon+\tfrac{1}{2}z^2)]\}\chi. \quad \text{(F37)}$$

χ in Eq. (F37) satisfies this Airy equation to first order:

$$\{d^2/dz^2+\tfrac{1}{2}\rho z\}\chi=0. \quad \text{(F38)}$$

The solution to the Airy equation [Eq. (F38)] is

$$\chi(z)=[-\tfrac{1}{3}(18\rho^{-1})^{-1/3}z]^{1/2}$$
$$\times K_{1/3}(2(-z)^{3/2}(18\rho^{-1})^{-1/2}). \quad \text{(F39)}$$

[29] BMP, Vol. 2, Sec. 7.3.7, p. 22.

As in Sec. IV, to calculate the asymptotic behavior of Φ_D we need to use Eq. (4.31) which is[30]

$$K_{1/3}(e^{3\pi i/2}x)=-\tfrac{1}{2}i\pi[e^{i\pi/6}H_{1/3}^{(1)}(x)+e^{-i\pi/6}H_{1/3}^{(2)}(x)]. \quad \text{(F40)}$$

Also, we need the asymptotic expansions of $H_{1/3}^{(1)}$ and $H_{1/3}^{(2)}$ to first order[31]:

$$H_{1/3}^{(1)}(x)\sim\frac{\sqrt{2}}{\sqrt{(\pi x)}}e^{i(x-5\pi/12)}\left(1+\frac{5}{i72x}\right) \quad \text{(F41a)}$$

and

$$H_{1/3}^{(2)}(x)\sim\frac{\sqrt{2}}{\sqrt{(\pi x)}}e^{-i(x-5\pi/12)}\left(1-\frac{5}{72ix}\right). \quad \text{(F41b)}$$

We combine Eqs. (F36), (F37), (F39), (F40), and (F41), and after some heavy algebra, we have the asymptotic expansion of Φ_D:

$$\Phi_D(R)\sim\frac{2^{-11/12}\pi^{1/2}3^{-1/3}\rho^{1/24}D}{R^{1/4}}\left(1+\frac{5\rho\epsilon}{24}+\frac{5R\sqrt{\rho}}{8}\right)\times\{\exp\{i[\tfrac{1}{3}\sqrt{2}\rho^{-1/4}R^{3/2}[1-\tfrac{3}{2}(\tfrac{5}{8}\rho\epsilon+\tfrac{1}{2}R\sqrt{\rho})]-\tfrac{1}{4}\pi-(5/24\sqrt{2})\rho^{1/4}R^{-3/2}[1+\tfrac{3}{2}(\tfrac{5}{6}\rho\epsilon+\tfrac{1}{2}R\sqrt{\rho})]\}+\exp\{-i[\cdots]\}\}. \quad \text{(F42)}$$

This completes the calculation of the asymptotic expansions for Φ_A, Φ_B, Φ_C, and Φ_D. It is necessary to asymptotically connect Φ_A with Φ_B and Φ_C with Φ_D as was done in the zeroth-order calculation in Sec. IV.

First, we match Φ_A in Eq. (F7) with Φ_B in Eq. (F24) and determine the ratio of C_2 to C_3:

$$\frac{C_2}{C_3}=(\tfrac{1}{8}r_0^2)^{\nu+1/2}e^{-i\pi/4}\frac{\Gamma(-\frac{1}{2}\nu)}{\Gamma(\frac{1}{2}+\frac{1}{2}\nu)}e^{i\epsilon/4}\times\exp\left[i\rho\left(1+\frac{15}{64}\epsilon^2\right)\right], \quad \text{(F43)}$$

where ν is given in Eq. (F5).

Second, we match Φ_C in Eq. (F34) with Φ_D in Eq. (F42) and, once again, determine the ratio of C_2 to C_3:

$$\frac{C_2}{C_3}=e^{i\pi/2}\exp\left[-2i\left(P+Q+\frac{3\rho}{8}-\frac{1}{12\epsilon}\right)\right], \quad \text{(F44)}$$

where P and Q are given in Eqs. (F30) and (F32), respectively.

It only remains to calculate the integrals P and Q. Both integrals may be treated by substituting

$$z^2=(r_1^2-r^2)/(r_1^2-r_0^2). \quad \text{(F45)}$$

After some algebra both P and Q are found to be linear combinations of $K(k)$ and $E(k)$. These are the complete elliptic integrals of the first and second kind.[32] $K(k)$ and $E(k)$ are defined by

$$K(k)\equiv\int_0^1\frac{dz}{(1-z^2)^{1/2}(1-k^2z^2)^{1/2}} \quad \text{(F46a)}$$

and

$$E(k)\equiv\int_0^1\frac{dz(1-k^2z^2)^{1/2}}{(1-z^2)^{1/2}}, \quad \text{(F46b)}$$

where in our case

$$k^2\equiv 1-r_0^2/r_1^2. \quad \text{(F46c)}$$

Using Eq. (F46), P and Q may be written as

$$P=\frac{(\sqrt{\rho})r_1^3}{2}\left[\frac{2-k^2}{3}E(k)+2\left(\frac{k^2-1}{3}\right)K(k)\right] \quad \text{(F47)}$$

and

$$Q=\frac{\sqrt{\rho}}{12r_1\epsilon(1-4\rho\epsilon)}[4\epsilon K(k)+(1-12\rho\epsilon)r_1^2E(k)]. \quad \text{(F48)}$$

We expand $K(k)$ and $E(k)$ to first order for k near 1 by means of the following formulas[33]:

$$K(k)=\tfrac{1}{2}\pi\,{}_2F_1(\tfrac{1}{2},\tfrac{1}{2};1;k^2) \quad \text{(F49a)}$$

and

$$E(k)=\tfrac{1}{2}\pi\,{}_2F_1(-\tfrac{1}{2},\tfrac{1}{2};1;k^2). \quad \text{(F49b)}$$

We then expand the hypergeometric functions in Eq. (F49) to first order for k near 1[34]:

$$K(k)\sim\ln\frac{4r_1}{r_0}+\frac{r_0^2}{4r_1^2}\left(\ln\frac{4r_1}{r_0}-1\right) \quad \text{(F50a)}$$

and

$$E(k)\sim 1+\frac{r_0^2}{4r_1^2}\left(2\ln\frac{4r_1}{r_0}-1\right)+\frac{3}{32}\frac{r_0^4}{r_1^4}\left(2\ln\frac{4r_1}{r_0}-\frac{13}{6}\right). \quad \text{(F50b)}$$

Equation (F2) allows us to write Eq. (F50) in terms of ρ and ϵ:

$$K(k)\sim\left(\ln\frac{4}{\sqrt{(\rho\epsilon)}}\right)\left(1+\frac{\rho\epsilon}{4}\right)-\frac{5\rho\epsilon}{4} \quad \text{(F51a)}$$

and

$$E(k)\sim 1-\frac{\rho\epsilon}{4}-\frac{77}{64}\rho^2\epsilon^2+\rho\epsilon\left(\frac{1}{2}+\frac{19}{16}\rho\epsilon\right)\ln\left(\frac{4}{\sqrt{(\rho\epsilon)}}\right). \quad \text{(F51b)}$$

Finally, we combine Eqs. (F47), (F48), and (F51) to

[30] BMP, Vol. 2, p. 5, Eq. (15) and p. 80, Eq. (43).
[31] BMP, Vol. 2, p. 85, Eqs. (1) and (2).
[32] BMP, Vol. 2, p. 317, Eqs. (1) and (2).
[33] BMP, Vol. 2, p. 318, Eqs. (5) and (6).
[34] For the expansion of $K(k)$ and $E(k)$ see Ref. 11.

get the first-order evaluation of P and Q:

$$P\sim-\frac{\epsilon}{4}\left(\ln\frac{4}{\sqrt{(\rho\epsilon)}}\right)\left(1+\frac{3\rho\epsilon}{8}\right)+\frac{1}{6\rho}-\frac{\epsilon}{8}+\frac{17}{128}\rho\epsilon^2 \quad \text{(F52)}$$

and

$$Q\sim\frac{1}{12\epsilon}-\frac{35\rho}{48}+\frac{3\rho}{8}\left(\ln\frac{4}{\sqrt{(\rho\epsilon)}}\right). \quad \text{(F53)}$$

Combining Eqs. (F52) and (F53) with (F44), we have

$$\frac{C_2}{C_3}=e^{i\pi/2}\exp\left\{i\left[\frac{\epsilon}{4}-\frac{1}{3\rho}+\rho\left(\frac{17}{24}-\frac{17}{64}\epsilon^2\right)+\left(\ln\frac{16}{\rho\epsilon}\right)\left(\frac{\epsilon}{4}-\frac{3\rho}{8}+\frac{3\rho\epsilon^2}{32}\right)\right]\right\}. \quad \text{(F54)}$$

We have thus calculated two independent expressions for C_2/C_3. Setting these expressions in Eqs. (F43) and (F54) equal gives an even-parity version of Eq. (4.35) correct to first order instead of zeroth order as previously computed in Sec. IV. Thus,

$$\frac{\Gamma(\frac{1}{2}+\frac{1}{2}\nu)}{\Gamma(-\frac{1}{2}\nu)}=\exp\left[(\nu+\tfrac{1}{2})\ln\frac{2}{\rho}+i\left(\frac{5\pi}{4}+\frac{1}{3\rho}\right)+i\rho\left(\frac{7}{24}-\frac{61E^2}{4}\right)\right], \quad \text{(F55)}$$

where

$$\nu=E-\tfrac{1}{2}+\tfrac{3}{2}i\rho(E^2+\tfrac{1}{4}).$$

This is the result we have sought. It is reassuring to observe that Eq. (F55) reduces to the zeroth-order calculation [Eq. (4.35)] if we neglect $\frac{3}{2}i\rho(E^2+\frac{1}{4})$ compared to $(E-\frac{1}{2})$ in ν and $\rho(7/24+E^2 61/4)$ compared to $5\pi/4$.

Considering the zeroth- and first-order results, it is tempting to conjecture that to all orders the WKB result corresponding to Eq. (F55) takes the form

$$\frac{\Gamma(\frac{1}{2}+\frac{1}{2}\nu(\rho))}{\Gamma(-\frac{1}{2}\nu(\rho))}=\exp\left\{[\nu(\rho)+\tfrac{1}{2}]\ln\frac{2}{\rho}+i\left(\frac{5\pi}{4}+\frac{1}{3\rho}\right)+i\alpha(\rho)\right\}, \quad \text{(F56)}$$

where $\nu(\rho)$ and $\alpha(\rho)$ are power series in ρ:

$$\nu(\rho)=\sum_{n=0}^{\infty}\nu_n\rho^n, \quad \text{(F57)}$$

with $\nu_0=E-\frac{1}{2}$ and $\nu_1=\frac{3}{2}i(E^2+\frac{1}{4})$;

$$\alpha(\rho)=\sum_{n=1}^{\infty}\alpha_n\rho^n, \quad \text{(F58)}$$

with $\alpha_1=7/24-61E^2/4$.

APPENDIX G

In Sec. VI, the result of performing the integral $\int c\Phi_{\mathrm{WKB}}^2(z)dz$ was stated in Eq. (6.3). In this appendix, we demonstrate explicitly the evaluation of this integral which we call J. We will calculate J only for even-parity wave functions Φ. The odd-parity case is similar and presents no new difficulties.

We chose the contour C to be the straight line $z=re^{-i\pi/4}$, where r runs from $-\infty$ to ∞. Because the WKB solutions have definite parity about $r=0$, we simplify J to

$$J=2e^{-i\pi/4}\int_{r=0}^{\infty}dr\,\Phi_{\mathrm{WKB}}^2(re^{-i\pi/4}). \quad \text{(G1)}$$

In Eq. (G1) we break the region of integration into four pieces:

(I) $0\leq r\leq\bar{r}_0$,

(II) $\bar{r}_0\leq r\leq\bar{r}_1$,

(III) $\bar{r}_1\leq r\leq r_2$,

(IV) $r_2\leq r$,

where

$$r_0<\bar{r}_0\ll\bar{r}_1<r_1<r_2. \quad \text{(G2)}$$

The $<$ sign in Eq. (G2) means that we disregard r_0 compared to $\bar{r}_0$ to zeroth order.

Φ_{WKB} is approximated by Φ_A [Eq. (4.12)] in region I, by the oscillating WKB solution [Eq. (4.16)] in region II, by Φ_D [Eq. (4.28)] in region III, and by the exponentially decreasing WKB solution [Eq. (4.5)] in region IV. The integrals in each of these regions must be treated separately using

$$J=J_{\mathrm{I}}+J_{\mathrm{II}}+J_{\mathrm{III}}+J_{\mathrm{IV}}. \quad \text{(G3)}$$

Region I. In region I, we evaluate

$$J_{\mathrm{I}}=2e^{-i\pi/4}\int_{r=0}^{\bar{r}_0}dr\,\Phi_A^2(re^{-i\pi/4}). \quad \text{(G4)}$$

Inserting Eq. (4.12), the definition of Φ_A, into Eq. (G4) we get

$$J_{\mathrm{I}}=2e^{-i\pi/4}C^2\int_{r=0}^{\bar{r}_0}[D_\nu(re^{-i\pi/4})+D_\nu(-re^{-i\pi/4})]^2dr, \quad \text{(G5)}$$

where $\nu=-\frac{1}{2}-\frac{1}{4}i\epsilon$ and $\epsilon=4iE$.

We expand the integrand in Eq. (G5) using identities of the parabolic cylinder functions[35] so that

$$J_{\mathrm{I}}=2e^{-i\pi/4}C^2\left[(1-e^{2\nu\pi i})\int_{r=0}^{\bar{r}_0}D_\nu^2(re^{-i\pi/4})dr+\left(\frac{\sqrt{(2\pi)}}{\Gamma(-\nu)}\right)^2e^{\pi i(\nu+1)}\int_{r=0}^{\bar{r}_0}D_{-\nu-1}^2(re^{i\pi/4})dr+2(1+e^{\pi i\nu})\int_{r=0}^{\bar{r}_0}D_\nu(re^{-i\pi/4})D_\nu(-re^{-i\pi/4})dr\right]. \quad \text{(G6)}$$

[35] BMP, Vol. 2, p. 117, Eq. (7).

We evaluate the integrals in Eq. (G6) by introducing a new function F into Eq. (G4) as follows:

$$J_{\mathrm{I}}=2e^{-i\pi/4}\left\{\int_{r=0}^{\bar{r}_0} dr[\Phi_A{}^2(re^{-i\pi/4})-F(r)] + \int_{r=0}^{\bar{r}_0}\right\} dr\, F(r). \quad \text{(G7)}$$

$F(r)$ is the zeroth-order asymptotic approximation to those terms in $\Phi_A{}^2(re^{-i\pi/4})$ which would have divergent tails if integrated to $r=\infty$. This definition of $F(r)$ implies that a good approximation to J_{I} is

$$J_{\mathrm{I}}\sim 2e^{-i\pi/4}\left\{\int_{r=0}^{\infty} dr[\Phi_A{}^2(re^{-i\pi/4})-F(r)] + \int_{r=0}^{\bar{r}_0} dr\, F(r)\right\}. \quad \text{(G8)}$$

All the integrations in Eq. (G8) can be done easily.

Explicitly these integrals are

$$J_{\mathrm{I}}\sim 2e^{-i\pi/4}C^2\left\{(1-e^{2\nu\pi i})\int_{r=0}^{\infty} D_\nu{}^2(re^{-i\pi/4})dr + \left(\frac{\sqrt{(2\pi)}}{\Gamma(-\nu)}\right)^2 e^{\pi i(\nu+1)}\int_{r=0}^{\infty} D_{-\nu-1}{}^2(e^{i\pi/4}r)dr + 2(1+e^{\pi i\nu}) \times\int_{r=0}^{\infty} dr[D_\nu(re^{-i\pi/4})D_\nu(-re^{-i\pi/4})-F(r)] + \int_{r=0}^{\bar{r}_0} F(r)dr\right\}. \quad \text{(G9)}$$

Asymptotically, $D_\nu(re^{-i\pi/4})D_\nu(-re^{-i\pi/4})$ behaves as $[\sqrt{(2\pi)}/\Gamma(-\nu)]r^{-1}e^{i\pi/4}$ for large r.[36] However, if we were to choose the counterterm $F(r)$ to have this form, we would introduce a spurious pole at $r=0$. Therefore, we pick a form for $F(r)$ with the same asymptotic behavior at $r=\infty$ but with no pole in the region of integration. We thus define

$$F(r)\equiv\frac{1}{r+1}\frac{\sqrt{(2\pi)}}{\Gamma(-\nu)}e^{i\pi/4}. \quad \text{(G10)}$$

After rotating the contours in the complex plane by $\pi/4$ and $-\pi/4$, the first two integrals in Eq. (G9) become known forms.[37] In order to perform the third integral in Eq. (G9) which is

$$\int_{r=0}^{\infty}\left[D_\nu(re^{-i\pi/4})D_\nu(-re^{-i\pi/4}) - \frac{\sqrt{(2\pi)}}{\Gamma(-\nu)}(r+1)^{-1}e^{i\pi/4}\right]dr, \quad \text{(G11)}$$

we introduce a small positive ϵ into Eq. (G11) as follows:

$$\lim_{\epsilon\to 0}\int_{r=0}^{\infty}\left[D_{\nu-\epsilon}(re^{-i\pi/4})D_\nu(-re^{-i\pi/4}) - \frac{\sqrt{(2\pi)}}{\Gamma(-\nu)}\frac{1}{(r+1)^{\epsilon+1}}e^{i\pi/4}\right]dr. \quad \text{(G12)}$$

After rotating the contour in Eq. (G12) by $\pi/4$, the integrals become known forms.[38] We evaluate the integrals in Eq. (G12) and take the limit as $\epsilon\to 0$. After considerable simplification[39] the final result of this evaluation is

$$J_{\mathrm{I}}\sim\frac{4C^2\sqrt{(2\pi)}\cos(\frac{1}{2}\nu\pi)e^{\nu\pi i/2}}{\Gamma(-\nu)} \times[2\ln\bar{r}_0-\psi(E+\tfrac{1}{2})+\tfrac{1}{2}\pi\cot(\tfrac{1}{4}-\tfrac{1}{2}E)\pi], \quad \text{(G13)}$$

where $\psi(x)\equiv d\ln\Gamma(x)/dx$.

Region II. In region II, we evaluate

$$J_{\mathrm{II}}\sim 2e^{-i\pi/4}\int_{r=\bar{r}_0}^{\bar{r}_1} dr(-\epsilon+r^2-\rho r^4)^{-1/2}2C_2C_3. \quad \text{(G14)}$$

To get this equation, we have substituted Eq. (4.16) into Eq. (G1) and squared the expression. In squaring, we have disregarded two small oscillatory terms because their contribution to the integral could only become significant if r were near r_0 or r_1. The choice of $\bar{r}_0$ and $\bar{r}_1$ as endpoints of the integration region prevents r from getting near r_0 or r_1.

To do the integral in Eq. (G14) we decompose the region of integration into three pieces:

$$J_{\mathrm{II}}\sim 4C_2C_3e^{-i\pi/4}\left(\int_{r=r_0}^{r_1}-\int_{r=r_0}^{\bar{r}_0}-\int_{r=\bar{r}_1}^{r_1}\right) \times dr(-\epsilon+r^2-\rho r^4)^{-1/2}. \quad \text{(G15)}$$

By substituting $x^2=(r_1{}^2-r^2)/(r_1{}^2-r_0{}^2)$ and $k^2=1-r_0{}^2/r_1{}^2$, the first integral in Eq. (G13) is shown to be $K(k)$, the elliptic integral of the first kind.[40] The last two integrals are approximated by factoring $(-\epsilon+r^2-\rho r^4)=\rho(r^2-r_0{}^2)(r_1{}^2-r^2)$. Combining these results gives

$$J_{\mathrm{II}}\sim 4C_2C_3e^{-i\pi/4}\left[-\ln\frac{2\bar{r}_0}{r_0}-\left(2-\frac{2\bar{r}_1}{r_1}\right)^{1/2} + \frac{1}{r_1\sqrt{\rho}}K(k)\right]. \quad \text{(G16)}$$

We now expand $K(k)$ for k near 1 [see Eq. (4.23b) for

[36] BMP, Vol. 2, pp. 122–123, Eqs. (1) and (2).
[37] BMP, Vol. 2, p. 122, Eq. (22).
[38] BMP, Vol. 2, p. 122, Eq. (21).
[39] BMP, Vol. 1, pp. 1–5 and 16.
[40] BMP, Vol 2, p. 317, Eq. (1).

this expansion] and find that the contribution from region II is

$$J_{\rm II}\sim 4C_2C_3e^{-i\pi/4}[\ln(2/\bar{r}_0\sqrt{\rho})-\rho^{1/4}\sqrt{2}(r_1-\bar{r}_1)^{1/2}]. \quad \text{(G17)}$$

Regions III and IV. Using Eqs. (4.20), (4.28), and (4.29), we can write down the integral contribution from region III:

$$J_{\rm III}=2e^{-i\pi/4}\int_{r=\bar{r}_1}^{r_2} dr\frac{D^2}{3}$$
$$\times K_{1/3}{}^2[2(18\sqrt{\rho})^{-1/2}(r-r_1)^{3/2}](18\sqrt{\rho})^{-1/3}(r-r_1). \quad \text{(G18)}$$

We notice that the contribution from region IV can be included in Eq. (G18) by increasing the upper limit of integration from r_2 to ∞. This is true because the $K_{1/3}$ Bessel function for region III and the WKB solution for region IV [Eq. (4.5)] have similar exponentially decreasing tails. Hence,

$$J_{\rm III}+J_{\rm IV}=2e^{-i\pi/4}\int_{r=\bar{r}_1}^{\infty} dr\frac{D^2}{3}$$
$$\times K_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}(r-r_1)^{3/2})(18\sqrt{\rho})^{-1/3}(r-r_1). \quad \text{(G19)}$$

We simplify Eq. (G19) by substituting $s=r-r_1$:

$$J_{\rm III}+J_{\rm IV}=\frac{2e^{-i\pi/4}D^2(18\sqrt{\rho})^{-1/3}}{3}$$
$$\times\int_{s=\bar{r}_1-r_1}^{\infty} sds\, K_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}s^{3/2}). \quad \text{(G20)}$$

Next, as we did in region I, we introduce a counterterm $G(s)$ in Eq. (G21) and extend the region of integration in Eq. (G22). This procedure facilitates the evaluation of the integrals.

$$J_{\rm III}+J_{\rm IV}=\tfrac{2}{3}e^{-i\pi/4}D^2(18\sqrt{\rho})^{-1/3}$$
$$\times\left\{\int_{s=0}^{\infty} sds\, K_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}s^{3/2})\right.$$
$$+\int_{s=\bar{r}_1-r_1}^{0} ds[sK_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}s^{3/2})-G(s)]$$
$$\left.+\int_{s=\bar{r}_1-r_1}^{0} G(s)ds\right\}. \quad \text{(G21)}$$

This may be approximated by

$$J_{\rm III}+J_{\rm IV}\sim\tfrac{2}{3}e^{-i\pi/4}D^2(18\sqrt{\rho})^{-1/3}$$
$$\times\left\{\int_{s=0}^{\infty} sds\, K_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}s^{3/2})\right.$$
$$+\int_{s=-\infty}^{0} ds[sK_{1/3}{}^2(2(18\sqrt{\rho})^{-1/2}s^{3/2})-G(s)]$$
$$\left.+\int_{s=\bar{r}_1-r_1}^{0} G(s)ds\right\}. \quad \text{(G22)}$$

Equation (G22) is a good approximation to Eq. (G21) because $G(s)$ is chosen to behave asymptotically as $K_{1/3}{}^2$ for s near $-\infty$.

We reduce the first integral Eq. (G22) to a known form by substituting

$$x=2(18\sqrt{\rho})^{-1/2}s^{3/2}, \quad \text{(G23)}$$

and by using[41]

$$\int_0^{\infty} K_{1/3}{}^2(x)x^{1/3}dx=2^{-5/3}3\Gamma^2(\tfrac{2}{3}). \quad \text{(G24)}$$

We simplify the second integral in Eq. (G22) by substituting Eq. (G23) again and by observing that[42]

$$K_{1/3}(xe^{\frac{3}{2}\pi i})=(-\pi i/\sqrt{3})[J_{1/3}(x)+J_{-1/3}(x)]. \quad \text{(G25)}$$

Three Bessel function terms arise from plugging the square of Eq. (G25) into the second term in Eq. (G22). The techniques for integrating only one of these three terms will be presented here because the other two terms can be integrated similarly. Investigation of Eq. (G25) shows that in terms of the variable x the counterterm G is proportional to $x^{-2/3}$. As in region I, a limiting procedure must be used to do the counterterm integration as follows.

We insert a positive ϵ and the first of the three terms becomes

$$\lim_{\epsilon\to 0}\int_0^{\infty}\left[J_{1/3}(x)J_{1/3}(x(1+\epsilon))x^{1/3}\right.$$
$$\left.-\frac{(\cos x\epsilon)x^{-2/3}}{(1+\epsilon)^{1/2}\pi}\right]dx. \quad \text{(G26)}$$

The first integral in Eq. (G26) is a Weber-Schafheitlin integral.[43] The second may be evaluated by changing the contour. This gives a Γ function. The results are

$$\lim_{\epsilon\to 0}\left(2^{1/3}(1+\epsilon)^{-5/3}\frac{F(1,\frac{2}{3};\frac{4}{3};(1+\epsilon)^{-2})}{\Gamma(\frac{4}{3})\Gamma(\frac{1}{3})}\right.$$
$$\left.-\frac{\Gamma(\frac{1}{3})\epsilon^{-1/3}\cos\frac{1}{6}\pi}{\pi}\right). \quad \text{(G27)}$$

We transform[44] the hypergeometric function in Eq. (G27) as follows:

$$F(1,\tfrac{2}{3};\tfrac{4}{3};(1+\epsilon)^{-2})=\frac{\Gamma(\frac{4}{3})\Gamma(-\frac{1}{3})}{\Gamma(\frac{1}{3})\Gamma(\frac{2}{3})}$$
$$\times(1+\epsilon)^2F(1,\tfrac{1}{3};\tfrac{4}{3};-2\epsilon-\epsilon^2)+\frac{\Gamma(\frac{4}{3})\Gamma(\frac{1}{3})}{\Gamma(\frac{2}{3})}(1+\epsilon)^{2/3}$$
$$\times\left[1-\frac{1}{(1+\epsilon)^2}\right]^{-1/3}F(\tfrac{1}{3},0;\tfrac{2}{3};-2\epsilon-\epsilon^2). \quad \text{(G28)}$$

[41] BMP, Vol. 2, p. 93, Eq. (36).
[42] BMP, Vol. 2, p. 5, Eq. (15), p. 80, Eq. (43), and p. 4, Eqs. (5) and (6).
[43] BMP, Vol. 2, Sec. 7.7.4, pp. 51–52.
[44] BMP, Vol. 1, p. 109, Eq. (4).

We simplify[39] Eq. (G28) and insert it into Eq. (G27). We can then take the limit as $\epsilon \to 0$ because the terms containing $\epsilon^{-1/3}$ cancel. The result is that

$$\lim_{\epsilon\to 0}\int_0^\infty dx\left(J_{1/3}(x)J_{1/3}((\epsilon+1)x)x^{1/3}-\frac{(\cos x\epsilon)x^{-2/3}}{\pi x(1+\epsilon)^{1/2}}\right)=-\frac{3\times 2^{1/3}}{\Gamma^2(\frac{1}{3})}. \quad \text{(G29)}$$

The second term $(J_{1/3}J_{-1/3})$ and the third term $(J_{-1/3}J_{-1/3})$ each contribute 0 to the second term in Eq. (G22).

Thus, the first two integrals in Eq. (G22) cancel. After substituting for G, we are left with the third term in Eq. (G22) which is

$$J_{\mathrm{III}}+J_{\mathrm{IV}}\sim -ie^{-i\pi/4}\frac{2D^2}{3}\left(\frac{\sqrt{\rho}}{3}\right)^{1/3}\pi\int_{s=\bar{r}_1-r_1}^{0}x^{-2/3}dx, \quad \text{(G30)}$$

where $x=2(18\sqrt{\rho})^{-1/2}s^{3/2}$. We evaluate Eq. (G30) and find that

$$J_{\mathrm{III}}+J_{\mathrm{IV}}\sim \pi D^2 e^{-i\pi/4}2^{7/6}\rho^{1/12}3^{-2/3}(r_1-\bar{r}_1)^{1/2}. \quad \text{(G31)}$$

We have now evaluated all of the integrals in Eq. (G1). Finally, we must relate the constants C, C_1, C_2, C_3, C_4, and D in Eqs. (G13), (G17), and (G31). To do so we use Eqs. (4.14)–(41.6), (4.32), (4.33), and (4.35) and show algebraically that

$$C^2=\frac{\Gamma^2(\frac{3}{4}-\frac{1}{2}E)e^{-\pi iE/2}2^{-E}C_1^2}{(2\pi)^2}, \quad \text{(G32a)}$$

$$C_2C_3=\frac{C_1^2}{\Gamma(\frac{1}{4}-\frac{1}{2}E)\Gamma(\frac{1}{4}+\frac{1}{2}E)}, \quad \text{(G32b)}$$

$$D^2=\frac{\rho^{1/6}2^{4/3}3^{2/3}C_1^2}{\pi\Gamma(\frac{1}{4}+\frac{1}{2}E)\Gamma(\frac{1}{4}-\frac{1}{2}E)}. \quad \text{(G32c)}$$

We may pick an arbitrary value for C_1^2 because we are free to choose the over-all normalization of the original WKB wave function. We let

$$C_1^2=\tfrac{1}{2}e^{i\pi/4}\Gamma(\tfrac{1}{4}+\tfrac{1}{2}E)\Gamma(\tfrac{1}{4}-\tfrac{1}{2}E). \quad \text{(G33)}$$

Substituting Eq. (G33) into Eq. (G32) and simplifying,[39] the results are

$$C^2=\frac{\Gamma(-\nu)e^{-\pi iE/2}(\frac{1}{2}\pi)^{1/2}e^{i\pi/4}}{4\pi\cos\frac{1}{2}\pi\nu}, \quad \text{(G34a)}$$

$$C_2C_3=\tfrac{1}{2}e^{i\pi/4}, \quad \text{(G34b)}$$

$$D^2=(18\sqrt{\rho})^{1/3}e^{i\pi/4}/\pi. \quad \text{(G34c)}$$

Combining Eq. (G34) with Eqs. (G13), (G17), and (G31) shows that the contributions to J are

$$J_{\mathrm{I}}\sim 2\ln\bar{r}_0-\psi(E+\tfrac{1}{2})+\tfrac{1}{2}\pi\cot(\tfrac{1}{4}-\tfrac{1}{2}E)\pi, \quad \text{(G35a)}$$

$$J_{\mathrm{II}}\sim -2\ln\bar{r}_0+\ln(4/\rho)-2\rho^{1/4}\sqrt{2}(r_1-\bar{r}_1)^{1/2}, \quad \text{(G35b)}$$

$$J_{\mathrm{III}}+J_{\mathrm{IV}}\sim 2\sqrt{2}\rho^{1/4}(r_1-\bar{r}_1)^{1/2}. \quad \text{(G35c)}$$

Referring to Eq. (G3), we add together the three expressions in Eq. (G35) to find the total contribution to J which is

$$J=-\psi(E+\tfrac{1}{2})+\tfrac{1}{2}\pi\cot(\tfrac{1}{4}-\tfrac{1}{2}E)\pi+\ln(4/\rho). \quad \text{(G36)}$$

Note that $\bar{r}_0$ and $\bar{r}_1$ have dropped out of this final expression. This completes the evaluation of J for even parity.

For odd parity the result is

$$J=-\psi(\tfrac{1}{2}+E)+\tfrac{1}{2}\pi\cot(\tfrac{3}{4}-\tfrac{1}{2}E)\pi+\ln(4/\rho). \quad \text{(G37)}$$

The only differences between the even- and odd-parity derivations occur in the algebraic manipulations in region I.

Automaton Model of Dynamic Organization in Microtubules

STUART R. HAMEROFF,[a] STEVEN A. SMITH,[b] AND RICHARD C. WATT[a]

Microtubules (MT) participate in a wide range of organized dynamical activities that apparently involve information processing. Cellular automata are dynamical systems that can generate and process patterns and information by way of rules based on lattice neighbor interactions.[1-3] Lattice structure and apparent information processing capabilities have suggested an MT-automaton behavior based on coherent dipole oscillations within MT subunits.[4-6]

Various models of dynamic activities in biomolecules predict functional organization and regulation. Among these, Frohlich has theorized that nonlinear dipole excitations among subunits of biomolecular arrays result in coherent oscillations (10^{-10} to 10^{-11} sec fluctuations), lower frequency metastable states, long-range cooperativity and order, and coupling of protein conformational states to dipole oscillations within protein hydrophobic regions.[7,8] Individual subunit conformation within a lattice array would thus depend on various factors (GTP, Ca^{++}, primary structure, lattice neighbor electrostatic interactions) influencing oscillation phase. Based on MT geometry, we have calculated MT-lattice neighbor electrostatic influences on dipole oscillations as rules for an MT-automaton computer simulation (FIGURE 1). Dimer states at each generation can be determined by neighbor states at the previous generation.

$$\text{state} = \alpha, \text{ if } \sum_{i=1}^{n} f(y) > 0, \text{ state} = \beta, \text{ if } \sum_{i=1}^{n} f(y) < 0,$$

where n = 7 as the number of neighbors, and f(y) the force from the "*i*th" neighbor in the y direction.

$$f(y) \propto \frac{\sin\theta}{r^2}, \sin\theta = \frac{y}{r}; f(y) \propto \frac{y}{r^3};$$

thus states may be determined by $\Sigma_{i=1}^{n}\, y/r^3$ and relative values calculated from known MT structure.

FIGURE 2 shows one sequence from an "opened" MT automaton simulation in which 13 MT protofilaments are arranged horizontally. Each generation represents one Frohlich oscillation period (~ one nanosecond). "a" represents an alpha-tubulin dipole oscillation phase, whereas dots connected by lines represent beta-tubulin oscillation phases. Generations 22, 28, 34, and 40 from a particular sequence

demonstrate stable patterns (during even-numbered generations) and a traveling kink pattern (~80 meters/sec), which leaves an altered "wake" (? memory). These traveling patterns are known as gliders in automaton nomenclature and have been shown by von Neumann to be capable of universal computing.

Stable and moving patterns of an MT-subunit oscillation phase could function as specific sites of ion or protein binding and transport, orchestration of biomolecular activities, as well as stored information or memory. Interaction and interference of these patterns could process information as in computers and provide "real time" biological information processing. Although the MT-automaton rules and patterns described here are somewhat arbitrary, they demonstrate that MT-automaton activities are feasible and are of potential importance in dynamic organization.

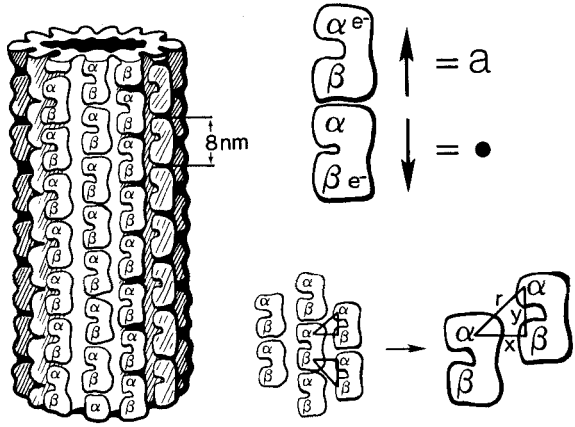

FIGURE 1. Left: MT structure from X-ray diffraction crystallography. Right top: MT-tubulin dimer subunits comprised of α and β monomers. Electron occupancy of either monomer may correlate with coherent dipole oscillations and are represented as "a" for α-monomer electron occupancy and dots connected by lines for β-monomer electron occupancy. Center bottom and right: hexagonal relations lead to neighbor rules based on lattice distances and electrostatic interactions. For neighbors shown (lower right), x = 5 nm, y = 4 nm, r = 6.4 nm.

BIOLOGICAL BOSE CONDENSATION AND THE TIME THRESHOLD FOR BIOLOGICAL EFFECTS ☆

T.M. WU and Steven AUSTIN
Department of Physics, State University of New York at Binghamton, Binghamton, NY 13901, USA

Received 13 June 1979

Fröhlich's model of Bose condensation in biological systems is analyzed using finite temperature Green's function techniques. The appropriate biological system excitation lifetime is calculated and represents the time needed to produce the condensed state. The possible relevance of this calculated lifetime to experiments concerning the microwave irradiation of biological organisms is discussed.

The dipole–dipole interaction within biological structure first suggested by Fröhlich [1–6] has stimulated many recent theoretical studies [7–12, 19–21]. Also some recent experimental reports [13–18] have appeared to conform in several aspects to the predictions of the Fröhlich model. The purpose of this paper is to extend the theoretical analysis utilizing a Green's function technique and to discuss the results in relation to biological experimentation that has been performed up to the present.

Fröhlich's model has been particularly useful in understanding recent experiments revealing the effects of low level microwaves on various biological systems. One important general characteristic that is reported in these experiments is the existence of a time threshold for the initiation of the differing biological effects. Sevastyanova and Vilenskaya [13] performed an experiment concerning the simultaneous irradiation of mice with X-rays and microwaves where they counted surviving bone marrow cells. The time threshold they determined before a protective effect occurred with simultaneous irradiation was 30 minutes of microwave exposure. Smolyanskaya and Vilenskaya [18] observed the effects of low level millimeter waves on the induction coefficient of colicin synthesis. Again, it was found that a minimum irradiation time is needed to produce measurable biological effects. The time threshold for this experiment was of the order of 30 minutes. One must keep in mind when considering these time effects that the threshold will depend on the particular biological activity being monitored and will also be temperature dependent. An example of the latter is clearly observed by analyzing Smolyanskaya and Vilenskaya's experiment. Irradiation for 30 minutes at $T = 20^{\circ}\mathrm{C}$ produced no change in the rate of colicin synthesis, whereas at $T = 37^{\circ}\mathrm{C}$, colicin synthesis was induced after 30 minutes of irradiation time. Therefore, it is expected that the analysis of the time threshold will not be a trivial matter. Both the detailed microscopic structure of the biological system and its thermodynamic behavior must be considered to provide a full understanding of the specific time thresholds encountered for different biosystems.

It is the authors' present intention to obtain an approximation for a segment of this time threshold using the Fröhlich model. In applying the Fröhlich hypothesis, one sees that the biological effects cannot begin until the condensed phase occurs. How long this condensation has to be maintained in order to produce biological effects is undetermined as yet. Most generally, the time needed to initiate biological effects will consist of two parts, τ_1 and τ_2. τ_1 represents the time from the beginning of irradiation to the onset of condensation. τ_2 represents the time elapsed from the on-

☆ This research was partially supported by grant number IROI GM 24502-02 from the National Institute of General Medical Sciences.

set of the condensed phase to the production of the actual biological effects. Thus, the total time, τ, elapsed before biological effects occur from the initiation of irradiation, is given by $\tau = \tau_1 + \tau_2$. In the following analysis, we calculated τ_1 to the lowest order in coupling strength using a Green's function method. An explicit form for τ_2 requires an in-depth biochemical analysis of the particular system under scrutiny and is beyond the scope of the present study. Undoubtedly, τ_2 represents an important part and should be studied in the future.

The hamiltonian of the biological system is:

$$H = \sum_p \omega_p a_p^\dagger a_p + \sum_{p'} \Omega_{p'} b_{p'}^\dagger b_{p'} + \sum_q \bar{\Omega}_q p_q^\dagger p_q + \sum_{p,p',p''} (\lambda a_p b_{p'}^\dagger b_{p''} + \lambda^* a_p^\dagger b_{p'} b_{p''}^\dagger) + \tfrac{1}{2} \sum_{p,p',p''} (\alpha a_p b_{p'}^\dagger b_{p''}^\dagger + \alpha^* a_p^\dagger b_{p'} b_{p''}) + \sum_{p,p',p''} (\chi a_p a_{p'}^\dagger b_{p''}^\dagger + \chi^* a_p^\dagger a_{p'} b_{p''}) + \tfrac{1}{2} \sum_{p,p',p''} (\beta a_p a_{p'} b_{p''}^\dagger + \beta^* a_p^\dagger a_{p'}^\dagger b_{p''}) + \sum_{p,q} (\xi p_q a_p^\dagger + \xi^* p_q^\dagger a_p). \quad (1)$$

All notations and the meanings ot the various coupling constants and operators are the same as those given in ref. [8]. For simplicity in the calculation, the excitations will be regarded as phonons for both the biological system and the heat bath. However, the heat bath quanta may also consist of fermions [8]. It should be noted that the lifetime (and thus self-energy) of interest is due to the terms with coupling constants χ and χ^* because these terms are responsible for creating the condensed phase. The contributions from the other terms that involve the simultaneous creation or destruction of two quanta within the biological system (i.e., those terms with the β and β^* coupling constants) are negligible compared to the above as shown in ref. [8]. The rest of the terms in the hamiltonian do not contribute to the condensation to the lowest order in coupling constant and therefore are not relevant to the present calculation.

Using finite temperature Green's function techniques the self-energy, $\Sigma(p, \omega_p)$, for the biological system phonon associated with operators a_p and $a_p^\dagger$ was calculated yielding:

$$\Sigma(p, \omega_p) = |\chi|^2 \sum_{p'} \left[\frac{1 + n(\Omega_{p'}) + n(\omega_{p-p'})}{\omega_p - \Omega_{p'} - \omega_{p-p'} + i\delta} + \frac{n(\Omega_{p'}) - n(\omega_{p-p'})}{\omega_p + \Omega_{p'} - \omega_{p-p'} + i\delta} \right], \quad (2)$$

where $n(\omega) = [\exp(\omega/kT) - 1]^{-1}$, Ω_p is the energy of a phonon with momentum p in the heat bath and ω_p is the energy of a phonon with momentum p in the biological system. Since at room temperature, these energies are much smaller than kT, $n(\omega_p)$ and $n(\Omega_{p'})$ are much larger than 1. Also $\Omega_{p'} = \pm(\omega_p - \omega_{p-p'})$ which is smaller than the width of the narrow energy band of the biological system under consideration which in turn is smaller than a typical energy in the set of vibrational modes (i.e., $\Omega_{p'} \ll \omega_p$). Thus, $n(\Omega_{p'}) \gg n(\omega_{p-p'})$. Therefore, the self-energy can be approximately written as:

$$\Sigma(p, \omega_p) = \frac{|\chi|^2 kT}{4\pi^2 \hbar^3} \int_{-1}^{1} dx \int_0^\infty \frac{p'^2 dp'}{\Omega_{p'}} \times \left[\frac{1}{\omega_p - \Omega_{p'} - \omega_{p-p'} + i\delta} + \frac{1}{\omega_p + \Omega_{p'} - \omega_{p-p'} + i\delta} \right], \quad (3)$$

where the sum over heat bath momenta has been converted to an integration. Using the Debye model, for the excitations in the heat bath, $\Omega_{p'} = v'p'$, where v' = the velocity of sound in the heat bath. The form of the dispersion relation for the biological system is unknown and depends in an intricate manner upon the biological structure. To obtain an approximate result, however, it is presumed that $\omega_p - \omega_{p-p'} = \pm\gamma\Delta$ where Δ = the width of the energy band (which is assumed narrow) and γ is a positive quantity less than 1. The value of γ depends on the form of the dispersion relation for the biological system.

Using the relation:

$$\tau_1 = \hbar/|\mathrm{Im}\,\Sigma|, \quad (4)$$

and the imaginary part of the self-energy in eq. (3):

$$\mathrm{Im}\,\Sigma \doteq -|\chi|^2 kT\gamma\Delta/\pi v'^3\hbar^3, \quad (5)$$

we have:

$$\tau_1 \doteq \hbar^4\pi v'^3/|\chi|^2 kT\gamma\Delta, \quad (6)$$

which is inversely proportional to T and to the square of the coupling constant. As seen from eq. (6), τ_1 decreases with increasing temperature. Thus, as the temperature is raised, the condensed phase should occur sooner also causing the biological effects to begin sooner. This agrees, at least qualitatively, with the example stated previously from Smolyanskaya and Vilenskaya's experiment where changing T from 20°C to 37°C brought the biological effects into play holding the irradiation time fixed at 30 minutes.

τ_1 given in eq. (6) represents the irradiation time needed to produce the condensation and is the minimum time needed to produce biological effects. In order to apply this equation to specific circumstances, model studies and more experiments need to be performed to obtain expressions for the coupling constants and the widths of the energy bands. Given this information, a more complete understanding of the Fröhlich model and all its implications can be obtained.

BOSE CONDENSATION IN BIOSYSTEMS

T.M. WU and Steven AUSTIN
Department of Physics, State University of New York at Binghamton, Binghamton, New York 13901, USA

Received 14 September 1977

A microscopic approach to Fröhlich's theory of Bose condensation in biological systems is discussed. The conclusions from this microscopic analysis offer further support for Fröhlich's hypothesis.

The possible importance of vibrational modes in the frequency range of 10^{11}–$10^{12}\,\mathrm{sec}^{-1}$ of biological macromolecules in stimulating important life processes was first suggested by Fröhlich [1–5]. Recently, several experimental results have been published which tend to support Fröhlich's theory [6–10].

Generally, biological systems possess constituents that are capable of electric dipolar oscillations. Long range Coulomb interaction between these dipoles establishes a branch or branches of longitudinal electric modes. Fröhlich has suggested if energy is supplied locally to one constituent (or removed from it), this energy variation will be shared by all the constituents within the branch of vibrational modes due to the long range coulomb interaction. He further concluded if energy is supplied beyond a certain critical rate, the energy redistribution among the dipolar modes will lead to its concentration in the lowest energy state (i.e. Bose–Einstein condensation).

Fröhlich's mathematical analysis was based upon the utilization of rate equations. We have approached the theoretical problem using microscopic techniques and the interaction Hamiltonian. As Fröhlich, we suppose that the biological system consists of the following:

(i) oscillating segments of giant dipoles occurring along macromolecules,

(ii) the remainder of the biosystem which forms a heat bath,

(iii) an external energy source which couples to the oscillating units.

The interaction between oscillating units produces a narrow band of frequencies, $\omega_i\,(\omega_0 \leqslant \omega_i \leqslant \omega_{\max})$ representing the normal electromagnetic modes. Assigned to each mode are creation and destruction operators, a_i^+ and a_i. The vibrational modes of the heat bath, Ω_k, are associated with creation and destruction operators, b_k^+ and b_k. Similarly, the external energy source has frequencies, $\bar{\Omega}_p$, and creation and destruction operators P_p^+ and P_p associated with it. Thus, the Hamiltonian of the biosystem can be given as:

$$H = \sum_i \hbar\omega_i a_i^+ a_i + \sum_k \hbar\Omega_k b_k^+ b_k + \sum_p \hbar\bar{\Omega}_p P_p^+ P_p + \hbar\sum_{i,k}(\lambda b_k^+ a_i + \lambda^* b_k a_i^+)$$

$$+ \tfrac{1}{2}\hbar \sum_{i,j,k}{}' (\chi a_i^+ a_i b_k^+ + \chi^* a_j a_i^+ b_k) + \hbar\sum_{p,i}(\xi P_p a_i^+ + \xi^* P_p^+ a_i)\,, \tag{1}$$

where λ, χ and ξ are coupling constants for the one quantum process, the two quantum process and the energy supply to the oscillating constituents respectively. Using the commutation relations the rate of change of ith mode quanta is

$$\dot{n}_i = (\mathrm{i}\hbar)^{-1}[n_i, H]\,, \tag{2}$$

where $n_i = a_i^+ a_i$.

Using the commutation relations for the various creation and destruction operators, we found the expectation value of $\dot{n}_i$ ($\langle\dot{n}_i\rangle = \langle\psi(t)|\dot{n}_i|\psi(t)\rangle$) to be:

$$\langle \dot{n}_i \rangle = S - \phi(T, \omega_i)[\langle n_i \rangle \exp(\hbar\omega_i/kT) - (1 + \langle n_i \rangle)] - \sum_j \Lambda(T, \omega_i, \omega_j)[\langle n_i \rangle (1 + \langle n_j \rangle) \exp(\hbar(\omega_i - \omega_j)/kT) - \langle n_j \rangle (1 + \langle n_i \rangle)], \tag{3}$$

where the angular brackets refer to thermal averaging in the grand ensemble appropriate to the entire system. $|\psi(t)\rangle$ is the state vector of the whole system at time t. Since $\langle \dot{n}_i \rangle$ cannot be solved exactly, perturbation theory was utilized to obtain it to lowest order in coupling strength. For stationarity, $\langle \dot{n}_i \rangle = 0$. As a result, we found the average number of ith mode quanta to be:

$$\langle n_i \rangle = \left[1 + \frac{S}{\phi(T, \omega_i) + \Sigma_j \Lambda(T, \omega_i, \omega_j)\langle n_j \rangle}\right] \{\exp[\hbar\omega_i - \mu)/kT] - 1\}^{-1}, \tag{4}$$

where

$$\exp(-\mu/kT) = \frac{1 - \Sigma_j \Lambda(T, \omega_i, \omega_j)(\langle n_j \rangle - (1 + \langle n_j \rangle) \exp(-\hbar\omega_j/kT)}{\phi + \Sigma_j \Lambda \langle n_j \rangle}, \tag{5}$$

$$S = 4\pi |\xi|^2 \sum_i \langle p_i^+ p_i \rangle, \tag{6}$$

$$\phi(T, \omega_i) = 4\pi |\lambda|^2 \exp(-\hbar\omega_i/kT)[1 + N(\hbar\omega_i)], \tag{7}$$

and

$$\Lambda(T, \omega_i, \omega_j) = \pi |\chi|^2 \exp[-\hbar(\omega_i - \omega_j)/kT] \times \begin{cases} [N(\hbar\omega_j - \hbar\omega_i)], & \omega_j > \omega_i, \\ [1 + N(\hbar\omega_i - \hbar\omega_j)], & \omega_i > \omega_j, \end{cases} \tag{8}$$

where $N(\hbar\omega)$ is the number of excitations with energy $\hbar\omega$ in the heat bath.

Eqs. (4) and (5) are of exactly the same form as those derived by Fröhlich. Bose–Einstein condensation into the lowest energy state occurs when μ approaches $\hbar\omega_0$. This takes place when the energy supplied exceeds a certain critical rate as shown by Fröhlich. Fröhlich formed the ansätze in his rate equations by requiring a Bose–Einstein distribution for thermal equilibrium when no external power is supplied. Otherwise, the form of the rate equations were rather arbitrary. However, by approaching Fröhlich's theory from a macroscopic point of view, we have arrived at the same conclusions as Fröhlich did and removed the arbitrariness. Our results, therefore, further strengthen the possibility that such a phenomenon as Bose condensation in biological systems exists.

BOSE CONDENSATION OF STRONGLY EXCITED LONGITUDINAL ELECTRIC MODES

H. FRÖHLICH
Department of Theoretical Physics, University of Liverpool, UK

Received 14 February 1968

If the energy fed into the branch of longitudinal electric modes exceeds a critical rate then, under stationary conditions, the excitation energy is channelled into the mode with lowest frequency in a manner typical for Bose condensation.

In the introductory talk to the recent conference on Theoretical Physics and Biology [1] I have conjectured that in living systems certain coherent longitudinal electric modes are strongly excited, and stabilized by deformations arising from non linear effects. This conjecture was stimulated by the extraordinary dielectric properties of cells and of some of the relevant giant molecules in conjecture with the requirement of a non-obvious long-range order (coherence) in systems which are relatively stable but not in all respects in thermal equilibrium. It is the purpose of the present note to show that under very general circumstances the energy fed into the branch of longitudinal electric modes gets channelled into a single mode in a manner which closely resembles the condensation phenomenon in a Bose gas.

Assume the system to consist of Z components suspended in a heat bath, and consider each component capable of dipolar electric oscillations. Such a component may be a repeated dipolar part of a giant molecule (e.g. H-bond) or it may be a larger unit. The long range interaction of these components then leads to the establishment of Z modes, usually in a relatively narrow frequency range, say

$$\omega_1 \leqslant \omega \leqslant \omega_2 . \tag{1}$$

Assume that energy is supplied locally to each component at a rate s, so that it may be considered supplied to each mode of the branch at the same rate s. Interaction with the heat bath then leads to emission of energy until a steady state has been reached. This interaction with the heat bath must depend on the excitation of the modes; processes of first and second order in the number of excited quanta will be considered. The condition for stationarity then requires for each l,

$$s = L_l , \tag{2}$$

where the rate of loss of energy L_l from mode ω_l (containing n_l quanta) is assumed of the form

$$L_l = \phi(T)(n_l \exp(\hbar\omega_l/kT) - (1+n_l)) + \tag{3}$$
$$+ \chi(T) \sum_j (n_l(1+n_j) \exp\{\hbar(\omega_l - \omega_j)/kT\} - n_j(1+n_l)) .$$

The interaction terms $\phi(T) > 0$ and $\chi(T) > 0$ with the heat bath will in general depend on temperature T. Clearly L_l vanishes in thermal equilibrium when n_l is a Planck distribution n_{lT}. With the notation $N = \sum n_j$ one finds from eqs. (2) and (3)

$$n_l = \left(1 + \frac{s}{\phi + \chi N}\right) \frac{1}{\exp\{(\hbar\omega_l - \mu)/kT\} - 1} , \tag{4}$$

which requires $\hbar\omega_1 > \mu \geqslant 0$ to satisfy $n_l \geqslant 0$. Also

$$\exp(-\mu/kT) = \frac{\phi + \chi \sum (1+n_j) \exp(-\hbar\omega_j/kT)}{\phi + \chi N} = \tag{5}$$
$$= 1 - \frac{\chi}{\phi + N\chi} \frac{S(T)}{\phi} > 0 ,$$

where

$$S(T) = \phi \sum \{n_j - (1+n_j) \exp(-\hbar\omega_j/kT)\} . \tag{6}$$

Clearly Bose condensation into the lowest mode ω_1 will take place when μ approaches $\hbar\omega_1$ very closely. One would expect this to occur when s becomes sufficiently large. We shall demonstrate this explicitly for the high temperature case,

$$kT \gg \hbar\omega_1 . \tag{7}$$

In this approximation one finds from (4)

$$n_l = \left(1 + \frac{s}{\phi + \chi N}\right) \frac{kT}{\hbar\omega_l - \mu} + \ldots . \tag{8}$$

Let $D(\omega)d\omega$ be the number of modes in a range $d\omega$. Then if no condensation has taken place $D(\omega_l)\, n_l$ can be considered a continuous function and one finds (N_n denotes the total number of quanta in this case)

$$N_n = \left(1 + \frac{s}{\phi + \chi N_n}\right) kT \int_{\omega_1}^{\omega_2} \frac{D d\omega}{\hbar\omega - \mu} < \left(1 + \frac{s}{\phi + \chi N_n}\right) N_0 \qquad (9)$$

and hence in the absence of condensation when $N = N_n$ one has

$$\frac{N(\phi + \chi N)}{\phi + \chi N + s} < N_0 = \frac{kT}{\hbar} \int_{\omega_1}^{\omega_2} \frac{D d\omega}{\omega - \omega_1} \,. \qquad (10)$$

Now N can also be estimated from the generally valid eq. (6), which yields

$$S(T) = \phi \frac{\hbar\bar{\omega}}{kT} (N - N_T) \,, \qquad (11)$$

where $\omega_1 \leqslant \bar{\omega} \leqslant \omega_2$, and N_T is the number of quanta in thermal equilibrium. Also in this approximation $S(T) \approx Zs$. It follows from eq. (11) that N is a linear function of s because $\bar{\omega}$ depends only weakly on s. Hence a value of s_0 of s exists above which (10) can no longer be fulfilled. The situation then closely resembles that in the Bose condensation of ideal gases. This implies that a continuous distribution $n_l D(\omega_l)$ can no longer accommodate the total number of quanta. $\mu/\hbar$ then takes a value below, but so close to the lowest frequency ω_1 that condensation into ω_1 takes place. The total number of quanta in this case becomes $N = N_n + kT/(\hbar\omega_1 - \mu)$.

Details depend, of course, strongly on the particular model. It can be seen, however, that in general N_0 will be larger than the number of thermal quanta by a factor of the order $\omega_1/(\omega_2 - \omega_1)$, but from (10) it follows that the critical number of quanta at which condensation starts is less than N_0. Finally it should be mentioned that N, according to eq. (11) is independent of χ, but χ is very relevant in the condensation condition.

CRYSTALLINE FIELD EFFECTS AND FIRST ORDER PHASE TRANSITION IN $ErCo_2$

G. PETRICH and R. L. MÖSSBAUER
Physics Department, Technische Hochschule München, Germany

Received 15 February 1968

The temperature dependence of the nuclear hyperfine splitting of ^{166}Er has been measured in the magnetically ordered $ErCo_2$ compound, showing a first order magnetic phase transition. The measurements indicate a crystalline field interaction which is large compared to the exchange interaction.

Measurements of the dependence upon temperature of the nuclear magnetic and quadrupole hyperfine splitting provide information on the influence of the crystalline electric field on the energy levels of ions embedded in a magnetically ordered metal. We report here the observation of a crystalline field interaction within the $J = \frac{15}{2}$ ground multiplet of Er^{3+} in the intermetallic Laves compound $ErCo_2$, which produces an over-all splitting of the multiplet which is large compared to the exchange splitting of about $100^{\circ}K$ of the lowest $|\pm\frac{15}{2}\rangle$ multiplet.

The hyperfine splitting was observed in the recoilless gamma resonance spectrum of the 80.6 keV transition of ^{166}Er in $ErCo_2$ as absorber material where the Er environment has cubic symmetry. The measurements employed sources of $HoAl_2$ which were kept at T =

Bose–Einstein Condensation in Biological Systems

T. M. Wu and Steven Austin

Department of Physics, State University of New York, Binghamton, New York 13901, *U.S.A.*

(*Received* 31 *January* 1977, *and in revised form* 15 *June* 1977)

Biological systems contain dipolar elements which are capable of electric oscillations at certain specific frequencies. Longitudinal electric modes in a frequency range of 10^{11}–10^{12} s^{-1} are typical. Fröhlich has suggested that if energy is supplied above a critical rate to the branch or branches of electric modes, Bose–Einstein condensation into the lowest energy state occurs. This phenomenon possibly represents a channel for various life processes such as cell division and protein synthesis.

Fröhlich's model is analyzed utilizing microscopic techniques, and it is subsequently concluded that Bose condensation in biosystems may occur under certain conditions.

1. Introduction

The possible participation of the vibrational modes of macromolecules in biological processes has been discussed repeatedly (Volkenshtein, 1964; Khurgin, 1967). It is well known that biological systems contain components capable of electric dipolar oscillations. For example, cell membranes possess a thickness on the order of 10^{-6} cm which maintains a strong dipolar layer. Local vibrations within the membrane could cause positively and negatively charged segments to vibrate against each other yielding an electric dipole oscillation. Similarly, biological macromolecules, e.g. proteins, DNA, etc. have marked dipolar characteristics due primarily to the presence of hydrogen bonds. The interaction between these giant dipoles through long range Coulomb forces establishes a branch or several branches of longitudinal electric modes in a frequency range of 10^{11}–10^{12} s^{-1}.

Recently, H. Fröhlich (Fröhlich, 1968*a*,*b*, 1970, 1972, 1975), has suggested that if energy is supplied locally to one component (or removed from there), then, due to the long range Coulomb interaction, this energy change will be shared by all the components comprising the branch of electric modes. If the rate of energy supply is sufficiently large, the redistribution of the energy between the various degrees of freedom will lead to its concentration in the

0022-5193/0320-0209 $01.00/0 © 1978 Academic Press Inc. (London) Ltd.

lowest energy mode. This phenomenon is known in physics as Bose–Einstein condensation. This coherent oscillation of electric modes might serve not only as a method for efficient energy storage, but also as a channel for specific bioprocesses.

The biological implications of Bose–Einstein Condensation are numerous. With the onset of condensation, a strong coherent electromagnetic oscillation is established in the system, and the energy channeled into the lowest energy mode could possibly disrupt the cell membrane. Thus, this effect might be one of the energetic mechanisms crucial to the production of cell division. A Soviet investigator (Devyatkov, 1974) has reported enhanced cell division in Rhodotorula and Candida cultures after irradiation by electromagnetic waves in the frequency range appropriate to the Fröhlich model. Similarly, the energy stored by biological Bose–Condensation could be directed to other life sustaining activities such as protein synthesis.

Besides the possible important participation of Bose–Einstein Condensation in the processes of cell division and protein synthesis, a variety of other biological effects could perhaps be attributed to this phenomenon. Recently, several investigators (Kiselev & Zalyuboskaya, 1974; Sevastyanova & Vilenskaya, 1974; Smolyanskaya & Vilenskaya, 1974) have reported interesting results concerning the microwave irradiation of various biological objects in the frequency range 10^{11}–10^{12} s^{-1}. Assuredly, the specific effects represent very complex biological processes. However, they exhibit two pronounced features: (i) they depend very strongly on frequency exhibiting typical resonance behavior, (ii) there exists a critical power supply threshold below which no effect is observed and above which there is a sharp increase in the biological effects which is essentially independent of the power supply. These features strongly support Fröhlich's Bose condensation theory as applied to biological systems. The complexity and diversity of the experimental results may reflect the possibility that different biological effects occur depending upon which dipolar elements are participating in the Bose condensation. For example, the vibrations of one type of macromolecule within the biological system would most likely produce different effects than a different type of macromolecule or the vibrations of the cell membrane itself.

Fröhlich arrived at his conclusions on the basis of rate equations. The general forms of the rate equations were dictated by requiring a Bose–Einstein distribution for thermal equilibrium when there is no power supplied. Beyond this, their forms were somewhat arbitrary. In this paper, the interaction Hamiltonian is utilized. It is subsequently shown that Fröhlich's ansätze in the rate equations are correct, and that there is a Bose–Einstein Condensation.

2. Theory

Similar to Fröhlich, it is presumed that the biological system consists of three parts: (i) oscillating units of giant dipoles occurring approximately periodically along the length of the macromolecules, (ii) the rest of the biosystem constituting a heat bath, (iii) an external energy source which couples to the oscillatory units. The interaction between the oscillatory units will produce a narrow band of frequencies, ω_i ($\omega_0 \leq \omega_i \leq \omega_{\max}$), corresponding to the normal modes of the electromagnetic oscillations.

To each mode, ω_i, a creation operator, a_i^+, and a destruction operator, a_i, are assigned. The normal modes of oscillation will then interact with the rest of the biological system (the heat bath) which is represented by a set of independent excitation frequencies, Ω_k, associated with creation and destruction operators, b_k^+ and b_k respectively. Furthermore, the external energy source, associated with creation and destruction operators P_p^+ and P_p respectively and frequency, $\overline{\Omega}_p$, feeds into the electromagnetic oscillating units and provides impetus for initiation of the biological effects. The Hamiltonian of the biological system can be written as:

$$\begin{aligned} H = & \sum_i \hbar\omega_i a_i^+ a_i + \sum_k \hbar\Omega_k b_k^+ b_k \\ & + \sum_p \hbar\overline{\Omega}_p P_p^+ P_p \\ & + \sum_{i,k} \lambda b_k^+ a_i + \lambda^* b_k a_i^+ \\ & + \sum_{i,j,k} (\chi a_j^+ a_i b_k^+ + \chi^* a_j a_i^+ b_k) \\ & + \sum_{p,i} (\xi P_p a_i^+ + \xi^* P_p^+ a_i) \end{aligned} \tag{1}$$

where λ, χ, and ξ are coupling constants for the one quantum process, two quanta process, and the energy supply to the oscillating units respectively. The electromagnetic oscillations are bosons. Yet the excitations within the heat bath can be either bosons, e.g. phonons, or fermions, e.g. electrons.

The operators a_i^+, a_i, b_k^+, b_k, P_p^+ and P_p satisfy the commutation relations:

$$\begin{aligned} & a_i a_j^+ - a_j^+ a_i = \delta_{ij} \\ & a_i^+ a_j^+ - a_j^+ a_i^+ = a_i a_j - a_j a_i = 0 \\ & b_k b_l^+ \pm b_l^+ b_k = \delta_{kl} \end{aligned} \tag{2}$$

($-$ sign for Bosons and $+$ sign for fermions)

$$\begin{aligned} & b_k b_l \pm b_l b_k = b_k^+ b_l^+ \pm b_l^+ b_k^+ = 0 \\ & P_p P_{p'}^+ - P_{p'}^+ P_p = \delta_{pp'} \end{aligned}$$

The operators corresponding to different excitations commute with one another.

The rate of change of the number of quanta in the ith mode is given by:

$$\dot{n}_i = \frac{1}{i\hbar}[n_i, H] \tag{3}$$

with $n_i = a_i^+ a_i$.

Using the commutation relations in equation (2), equation (3) becomes:

$$\begin{aligned}\dot{n}_i = & -\frac{i}{\hbar}\sum_{i,k}(\lambda^* b_k a_i^+ - \lambda b_k^+ a_i) \\ & -\frac{i}{\hbar}\sum_{j,k}\{\chi(a_i^+ a_j b_k^+ - a_j^+ a_i b_k^+) + \chi^*(a_i^+ a_j b_k - a_j^+ a_i b_k)\} \\ & -\frac{i}{\hbar}\sum_{p,i}(\xi P_p a_i^+ - \xi^* P_p^+ a_i)\end{aligned} \tag{4}$$

The expectation value of $\dot{n}_i$ is given by:

$$\langle \dot{n}_i \rangle = \langle \psi(t) | \dot{n}_i | \psi(t) \rangle \tag{5}$$

where the angular brackets refer to thermal averaging in the grand ensemble describing the whole system, and $|\psi(t)\rangle$ is the state vector of the whole system at time t. Since equation (5) cannot be evaluated exactly, perturbation theory is utilized to solve it to the lowest order in coupling strength. To this end, it is presupposed that the interactions between the electromagnetic oscillations of the system with the heat bath and energy source are turned on adiabatically from the past. Then, if $|\psi_0\rangle$ is the exact eigenstate of the non-interaction system with the Hamiltonian

$$\begin{aligned}H_0 = & \sum_i \hbar\omega_i a_i^+ a_i + \sum_k \hbar\Omega_k b_k^+ b_k \\ & + \sum_P \hbar\bar{\Omega}_p P_p^+ P_p,\end{aligned}$$

it is then possible to write the state vector at time t, to the lowest order in coupling constants as:

$$\begin{aligned}|\psi(t)\rangle = e^{-iH_0 t/\hbar} \Bigg[& 1 - \sum_{i,k} \frac{\lambda b_k^+ a_i \, e^{i(\Omega_k - \omega_i)t}}{(\omega_i - \Omega_k) + i\delta} \\ & - \sum_{i,k} \frac{\lambda^* b_k a_i^+ \, e^{-i(\Omega_k - \omega_i)t}}{(\omega_i - \Omega_k) - i\delta} \\ & - \sum_{i,j,k} \frac{\chi a_j^+ a_i b_k^+ \, e^{i(\Omega_k + \omega_j - \omega_i)t}}{(\Omega_k + \omega_j - \omega_i) + i\delta} \\ & - \sum_{i,j,k} \frac{\chi^* a_j a_i^+ b_k \, e^{-(\Omega_k - \omega_j + \omega_i)t}}{(\Omega_k - \omega_j + \omega_i) - i\delta} \\ & - \sum_{p,i} \frac{\xi P_p a_i^+ \, e^{i(\omega_i - \bar{\Omega}_p)t}}{(\omega_i - \bar{\Omega}_p) - i\delta} \\ & - \sum_{p,i} \frac{\xi^* P_p^+ a_i \, e^{-i(\omega_i - \quad p)t}}{(\omega_i - \bar{\Omega}_p) + i\delta} \Bigg] \; |\psi_0\rangle\end{aligned} \tag{6}$$

Where δ is an infinitesimally small positive value, changing the summations over Ω_k and $\bar{\Omega}_p$ to integrations and using appropriate contours yields:

$$\begin{aligned}|\psi(t)\rangle = e^{-iH_0t/\hbar}\Big[1 &- 2i\pi\sum_i(\lambda b_i^+ a_i - \lambda^* b_i a_i^+) \\ &- 2i\pi\sum_{i,j}(\chi a_j^+ a_i b_{i-j}^+ + \chi^* a_j a_i^+ b_{j-i}) \\ &- 2i\pi\sum_i(\xi P_i a_i^+ + \xi^* P_i^+ a_i)\Big]\ |\psi_0\rangle \end{aligned} \tag{7}$$

Substituting equation (7) into equation (5) and using the commutation relations, one obtains:

$$\begin{aligned}\langle\dot{n}_i\rangle = S &- \phi(T,\omega_i)[\langle n_i\rangle e^{\hbar\omega_i/kT} - (1+\langle n_i\rangle)] \\ &- \sum_j \Lambda(T,\omega_i,\omega_j)[\langle n_i\rangle(1+\langle n_j\rangle)\, e^{[\hbar(\omega_i-\omega_j)]/kT} \\ &\qquad - \langle n_j\rangle(1+\langle n_i\rangle)]\end{aligned} \tag{8}$$

where $\langle n_i\rangle$ is the thermal average of the number of ith quanta and $S = 4\pi/\hbar|\xi|^2\sum_i\langle P_i^+ P_i\rangle_0$ is the number of quanta supplied to the ith mode from the external source. $\phi(T,\omega)$ and $\Lambda(T,\omega_i,\omega_j)$ are given by:

$$\begin{aligned}\phi(T,\omega_i) &= 4\pi/\hbar|\lambda|^2\, e^{-(\hbar\omega_i/kT)}\ [1\pm N(\hbar\omega_i)] \\ \Lambda(T,\omega_i,\omega_j) &= 2\pi/\hbar|\chi|^2\, e^{-[\hbar(\omega_i-\omega_j)]/kT} \\ &\qquad \begin{cases}[N(\hbar\omega_j-\hbar\omega_i)], & \text{for } \omega_j > \omega_i \\ [1\pm N(\hbar\omega_i-\hbar\omega_j)], & \text{for } \omega_i > \omega_j\end{cases}\end{aligned} \tag{9}$$

where $N(\hbar\omega)$ is the number of excitations with energy $\hbar\omega$ in the heat-bath and the plus or minus sign corresponds to bosons or fermions respectively. Note that the 2nd and 3rd terms in equation (8) possess exactly the same forms as Fröhlich's ansätze for loss rates of ith quanta in one and two quanta processes respectively.

The condition for stationarity requires for each oscillator $\langle\dot{n}_i\rangle = 0$. From this, it is found from equation (8) that:

$$\langle n_i\rangle = \left[1 + \frac{S}{\phi(T,\omega_i) + \sum_j \Lambda(T,\omega_i,\omega_j)\langle n_j\rangle}\right] e^{[(\hbar\omega_i-\mu)/kT]^{-1}} - 1, \tag{10}$$

and

$$e^{-(\mu/kT)} = 1 - \frac{\sum_j \Lambda(T,\omega_i,\omega_j)[\langle n_j\rangle - (1+\langle n_j\rangle)\, e^{-(\hbar\omega_j/kT)}]}{\phi + \sum_j \Lambda\langle n_j\rangle} \leq 1. \tag{11}$$

The inequality of equation (11) together with the requirement that $\langle n_i\rangle \geq 0$ dictates that:

$$\hbar\omega_0 \geq \mu \geq 0.$$

3. Conclusion

Equations (10) and (11) are precisely the same equations obtained by Fröhlich. Clearly, from equation (10) one sees that Bose Condensation into the lowest energy mode occurs when μ is approximately equal to $\hbar\omega_0$. As demonstrated by Fröhlich, this takes place when the energy supply becomes sufficiently large and exceeds a certain specific rate which depends on the coupling strength of the heat bath. If there is no energy supplied, $s = 0$, $\mu = 0$, and equation (10) becomes the thermal equilibrium distribution as required. Also it is interesting to take note that if there are no two quanta processes, i.e. $\chi = 0$, then $\mu = 0$, and no Bose Condensation occurs even if energy is supplied externally.

By approaching this theoretical problem using microscopic techniques, a better understanding of the possible existence of Bose–Einstein Condensation in biological systems has been obtained. This model, therefore, is a useful tool for gaining insight into intricate biological structures via straightforward physical concepts. However, the explicit understanding of the complex biochemical aspects of this problem and how they relate to specific life processes is yet to be developed.

CANONICAL TRANSFORMATIONS IN QUANTUM FIELD THEORY AND SOLITONS

L. MERCALDO, I. RABUFFO and G. VITIELLO[1]

Istituto di Fisica, Università di Salerno, 84100-Salerno, Italia

Received 22 December 1980
(Revised 9 March 1981)

In a sine-Gordon model we discuss a transformation which can be viewed as a quantum image of the Bäcklund transformation. The soliton is described in terms of condensation of quanta; their confinement is ascribed to the non-implementability of unitary transformations among unitarily inequivalent representations of canonical commutators and to the related topological conservation law.

1. Introduction

In many-body physics, as well as in high-energy particle physics, much attention has been devoted to the study of soliton-like solutions to non-linear evolution equations [1, 15]. Such solutions could be indeed useful in the description of "extended objects" such as dislocations in crystals, vortices in superconductivity or, in high-energy physics, monopoles in non-abelian gauge theories, bag models for elementary particles, etc. The quantum origin of these extended objects requires, however, an understanding of the soliton-like solutions in terms of basic quantum constituents.

It is known that for classical non-linear evolution equations the Bäcklund transformation is a canonical one which keeps the hamiltonian form invariant [2].

In the quantum field theory an operator has been constructed generating a canonical transformation among Heisenberg fields and leading to a coherent state representation for a soliton solution [3]. In the present work we consider a quantum sine-Gordon $1+1$ dimensional model. The condition that the vacuum expectation value (v.e.v.) of the Heisenberg scalar field reproduces the static soliton solution is found to be satisfied when the LSZ asymptotic quantum field (constituent) undergoes a canonical transformation.

The same condition leads us to consider the tree approximation only.

It will be seen that although the transformation for the asymptotic field cannot be defined for $x_1 \to -\infty$ (or $x_1 \to +\infty$), the transformation for the Heisenberg field

[1] Gruppo Nazionale di Struttura della Materia, Unità di Salerno, Italia.

can be formally extended to the full x_1 axis. This fact expresses a well-known property characterizing the classical behaviour of the soliton, namely its interpolation between degenerate vacua. In sect. 3 we see that this is related, on the other hand, to the existence of a topological conservation law and to the stability of the soliton.

By successive canonical transformations of the LSZ asymptotic field, n-soliton solutions can be generated; they appear thus as the "quantum image" of the Bäcklund transformations. Their generator is considered in sect. 3, where the soliton solution is represented in terms of coherent state; the relation to the coherent representation of ref. [3] is also discussed.

Finally let us observe that the reconstruction of the soliton in terms of the v.e.v. of a quantum field has been presented in refs. [4–6]. There the tree approximation has also been used and a canonical transformation ("the boson transformation") for the asymptotic field has been assumed. Canonical transformations from the free field base have been also used in ref. [18].

2. Canonical transformations and the soliton solution

We first introduce the quantum field theory framework. Let us consider the 1 + 1 dimensional quantum sine-Gordon model whose Heisenberg field equation is given by

$$\partial^2\hat{\phi}(x)+\frac{m^3}{g}\sin g\frac{\hat{\phi}(x)}{m}=0, \qquad x\equiv(x_0,x_1), \qquad \partial^2\equiv\partial_0^2-\partial_1^2. \tag{1}$$

$\hat{\phi}(x)$ is a Heisenberg scalar field. Eq. (1) can be written, upon expansion of the sine, as

$$(-\partial^2-m^2)\hat{\phi}(x)=-\frac{m^3}{g}\sum_{k=1}^{\infty}\frac{(-1)^{k+1}}{(2k+1)!}\left(\frac{g}{m}\right)^{2k+1}\hat{\phi}(x)^{2k+1}, \tag{2}$$

i.e., with obvious notation,

$$\Lambda(\partial)\hat{\phi}(x)=J\left[\hat{\phi}(x)\right]. \tag{3}$$

In the previous equations m is the physical mass. Let $\hat{\phi}^{\mathrm{in}}(x)$ denote the LSZ asymptotic in-field (equivalently we could work with the out-field $\hat{\phi}^{\mathrm{out}}(x)$):

$$\Lambda(\partial)\hat{\phi}^{\mathrm{in}}(x)=0. \tag{4}$$

Our quantum field theory is completely specified only when the Hilbert space on which the field operators are to be realized is given. We choose as our Hilbert space

the Fock space for the in-field $\hat{\phi}^{\text{in}}(x)$ denoted by $\{|0\rangle\}$, with the vacuum state $|0\rangle$:

$$\hat{\phi}^{\text{in}}(x)^{(+)}|0\rangle = 0. \tag{5}$$

$\hat{\phi}^{\text{in}}(x)^{(+)}$ denotes the annihilation operator of $\hat{\phi}^{\text{in}}(x)$. Also we assume that

$$\langle 0|\hat{\phi}(x)|0\rangle = 0. \tag{6}$$

The Heisenberg field operates on the states of $\{|0\rangle\}$ when expressed in terms of $\hat{\phi}^{\text{in}}(x)$. In other words a solution of the dynamics in terms of $\hat{\phi}^{\text{in}}$ is determined when the "dynamical map" [7]

$$\langle a|\hat{\phi}(x)|b\rangle = \langle a|F\left[\hat{\phi}^{\text{in}}(x)\right]|b\rangle \tag{7}$$

is found. Here F denotes a functional of normal products of $\hat{\phi}^{\text{in}}$ and is determined by the dynamics; $|a\rangle$ and $|b\rangle$ belong to $\{|0\rangle\}$. It is important to note that $|a\rangle$ and $|b\rangle$ are wave-packet states since $\{|0\rangle\}$ is the space of physical states.

Let us observe that eq. (3) leads to the Yang-Feldman equation

$$\langle a|\hat{\phi}(x)|b\rangle = \langle a|\left[\hat{\phi}^{\text{in}}(x) - i\int \mathrm{d}^2 y \Delta_{\text{R}}(x-y)\right] J\left[\hat{\phi}(y)\right]|b\rangle, \tag{8}$$

where $\Delta_{\text{R}}(x-y)$ is the retarded Green function:

$$\Lambda(\partial)\Delta_{\text{R}}(x-y) = i\delta^{(2)}(x-y). \tag{9}$$

Let us now turn our attention to the classical Euler equation framework. The static Euler equation is

$$\Lambda_{\text{s}}(\partial)\phi_{\text{c}}^{(1)}(x_1) = J\left[\phi_{\text{c}}^{(1)}(x_1)\right] \tag{10}$$

where $\Lambda_{\text{s}}(\partial) \equiv \partial_1^2 - m^2$ and J has the same form as in eq. (3). $\phi_{\text{c}}^{(1)}(x_1)$ is the c-number function for the single-soliton solution:

$$\phi_{\text{c}}^{(1)}(x) = -\frac{4m}{g}\,\text{tg}^{-1}\text{e}^{-m(x_1-a)}. \tag{11}$$

Let $f(x_1)$ denote a solution of

$$\Lambda_{\text{s}}(\partial)f(x_1) = 0; \tag{12}$$

e.g.

$$f(x_1) = \text{const}\cdot\text{e}^{-mx_1}. \tag{13}$$

We do not choose as $f(x_1)$ a superposition of e^{-mx_1} and e^{+mx_1} since it would be divergent both as $x_1 \to -\infty$ and as $x_1 \to +\infty$. When the constant in (13) is chosen to be $-4(m/g)e^{ma}$, $\phi_c^{(1)}(x_1)$ can be written as

$$\phi_c^{(1)}(x_1) = f(x_1) + \int dy_1 K(x_1 - y_1) J\left[\phi_c^{(1)}(y_1)\right] \tag{14}$$

$$= f(x_1) - \frac{g^2}{3!} \int dy_1 K(x_1 - y_1) f^3(y_1) + \cdots, \tag{15}$$

with

$$\Lambda_s(\partial) K(x_1 - y_1) = \delta(x_1 - y_1). \tag{16}$$

The choice (13) and the convergence of the integrals in (15) require that

$$K(x_1 - y_1) = -\theta(y_1 - x_1) \frac{1}{m} \sinh m(x_1 - y_1). \tag{17}$$

Our assumption is now that a correspondence can be established between the quantum level and the classical level. To exhibit such a correspondence let us assume that there exists an invariant transformation B for the static Heisenberg field equation:

$$\hat{\phi}^{(1)}(x) = B\hat{\phi}(x), \tag{18}$$

$$\Lambda(\partial)\hat{\phi}^{(1)}(x) = J\left[\hat{\phi}^{(1)}(x)\right]. \tag{19}$$

We want to relate the v.e.v. of $\hat{\phi}^{(1)}$ to $\phi_c^{(1)}$. Since the Heisenberg field operates on the Fock space through the physical particle field $\hat{\phi}^{in}(x)$, we have to find a transformation β,

$$\hat{\phi}^{in}(x) \to \hat{\phi}^{in\prime}(x) = \beta\hat{\phi}^{in}(x), \tag{20}$$

such that, as an effect of the non-linearity of the dynamical map eq. (7), it "dynamically rearranges" [8, 9] as

$$\langle a | B\hat{\phi}(x) | b \rangle = \langle a | F\left[\beta\hat{\phi}^{in}(x)\right] | b \rangle . \tag{21}$$

Furthermore, we require that β is a canonical transformation for $\hat{\phi}^{in}(x)$, i.e. it preserves the canonical commutation relation (c.c.r.)

$$\left[\hat{\phi}^{in}(x), \dot{\hat{\phi}}^{in}(y)\right]_{x_0 = y_0} = i\delta(x_1 - y_1), \qquad \left[\hat{\phi}^{in}(x), \hat{\phi}^{in}(y)\right]_{x_0 = y_0} = 0, \quad \text{etc.} \tag{22}$$

and is an invariant transformation for the free field equation (4):

$$\Lambda(\partial)\hat{\phi}^{\mathrm{in}\prime}(x)=0. \tag{23}$$

The Yang-Feldman equation for $\hat{\phi}^{(1)}$ is

$$\langle 0|\hat{\phi}^{(1)}(x)|0\rangle=\langle 0|\hat{\phi}^{\mathrm{in}\prime}(x)|0\rangle-i\int \mathrm{d}^2y\Delta_{\mathrm{R}}(x-y)\langle 0|J\big[\hat{\phi}^{(1)}(y)\big]|0\rangle\,. \tag{24}$$

Observe now that

$$\langle 0|J\big[\hat{\psi}(x)\big]|0\rangle=J\big[\langle 0|\hat{\psi}(x)|0\rangle\big]+\mathrm{O}(h), \tag{25}$$

where $\mathrm{O}(h)$ denotes contribution of the order of h, the Planck constant, due to the contraction of in fields which create loop diagrams. Thus

$$\begin{aligned}\lim_{h\to 0}\langle 0|\hat{\phi}^{(1)}(x)|0\rangle &= \langle 0|\hat{\phi}^{\mathrm{in}\prime}(x)|0\rangle-i\int \mathrm{d}^2y\Delta_{\mathrm{R}}(x-y)J\Big[\lim_{h\to 0}\langle 0|\hat{\phi}^{(1)}(y)|0\rangle\Big]\\ &= \langle 0|\hat{\phi}^{\mathrm{in}\prime}(x)|0\rangle-i\int \mathrm{d}^2y\Delta_{\mathrm{R}}(x-y)\big[\langle 0|\hat{\phi}^{\mathrm{in}\prime}(y)|0\rangle\big]^3+\cdots.\end{aligned} \tag{26}$$

If the v.e.v. of $\hat{\phi}^{\mathrm{in}\prime}(x)$ is time independent, when the static case is considered, Δ_{R} is replaced by $K(x_1-y_1)$ and d^2y by $i\mathrm{d}y_1$. Therefore, we can put

$$\phi_{\mathrm{c}}^{(1)}(x_1)=\lim_{h\to 0}\langle 0|\hat{\phi}^{(1)}(x)|0\rangle=\lim_{h\to 0}\langle 0|B\hat{\phi}(x)|0\rangle\,. \tag{27}$$

The limit $h\to 0$ suggests use of the tree approximation when explicit computation is to be carried out [4–6]*. To find β we compare eq. (15) with eq. (26) for the static case:

$$\begin{aligned}&f(x_1)-\frac{g^2}{3!}\int \mathrm{d}y_1K(x_1-y_1)f^3(y_1)+\cdots\\ &\quad=\langle 0|\hat{\phi}^{\mathrm{in}\prime}(x)|0\rangle-\frac{g^2}{3!}\int \mathrm{d}y_1K(x_1-y_1)\big(\langle 0|\hat{\phi}^{\mathrm{in}\prime}(y)|0\rangle\big)^3+\cdots,\end{aligned} \tag{28}$$

* It could be observed that in refs. [4–6] use of the tree expansion from the beginning is equivalent to finding just a perturbative solution of the classical equation. However it can be shown (cf. refs. [12, 13]) that quantum corrections, including renormalization effects, can be calculated from the dynamical map in the tree approximation. These problems are extensively analyzed in refs. [12–14] where interaction between quanta and static soliton are also studied.

so that

$$\langle 0|\hat{\phi}^{\mathrm{in}\prime}(x)|0\rangle = f(x_1). \tag{29}$$

In conclusion

$$\hat{\phi}^{\mathrm{in}\prime}(x) = \beta\hat{\phi}^{\mathrm{in}}(x) = \hat{\phi}^{\mathrm{in}}(x) + f(x_1). \tag{30}$$

It should be observed, however, that $\hat{\phi}^{\mathrm{in}\prime}(x)$ is *not* well definite as $x_1 \to -\infty$; so we restrict eq. (30) to the domain $x_1 > 0$. Nevertheless, the B transformation can be formally extended to the full x_1 axis since $\phi_c^{(1)}(x_1)$ [cf. eq. (27)] is everywhere well behaved*. This is related to the interpolating character of the soliton solution between degenerate vacua:

$${}_{2\pi}\langle 0|\hat{\phi}(x)|0\rangle_{2\pi} = -2\pi\frac{m}{g} \underset{-\infty \leftarrow x_1}{\leftarrow} \phi_c^{(1)}(x_1) \underset{x_1 \to +\infty}{\rightarrow} 0 = {}_0\langle 0|\hat{\phi}(x)|0\rangle_0, \tag{31}$$

which expresses, equivalently, the existence of a topological conservation law (topological charge $Q = \phi_c^{(1)}(x_1 = +\infty) - \phi_c^{(1)}(x_1 = -\infty)$). $|0\rangle_0$ denotes the Fock vacuum introduced in eq. (5). The state $|0\rangle_{2\pi}$ denotes the degenerate vacuum for which

$${}_{2\pi}\langle 0|\hat{\phi}(x)|0\rangle_{2\pi} = -2\pi\frac{m}{g}. \tag{32}$$

The related space $\{|0\rangle_{2\pi}\}$ is one of the infinitely many unitarily inequivalent representations of the c.c.r. allowed in our theory in the infinite volume limit ($x_1 \to \pm\infty$) [11]. Due to the unitary inequivalence, there does not exist a well defined unitary operator generating the transformation $|0\rangle_0 \to |0\rangle_{2\pi}$ or vice versa. Nevertheless, the interpolation between expectation values of $\hat{\phi}$ in $|0\rangle_0$ and $|0\rangle_{2\pi}$, as expressed in eq. (31), is characteristic of the non-trivial topology of the soliton $\phi_c^{(1)}(x)$. This is a manifestation of the classical nature of the soliton solution: it allows the interpolation between unitarily inequivalent representations. At the quantum level, such an interpolation is strictly forbidden since quantization requires a unique definite choice of the representation**.

Let us remark that when $\hat{\phi}$ is written through the dynamical map in terms of $\hat{\phi}^{\mathrm{in}}$, B does not preserve the canonical commutators [12–14]

$$\left[\hat{\phi}(x), \dot{\hat{\phi}}(y)\right]_{x_0=y_0} = i\delta(x_1 - y_1), \qquad \left[\hat{\phi}(x), \hat{\phi}(y)\right]_{x_0=y_0} = 0, \qquad \text{etc.}$$

* It can be proved that if $\hat{\psi}(x) = \Psi(x, \hat{\psi}^{\mathrm{in}}(x))$ satisfies the Heisenberg equation, then $\hat{\psi}'(x) = \Psi(x, \hat{\psi}^{\mathrm{in}} + f)$ satisfies the same Heisenberg equation, with $f(x)$ the solution of the free field equation for field $\hat{\psi}^{\mathrm{in}}$; in our case, cf. eq. (19). This is the content of the boson transformation theorem, see ref. [10].

** In problems involving order parameters $\alpha_i = {}_{\alpha_i}\langle 0|\hat{\phi}(x)|0\rangle_{\alpha_i}$, $i = 1,2\ldots$ where $|0\rangle_{\alpha_i}$ denote inequivalent degenerate vacua, soliton solutions can be relevant in the study of transitions between different α_i.

To reintegrate them (which may be interpreted as completeness relations) the inclusion of bound state modes and the introduction of a "quantum coordinate" (collective coordinate) for the soliton are required. When fluctuations of this coordinate are negligible with respect to the size of the soliton, it behaves as a classical object; otherwise it behaves as a quantum soliton. In ref. [14] an extensive discussion of these problems can be found.

Since the above considerations are independent of the particular form of J in eq. (3), they also apply to a scalar $1+1$ dimensional $\lambda\phi^4$ theory.

In the case of the sine-Gordon model one can consider a n-soliton solution $\phi_c^{(n)}(x_0, x_1)$ with $n > 1$, which is characterized by n parameters [1, 15]. We have to boost $f(x_1)$ given in eq. (13):

$$x_1 \to x_1' = \gamma(x_1 - ux_0) + \gamma u \frac{\Delta}{2m}$$

$$c = 1, \qquad 0 < u < 1, \qquad \gamma = (1-u^2)^{-1/2}, \qquad \tfrac{1}{2}\Delta = \frac{1}{u\gamma}\log u,$$

$$f(x_1) = \text{const} \cdot e^{-mx_1} \to \text{const} \cdot e^{-m\gamma x_1 + m\gamma u x_0 - \Delta u\gamma/2} = f(x_0, x_1) = f(x_1'). \quad (33)$$

Here we are partially using notations and conventions of ref. [15]. Of course $f(x_1')$ solves the free field equation (4) due to its Lorentz invariance. As we did for the one-soliton case, we can write in this case

$$\phi_c^{(n)}(x_1') = f^{(n)}(x_1') + \int dy_1' K(x_1' - y_1') J\left[\phi_c^{(n)}(y_1')\right],$$

where $f^{(n)}(x_1')$ is a solution of the free field equation (4) of the general form

$$f^{(n)}(x_1') = f^{(n)}(x_0, x_1) = \sum_{i=1}^{n} f_i(x_1'). \quad (34)$$

f_i are of the form (33) and characterized by the velocity parameters u_i.

We assume now that a correspondence can be established between the quantum level and the classical level such that

$$\lim_{h \to 0} \langle 0|\hat{\phi}^{(n)}(x_0, x_1)|0\rangle = \phi_c^{(n)}(x_0, x_1), \quad (35)$$

with $\hat{\phi}^{(n)}$ solution of the Heisenberg field equation. Then we look for a canonical transformation $\beta^{(n)}$ for $\hat{\phi}^{\text{in}}$ such that

$$\langle 0|\hat{\phi}^{(n)}(x_0, x_1)|0\rangle = \langle 0|B^{(n)}\hat{\phi}(x_0, x_1)|0\rangle = \langle 0|F\left[\beta^{(n)}\hat{\phi}^{\text{in}}(x_0, x_1)\right]|0\rangle, \quad (36)$$

and such that it is an invariant transformation for the free field equation (4). We can

repeat the procedure followed in the one-soliton case by changing the label (1) into (n) everywhere. Under our assumptions, we thus find $\beta^{(n)}$:

$$\hat{\phi}^{\text{in}} \to \hat{\phi}^{\text{in}\prime} = \hat{\phi}^{\text{in}} + f^{(n)} = \hat{\phi}^{\text{in}} + \sum_{i=1}^{n} f_i \tag{37}$$

as the transformation which induces $B^{(n)}$

$$\hat{\phi} \to \hat{\phi}^{(n)} = B^{(n)}\hat{\phi}. \tag{38}$$

Like eq. (30), eq. (37) must be restricted to a convenient x_1 domain to make $\hat{\phi}^{\text{in}\prime}(x)$ a well-defined field operator. We can also think of (37) as

$$\hat{\phi}^{\text{in}} \overset{\beta}{\to} \hat{\phi}^{\text{in}} + f_1 \overset{\beta}{\to} \hat{\phi}^{\text{in}} + f_1 + f_2 \to \cdots, \tag{39a}$$

in such a way that

$$\hat{\phi} \overset{B}{\to} \hat{\phi}^{(1)} \overset{B}{\to} \hat{\phi}^{(2)} \to \cdots. \tag{39b}$$

In this sense we refer to (38) [or to (39)] as to the "quantum image" of the Bäcklund transformation. Eq. (37) suggests that the soliton can be viewed as an extended object created by the condensation of $\hat{\phi}^{\text{in}}$ quanta (constituents) controlled by the f shift. By using $f^{(n)}$ as given in eq. (34) with $n = 2$, an explicit reconstruction of the 2-soliton case is presented in ref. [5]; there the n-soliton case, $n > 2$, is also discussed.

3. The coherent state representation and the confinement of the constituents

To study the coherent state representation, we introduce the generator of the transformation (30); it is given by

$$D^{\text{in}} = -\int_{-\infty}^{+\infty} \mathrm{d}y_1 g(y_1)\dot{\hat{\phi}}^{\text{in}}(y), \tag{40}$$

with $g(x_1) = \theta(x_1)f(x_1)$ and $\theta(x_1)$ the step function. Use of the c.c.r. shows indeed that

$$\hat{\phi}^{\text{in}\prime}(x) = \mathrm{e}^{-iD^{\text{in}}}\hat{\phi}^{\text{in}}(x)\mathrm{e}^{iD^{\text{in}}}. \tag{41}$$

Thus, eq. (29) gives

$$\langle 0|\mathrm{e}^{-iD^{\text{in}}}\hat{\phi}^{\text{in}}(x)\mathrm{e}^{iD^{\text{in}}}|0\rangle = \langle f|\hat{\phi}^{\text{in}}(x)|f\rangle = f(x_1), \tag{42}$$

where we have put

$$|f\rangle = e^{iD^{in}}|0\rangle \tag{43}$$

and a restriction to a convenient x_1 domain must be introduced to make (41) well defined. Due to the isometry of the transformation induced by (40), it is

$$\langle f|f\rangle = 1. \tag{44}$$

The state (43) is thus a coherent state for $\hat{\phi}^{in}(x)$ [16]:

$$\hat{a}^{in}_k|f\rangle = \alpha(k)|f\rangle, \tag{45}$$

where $\hat{a}^{in}_k$ denotes the annihilation operator of $\hat{\phi}^{in}$ and the c-number function $\alpha(k)$ is related (in a convenient x_1 domain) to the $f(x_1)$ Fourier amplitude. By using the dynamical map (7) and eq. (42) we have

$$\langle f|\hat{\phi}(x)|f\rangle = F[f(x_1)],$$

$$\langle f|J[F(\hat{\phi}^{in}(x))]|f\rangle = J[F(f(x_1))]. \tag{46}$$

Thus $\langle f|\hat{\phi}(x)|f\rangle$ solves the static Euler equation

$$\Lambda_s(\partial)\langle f|\hat{\phi}(x)|f\rangle = J[\langle f|\hat{\phi}(x)|f\rangle],$$

$$\langle f|\hat{\phi}(x)|f\rangle = \phi^{(1)}_c(x_1). \tag{47}$$

Again we stress that, although (42) is restricted to $x_1 > 0$ only, eq. (47) can also be formally extended to $x_1 < 0$, which expresses the interpolating character of the soliton between degenerate vacua [cf. eq. (31)].

Let us note that $|f\rangle$ is not the soliton coherent state for $\hat{\phi}(x)$ as usually given in the literature (cf. refs. [3, 17, 18]), i.e.

$$|\phi^{(1)}_c\rangle = e^{iD}|0\rangle \tag{48}$$

with

$$D = -\int dy_1 \phi^{(1)}_c(y_1)\dot{\hat{\phi}}(y), \tag{49}$$

which is indeed different from D^{in}. Since $|0\rangle$ is the free field vacuum state, to compute the r.h.s. of (48), the dynamical map for $\hat{\phi}$ must be used to express D in terms of $\hat{\phi}^{in}$. In this way the non-linearity of the dynamics is taken into account. It

should be noticed, however, that in the infinite volume limit ($x_1 \to \pm\infty$), since the soliton solution goes to a constant ($\phi_c^{(1)}(x_1 = \pm\infty) = \text{const}^{(\pm)}$) a generator such as the one in eq. (49), cannot be safely defined for the transformation

$$\hat{\phi}(x) \to \hat{\phi}(x) + \text{const}^{(\pm)}, \qquad \text{at } x_1 \to \pm\infty \text{ and } \text{const}^{(+)} \neq \text{const}^{(-)} \tag{50}$$

as is well known [19]. This fact expresses the stability of the soliton state against decay into a finite number of constituents $\hat{\phi}^{\text{in}}(x)$. By following ref. [18] indeed, we can evaluate the overlap between the soliton state $|\phi_c^{(1)}\rangle$ at $x_0 = \pm\infty$ and a state of a finite number of constituents. We compute (cf. ref. [18], sect. 3)

$$\langle 0|\phi_c^{(1)}\rangle\big|_{x_0=\pm\infty} = \exp\left[-\tfrac{1}{2}\int \mathrm{d}k\,|\tilde{\phi}_c^{(1)}|^2\,\omega_k\right], \tag{51}$$

where eq. (49) and the asymptotic field for $\hat{\phi}(x)$ have been used. In eq. (51) $\tilde{\phi}_c^{(1)}$ is the Fourier amplitude of $\phi_c^{(1)}(x_1)$ and $\omega_k = (m^2 + k^2)^{1/2}$. Since

$$\infty = \int |\phi_c^{(1)}|^2\,\mathrm{d}x_1 = \int |\tilde{\phi}_c^{(1)}|^2\,\mathrm{d}k < \int \omega_k |\tilde{\phi}_c^{(1)}|^2\,\mathrm{d}k,$$

the resulting transition probability is zero. We thus conclude that the confinement of the constituents of an extended object finds its origin in the fact that the transformation

$$\hat{\phi}^{\text{in (out)}} \to \hat{\phi}^{\text{in (out)}\prime} = \hat{\phi}^{\text{in (out)}} + \text{const}^{(\pm)} \tag{52}$$

is not unitarily implementable. To implement (52) an infinite amount of energy would be required, because it is not an invariant transformation for the free field equation (4). As in ref. [18], this can be expressed by saying that the existence of a topological conservation law [topological charge $Q = \phi_c^{(1)}(x_1 = +\infty) - \phi_c^{(1)}(x_1 = -\infty)$] corresponds to the soliton being a stable bound state of infinite constituents.

4. Conclusion

We have discussed the transformations which the Heisenberg and asymptotic fields undergo when one looks at the classical soliton from the point of view of quantum basic constituents*. We have considered the 1 + 1 dimensional sine-Gordon model.

Suppose that there exists a quantum field operator $\hat{\phi}^{(1)}(x)$ which solves the static Heisenberg equation, and whose v.e.v. in the $h \to 0$ limit is given by the static soliton

* For an interesting example of condensation generating solitons see ref. [20]. See also refs. [18, 21] for solitons in terms of free fields.

$\phi_c^{(1)}(x_1)$. Suppose also that there exists a transformation B such that $\hat{\phi}^{(1)}(x) = B\hat{\phi}(x)$, with $\hat{\phi}(x)$ a solution of the Heisenberg equation with zero v.e.v.

When $\hat{\phi}(x)$ is expressed in terms of the LSZ asymptotic in-field we have that the transformation B is induced by

$$\hat{\phi}^{\text{in}}(x) \overset{\beta}{\to} \hat{\phi}^{\text{in}}(x) + f(x_1),$$

with $f(x_1) = \text{const} \cdot e^{-mx_1}$, $x_1 > 0$ solving the free field equation. It is interesting to note that although β is definite for $x_1 > 0$ only, B can be formally extended to $x_1 < 0$ also. We have observed that this is a manifestation of the soliton interpolation between degenerate vacua expectation values of $\hat{\phi}$:

$$_{2\pi}\langle 0|\hat{\phi}(x)|0\rangle_{2\pi} = -2\pi\frac{m}{g} \underset{-\infty \leftarrow x_1}{\leftarrow} \phi_c^{(1)}(x_1) \underset{x_1 \to +\infty}{\to} 0 = {}_0\langle 0|\hat{\phi}(x)|0\rangle_0,$$

which expresses the non-trivial topology of the soliton ($\phi_c^{(1)}(x_1 \to +\infty) - \phi_c^{(1)}(x_1 = -\infty) \neq 0$). $|0\rangle_{2\pi}$ and $|0\rangle_0$ belong to representations of the free field c.c.r. which are unitarily inequivalent in the infinite volume limit ($x_1 \to \pm\infty$) [11]. Since quantization requires a unique definite choice of the representation, we have ascribed this interpolation property to the fact that the soliton is the solution to the classical Euler equation. A discussion of a coherent state representation has been presented in sect. 3 where the interpolating character of the soliton has been related to the existence of a topological conservation law and to the "confinement" of the constituents (stability of the soliton, see ref. [18]). In the infinite volume limit the "confinement" has indeed its origin in the non-implementability of transformation among unitarily inequivalent representations.

This paper is an extended version of a talk delivered at the Workshop on non-linear evolution equations and dynamical systems, Crete, July 9–23, 1980. J. Honerkamp, Y. Kodama, P. Kulish, V.G. Makhanov, G.P. McCauley are gratefully acknowledged for useful comments. Finally, it is a pleasure to thank Professor H. Umezawa for stimulating discussions.

CELLULAR AUTOMATA IN CYTOSKELETAL LATTICES

Steven A. SMITH

Dept. Anesthesiology, Univ. of Arizona Health Sciences Center, Tucson, Arizona 85724, USA

Cellular automata (CA) activities could mediate biological regulation and information processing via nonlinear electrodynamic effects in cytoskeletal lattice arrays. Frohlich coherent oscillations and other nonlinear mechanisms may effect discrete 10^{-10} to 10^{-11} s interval events which result in dynamic patterns in biolattices such as cylindrical protein polymers: microtubules (MT). Structural geometry and electrostatic forces of MT subunit dipole oscillations suggest neighbor rules among the hexagonally packed protein subunits. Computer simulations using these suggested rules and MT structural geometry demonstrate CA activities including dynamical and stable self-organizing patterns, oscillators, and traveling "gliders". CA activities in MT and other cytoskeletal lattices may have important biological regulatory functions.

1. Introduction

Cellular automata (CA) are dynamical systems which can generate and process patterns and information via lattice neighbor interactions [1–3]. Various biomolecular systems have lattice structures and participate in organized dynamical functions. These structures include membrane lipids and proteins, extracellular glycoproteins, DNA, and the cytoskeleton: microtrabecular lattice, protein filaments and microtubules (MT) [4–7] (fig. 1). Coherent dipole oscillations resulting in long-range cooperativity, as well as other nonlinear electrodynamic effects have been theorized to regulate activities in these structures [8–9]. Coherent oscillations among biolattice grid subunits could mediate information processing via CA-like activities. This paper considers the possibilities and potential significance of CA-like activities in a particular biolattice: cytoskeletal MT.

2. Coherent excitations in biological systems

Frohlich has theorized that non-linear dipole excitations among subunits of biomolecular arrays will result in coherent oscillations (10^{-10} to 10^{-11} s fluctuations), lower frequency metastable states, and long range order [8–9]. Frohlich also theorized that protein conformational states are coupled to electron dipole oscillations within protein hydrophobic regions [8]. Conformational coupling to coherent electronic excitation by individual sub-

(North-Holland Physics Publishing Division)

units in biomolecular arrays would apparently depend on various (genetic and environmental) biochemical factors as well as neighbor interactions. Neighbor interactions in a protein polymer can be mediated by factors which include electrostatic dipole interactions, water and calcium ion binding, conformational changes, binding of various substances including GTP and associated proteins, intrinsic subunit factors, or solitons [10, 11]. Such influences could alter the oscillatory phase of particular subunits in a coherent biomolecular array, resulting in dynamic patterns and CA-like activities.

Dynamic and stable patterns of excitation and conformational states in biomolecular structures could have direct, profound effects on regulation and organization of cellular processes. Patterns of resonant excitation and conformational states in various structures could mediate protein binding sites, ion fluxes, transport of biomolecules, growth, organization of cellular activities, and information processing. CA are thus theoretically possible and of potential significance in biological systems.

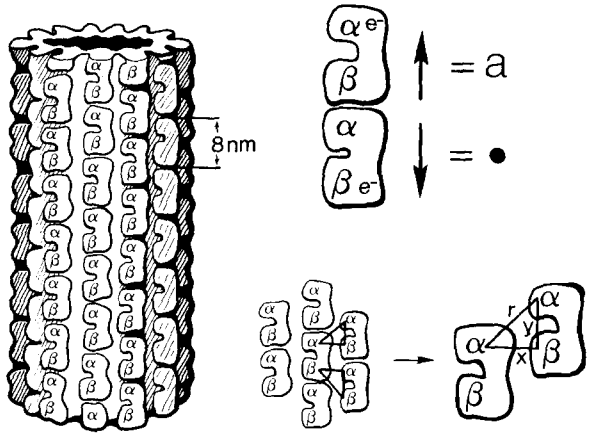

Fig. 2. Left: microtubule (MT) structure from X-ray diffraction crystallography [15]. Right top: MT tubulin dimer subunits comprised of α and β monomers. Electron occupancy of either monomer may correlate with coherent dipole oscillations and are represented [figs. 3–6] as "a" for α monomer electron occupancy and "." for β monomer electron occupancy. Center bottom and right: hexagonal relations lead to neighbor rules based on lattice distances. For neighbors shown (lower right), $x = 5$ nm, $y = 4$ nm, $r = 6.4$ nm.

3. Cytoskeletal lattices

Cytoskeletal lattices including protein polymers, microtubules (MT), actin, intermediate filaments, and the microtrabecular lattice interconnect and organize nearly all cell components and dynamic activities (fig. 1). Intracellular movement and coordination, growth, mitosis, transport and turnover of membrane proteins are accomplished by cytoskeletal lattices and attached proteins. MT are cylindrical polymers which comprise cilia, mitotic spindles, other organelles, and are the major cellular architectural elements [6, 12]. MT are intimately involved in dynamic biological activities, but mechanisms of "real time" regulation and control by MT or other structures are unknown [13]. The particular structure and geometry of MT will be considered as potential CA lattices.

Most MT are assemblies of 13 longitudinal protofilaments which are each a series of polar, tubulin dimers (fig. 2). A dimer consists of two slightly different 55,000 molecular weight monomers (α and β tubulin) which are each 4 nm in diameter. Hexagonal packing of the dimers results in 5 and 8 start helical patterns [14–16]. MT outer diameters are 25–30 nm and inner diameters are 14–15 nm [17]. MT outer surfaces are surrounded by a "clear zone" of several nm which apparently represents electronegative charges on tubulin [18]. Functional MT lengths may range from hundreds of nm to micrometers and meters in some mammalian neurons [19, 20]. Contractile or enzymatic proteins may be attached at specific dimer sites resulting in various helical patterns [16]. Various proteins are transported by MT at rates from one to 400 millimeters/day [21, 22]. Also binding reversibly at specific dimer sites are GTP molecules, hydrolysis of which can yield phosphate bond energies capable of oscillations or soliton formation [23]. Thus programming modes by genetic or environmental factors can introduce solitons or oscillatory phase shifts at specific lattice sites.

Table I

Neighbor position (fig. 2)	Central dimer α		Central dimer β	
	Neighbor α	Neighbor β	Neighbor α	Neighbor β
North	+0.063	+0.254	+0.028	+0.063
Northeast	+0.063	+0.007	+0.040	+0.063
Southeast	−0.061	−0.037	−0.007	−0.061
South	−0.063	−0.028	−0.254	−0.063
Southwest	−0.063	−0.040	−0.007	−0.063
Northwest	+0.061	+0.007	+0.037	+0.061

Configuration of tubulin dimer subunits may favor dipole oscillations between α and β states (fig. 2). In the context of Frohlich coherent excitation, various factors could modulate oscillatory phase of individual lattice subunits. (See section on Coherent excitations in biological systems.) The most predictable and consistent of these factors, electrostatic forces due to MT subunit neighbor dipoles, will be considered as the rules for CA activity in the structural geometry of MT lattices.

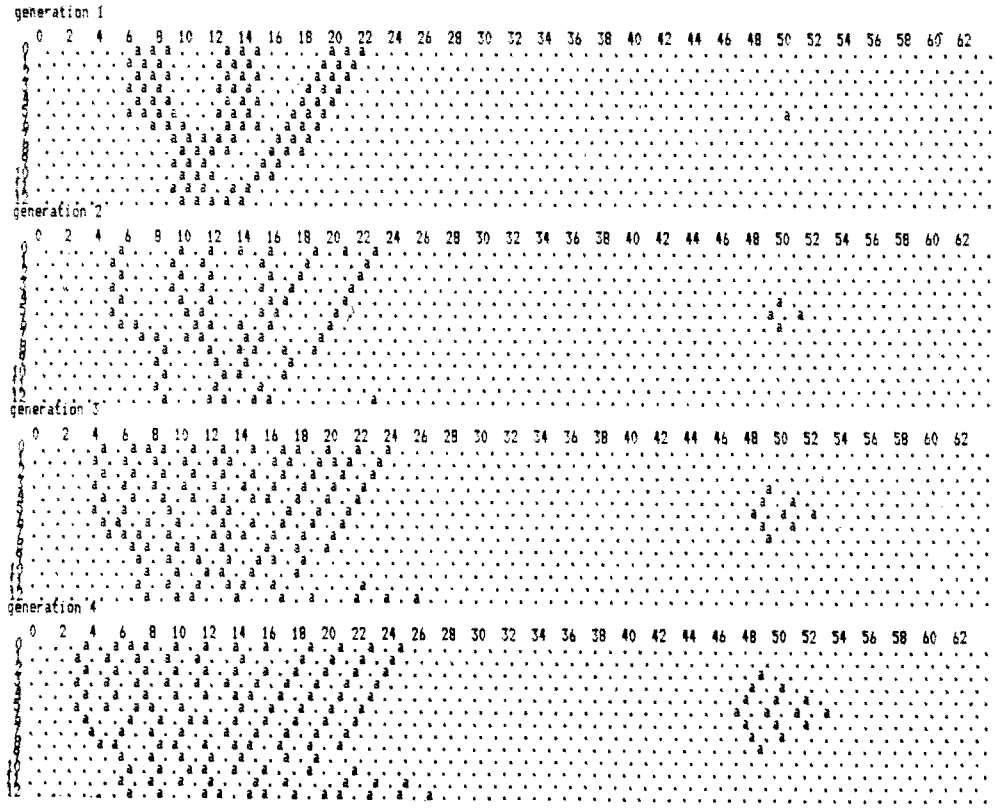

Fig. 3. Unfolded MT lattice with 13 protofilaments (0–12) on vertical axis, and "north" neighbors and dimer orientation on horizontal axis. An organized (arbitrary) pattern of α states starts on the left side and a single α state originates on the right. In generations 1–4 (generation numbers are on top of accompanying lattice) both the pattern and single α state develop and grow according to rules described in text.

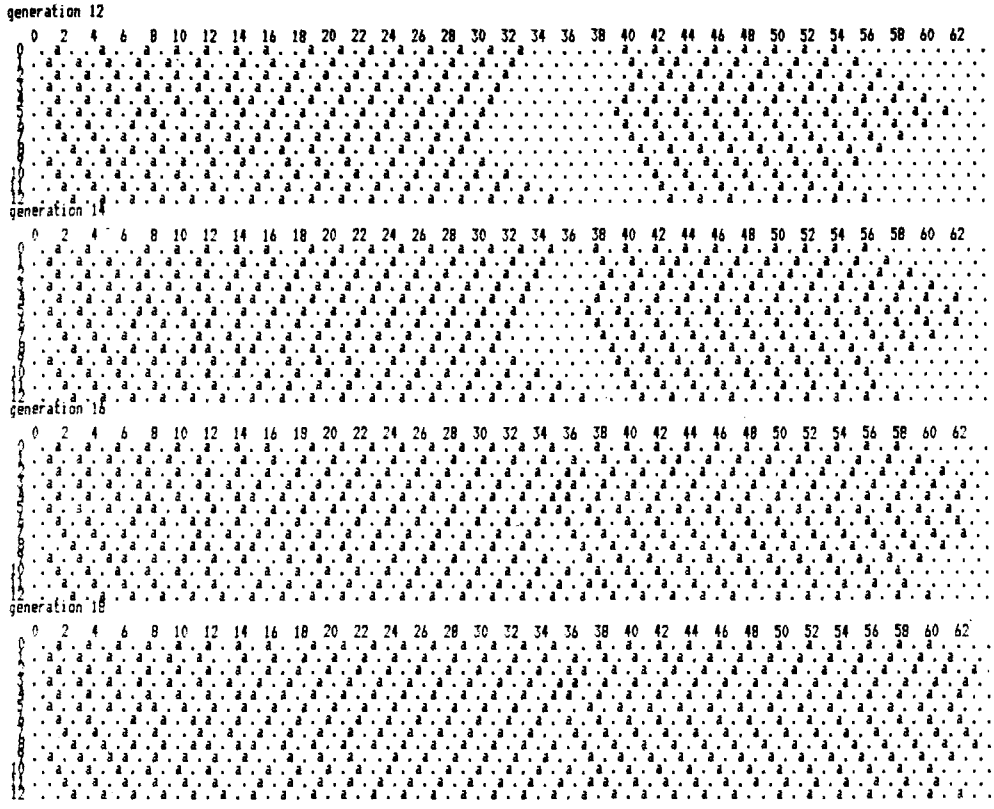

Fig. 4. Generations 12, 14, 16, and 18 of the same sequence as fig. 3. The two patterns have evolved and begin to interact.

4. CA rules for MT lattices

Frohlich's theory predicts 10^{-10} to 10^{-11} s coherent dipole oscillations of MT subunit dimers. If dipole polarities may exist in either the α and β orientation (fig. 2) then the state of each dimer at each oscillation may depend largely on neighbor dipole electrostatic forces.

Relative contributions of neighbor dipoles will consist of the y-component of the electrostatic force (along the axis of the dimers and protofilaments). The state of a dimer in the subsequent 10^{-10} s generation may thus be expressed:

$$\text{state} = \alpha, \quad \text{if } \sum_{i=1}^{n} f(y) > 0,$$

where n is the number of neighbors ($n = 7$);

$$\text{state} = \beta, \quad \text{if } \sum_{i=1}^{n} f(y) < 0,$$

$f(y)$ is the force from the "ith" neighbor in the y direction,

$$f(y) \propto \frac{\sin\theta}{r^2}, \quad \sin\theta = \frac{y}{r}; \quad f(y) \propto \frac{y}{r^3}.$$

x, y, and r are distances and θ the angle between neighboring monomers (fig. 2).

Thus states may be determined by $\Sigma_{i=1}^{n} y/r^3$ and relative values calculated from known MT structural geometry; see table I.

5. Computer simulation of CA patterns in MT lattices

Using the described rules, the following computer simulations were done. The cylindrical MT structures are represented as unfolded, horizontal ("North" neighbors are now "East") planes. α states are shown as "a", and β states by dots (figs. 2–6). The number of each successive generation indicating an oscillation period of 10^{-10} to 10^{-11} s is shown at the top of each lattice. In fig. 3, an organized pattern of "a" states starts on the left side, and a single, isolated "a" state starts on the right side. In generations 1–4 both the pattern and single state develop. Fig. 4 demonstrates generations 12, 14, 16 and 18 in which the 2 patterns begin to interact. In figs. 5 and 6, the β dots have been connected to enhance contrast. Fig. 5 demonstrates generations 22, 28, 34, and 40 from the same sequence. Even numbered stable patterns have evolved. The right side reveals a traveling pattern moving at maximum velocity (8 nm/nanosecond if based on 10^{-11} s oscillations) and leaving an altered wake. In fig. 6 generations 44, 46, 47, and 48 demonstrate the traveling pattern, which may be likened to a "glider" [3], Frohlich metastable state, or soliton reaching the end of the display. A single odd numbered generation (47) is a stable oscillator which includes a noticeable crossing pattern. Thus CA rules based

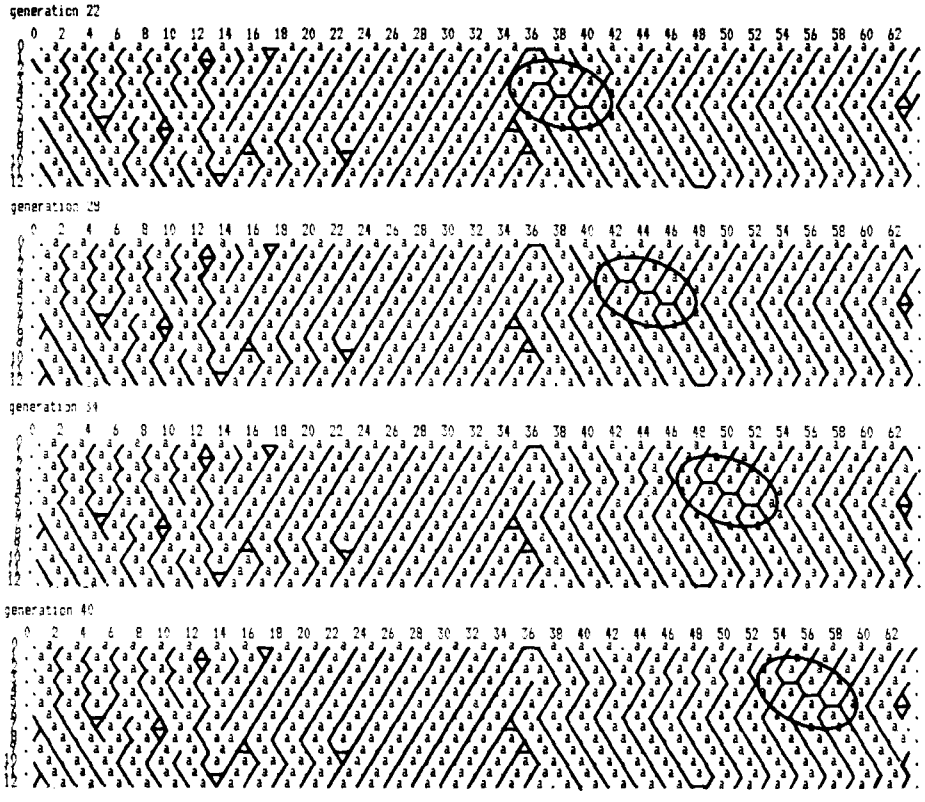

Fig. 5. Generations 22, 28, 34, and 40 from the same sequence. In figs. 5 and 6, β states represented by dots have been connected by lines to enhance contrast. Stable patterns have evolved (during even numbered generations) except for a traveling pattern which may be likened to a "glider", and the "glider's" altered "wake".

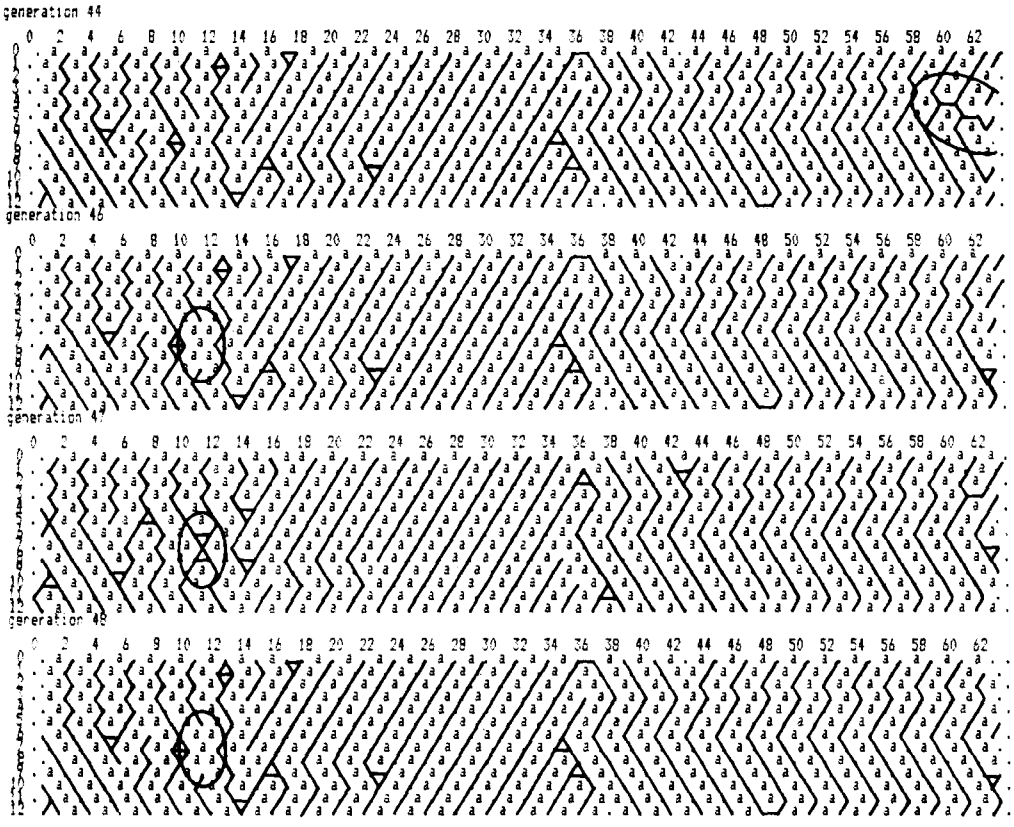

Fig. 6. Generations 44, 46, 47, and 48 demonstrate the "glider" leaving the display. Odd numbered generation 47 reveals a stable oscillator patterns which includes a noticeable crossing pattern.

on electrostatic dipole interactions in cytoskeletal geometries can result in stable patterns, oscillators, and traveling patterns ("gliders").

6. Conclusion

Stable and moving patterns of MT subunit oscillation phase could function as specific sites of protein binding and transport, orchestration of biomolecular activities, as well as stored information or memory. Interaction and interference of these patterns including "gliders" could process information as in computers. Although the CA rules and patterns described are somewhat arbitrary, they demonstrate that CA-like activities in cytoskeletal lattices are thus feasible and of potentially great importance.

Ch'i: A Neural Hologram? Microtubules, Biohology, and Acupuncture

Stuart Roy Hameroff

Tucson Medical Center, Tucson, Arizona

Abstract: Structure, occurrence, and functions of microtubules are reviewed. The theoretical principles of biohology are outlined and the neuronal microtubular system is offered as an anatomical substrate for such a mechanism. This entails microtubules acting as coherency inducing, dielectric waveguides and resonators for atmospheric ultraviolet radiation which is refracted by the stratum corneum and other tissues. The proposed corporeal energy and its pathways are correlated with Ch'i, the ancient Chinese life energy and medium of acupuncture.

MICROTUBULES ARE CYLINDRICAL cytoplasmic inhabitants whose existence was unknown prior to the advent of the electron microscope. Even then they were only occasionally observed until 1963, when glutaraldehyde gained prominence as a fixative. Osmium tetroxide, the previously used agent is now known to commonly dissolve microtubules. Since then their presence has been noted in so many plant and animal cells that they are now considered universal cytoplasmic components(1,2).

Microtubules (MT's) are hollow cylinders and seem to be a uniform size although their diameters are variously listed from 200 to 270 angstroms (A). This range is thought to be due to variations among investigators since the measurement is usually constant from each laboratory over a wide range of cells and MT's studied. The walls of the cylinders are 50 to 70 A thick and they may be as long as a neuron. The walls seem to be composed of about 13 subfilaments which are either arrayed parallel or in a mild helix. These subfilaments appear to be strands of globular protein units, roughly 50 A x 60 A x 55 A. This molecular length coincides with observed striations at 80 A intervals in negatively stained samples, the slight pitch to the striations suggesting a helical arrangement of the subfilaments(3). The globular protein units ("tubulin") are a labile pool which may polymerize and dissolve repeatedly, even in vitro(4). Hemoglobin (A,S, or C) will form MT's under gel condi-

tions(5,6) so the labile pool may vary among tissues. MT's are dissolved by low temperature, increased hydrostatic pressure, and certain drugs, and may re-form upon return to prior conditions(7,8). Their origins and terminations are rarely seen but have been described as being embedded in a dendritic cortex or, if loose in the cytoplasm, capped by a dense blob(9). A second set of MT's, the neurofilaments, similar in structure but only 100 A in diameter is prevalent among MT's in neurons, and a third, smaller set, the "microfibrils" resides in astrocytes(10).

MT's may occur in several patterns. In cilia, flagella, and centrioles they are in couplets and arranged in a circle in the 9&2 or 9&0 formations that are familiar to all biologists. In mitosis, microtubular spindle fibers form between the centrioles and guide the chromosomes to their proper poles. They then dissolve, their constituent protein becoming available for subsequent MT formation(11). This may be to establish or support any cell asymmetry or to direct (in conjunction with a sol-gel transformation) a transient cytoplasmic rearrangement such as cyclosis or pseudopod formation(12). In permanently asymmetric cells, MT's seem to direct cytoplasmic flow and then to act as a cytoskeleton to maintain cell shape. This can occur longitudinally, as in axons, dendrites, glial cells, and spermatazoa, or circumferentially, as in platelets and discoidal nucleated erythrocytes. Muscular sarcotubules are morphologically indistinguishable from MT's.

How MT's function remains a mystery. It seems they give direction and guidance to cytoplasmic flow and they may participate in a propulsion mechanism. An associated contractile protein or ATPase substance has been found on several occasions(13, 14,15). In axons, peristaltic contractions of the overlying Schwann cells, or activity of extra-microtubular finger like projections have been credited with propelling axoplasm parallel to and among MT's(16). This flow achieves great velocity relative to the size of the organelles carried and the diameter of the axon. In this instance MT's may only be passive guides but they undoubtedly play a role in the development and orientation of the axon along distances up to meters. In megakaryocytes, MT's align to form cytoplasmic projections which break off, creating platelets. They then arrange circumferentially and participate in a spiral contraction during the second phase of platelet aggregation or clot retraction(17.) MT's have been observed outlining and establishing the cleavage furrow following mitosis, thus effecting daughter cell shape before cell division has concluded(18,19). Regardless of the motile force, MT's may be seen to orient, shape, and direct cytoplasmic movement and cell polarity, and subsequently to serve a cytoskeletal role. MT's are known to be strong and rigid enough to provide such support(20), but how they can function in a guidance capacity is as yet unanswered.

Perhaps MT's work like radar? Klystron tubes which are used in radar and other electronic devices utilize cavity resonators(21). These are geometric waveguides in which a specific electromagnetic wave may resonate and dwell, not unlike air in a tuned organ pipe. Cylinders are a particularly good shape for this purpose, and the radius of a cylindrical cavity resonator is related to the frequency of the resonant energy by the equation: $\gamma = 1.19\ c\ /\ 2\ \pi\ a$

where c is the *speed of light*, *a is the cavity* radius, and γ the resonant frequency(22). The function is independent of cylindrical length. In the radio-wave and micro-wave regions, a is in millimeters and cavity resonators (i.e., Klystron tubes)

are a convenient size. If a is set equal to the radius of microtubules, γ is on the order of 10^{16} cycles per second. This energy is in the far ultra-violet (UV) range, beyond the visible spectrum and the upper limit of the narrow window of solar and celestial nonionizing radiation that our atmosphere admits. The equation is given for a vacuum and an intra-microtubular dielectric (as well as skin and other intervening tissue) would alter the propagative properties according to the refractive index of that dielectric. The stratum corneum of the skin is known to have powerful refractile properties due to the abundance of birefringent keratin polymers(23). Thus the velocity and wave length of refracted penetrating radiation are decreased (24,25). Longer wave length energy readily available in our atmosphere (mid to near UV), upon attenuation and refraction, would be available to MT's, tuned to the new refracted wave length, in neurons and other cells. It would be difficult to measure the attenuation of light which is refracted subcutaneously to the specific resonant wave length of MT's (i.e., without constructing resonators the size of MT's). Permeating, or ambient light in the visible and UV ranges has been measured however, and there is some evidence of a physiological role for such energy.

Ganong and co-workers(26) measured extra ocular sunlight penetration into the mammalian brain. Stereotactically placed photoreceptors recorded intensities of 10^{-3} lumens in a sheep's hypothalamus when surface intensity was 0.4 lumens, with a logarithmic diminution. The most light permeable areas were lateral to the orbits, the temporal poles and hippocampus receiving maximum intensity. Light penetration remained constant for about 30 minutes after the animal's demise, at which time tissue opacity rose sharply. To the pineal gland has been attributed regulation of circadian rhythms, although no optic-pineal pathway has been demonstrated(27). (The pineal gland, along with retinal rod cells and hair cells of the inner ear are rich in "sensory" cilia, nine MT couplets with no central pair(28,29,30)). Cyclical, light dependent functions independent of the visual apparatus have been demonstrated in new born rats(31), and continuous photic stimulation by hypothalamic fiber optic implants have been shown to elicit neuroendocrine responses(32). Whether MT's act as inherent fiber optic waveguides remains to be seen.

Apparently analogous and homologous tubular dielectric waveguide structures have been well studied in the antenna sensillae of certain moths and provide a theoretical basis for electromagnetic communication among them, particularly between mating pairs(33). The waveguides are of a diameter considerably greater than MT's and the energy received and transmitted is consequently in the longer wave length infra-red and micro-wave regions. Similarly, EEG evoked responses have been obtained from a boa constrictor following infra-red and micro-wave stimulations, and potentially dangerous, internal human micro-wave sensors have been postulated(34).

The fate of the proposed intra-microtubular wave energy at synaptic junctions throughout the nervous system might include components of: transmission to post synaptic MT's (refracted to fit 100 A MT's ?), reflection to promote standing waves, and dissipation into surrounding tissue. Dissipation at MT terminals near synapses and along MT lengths would seem to be a physiological condition in surrounding tissue. A metabolic role might be surmised, and indeed, mitochondria have been observed aggregating at nodes of Ranvier(35). The physical properties of wave-

guides and resonators include absorption of kinetic energy in linear and angular fashions(36). MT orientation, and hence cell orientation can then theoretically be viewed as reflecting the flux in the resonant wave length (phototropism ?). Colchicine induced dissolution of MT mitotic spindles has reportedly been reversed with low intensity UV light(37). Aberration of endogenous resonant wave fields could retard spindle formation and could conceivably play a role in teratogenic or malignant change.

The observed striations at 80 A intervals along MT's correspond to one half of the resonant wave length. This could serve to foster coherent waves within MT's by diffraction. Assuming the 80 A intervals represent the globular protein units (as they are known to in hemoglobin gels) the waves which strike the dense protein would be reflected and remain in the tubule while those striking the gap areas would be dissipated into the cytoplasm. The intra-tubular wave energy, including reflection from MT endings would be "in phase" or coherent. (A well known technological source of coherent photic energy is the laser.) The dissipated cytoplasmic energy would also be coherent due to diffraction by the MT wall. Dissipated coherent energy from among various MT's would interfere in the cytoplasm. An interference pattern from among two or more coherent sources is, by definition, a hologram.

The 1971 Nobel prize in Physics was awarded to Dennis Gabor for his invention (in 1947) and development of holography. A laboratory curiosity at first, holography became important with the advent of the laser in the 1950's. Briefly, holography employs coherent light to record a three dimensional image of an object. One method utilizes a partially transmitting mirror by which a laser simultaneously illuminates a photographic plate directly, and an object which reflects the light onto the plate secondarily. The plate records an interference pattern between the two impingent wave trains. This pattern, the hologram looks like a garbled mess, but it contains all the information in three dimensions of the object expressed as the phase differences between the two impingent, originally coherent, wave trains. If the hologram is reilluminated by the laser source, the object appears due to cancellation of "non object"(38). A detailed treatment of holography is beyond the scope of this paper, but several properties of holograms are particularly interesting and may prove pertinent. One is that holograms have an enormous capacity to store information in a small area, although it is necessary to reilluminate that area to translate that information. A second property is that all the information in a given hologram is contained in any one, small discreet portion of it, although not as sharp or well focused as the entire hologram. These properties have prompted certain analogies:

> "Indeed it has been suggested that the human brain may store information in this way. It has always been a great puzzle how the vast amount of information stored in the human memory can be contained in the volume of the brain and the holographic method might well be the way it is done."
>
> Ronald Brown
> "Lasers: Tools of Modern Technology"(39)

> "For some years now this property of holograms has attracted the interest of neurophysiologists who were puzzled by the difficulty in locating the 'engram'

in the human or animal memory. As is well known, especially since the famous experiments of Lashley, large parts of the brain can be destroyed without wiping out a learned pattern of behavior. This has led to speculation that the brain may contain a holographic mechanism."

Dennis Gabor, 1969(40)

It has been suggested that bats, dolphins, and whales employ an ultra-sonic holographic system of information processing(41). Several scientists, including Dr. Gabor have created mathematical expressions for theoretical holographic systems of temporal recall(42,43,44,45). A psychiatrist, Dr. H.C. Tien has devised a holographic cybernetic model which relates consciousness, personality, time, memory, and acupuncture(46,47). Dr. Karl H. Pribram has proposed a model of brain function with two basic processes: spatially organized states and operations on that state by pulsed neural transmissions(48). He as well as Dr. Philip R. Westlake(49), suggest holography, expressed in Fourier transforms, to be the stratum of that spatially organized state.

But as yet this is all conjecture, for as Dr. Gabor has remarked:

"I am inclined to believe that there exists an abstract mathematical similarity but I am rather skeptical regarding the existence of waves or even of tuned resonators in the brain(50).

But we now know the neurons of the brain and nervous system are packed with MT's which are at least the right size, shape, and configuration to be tuned resonators. If such electromagnetic waves do exist within neuronal MT's, they would seem to be in equilibrium with, or at least affected by the state of surface membrane polarization and ionic flow. Neuronal transmission might then result in an increased dissipation of wave energy by a transient ionic effect upon MT structure (vice versa ?). This interaction fits well with the holographic models, the net coherent wave fields providing a spatially organized state within neuronal groups. Recent evidence has shown MT structure and function to be sensitive to lidocaine and the volatile anesthetics(51) and MT's "may be involved in impulse propagation in ways as yet completely unsuspected"(52).

Subtle magnetic fields have been detected outside the human head which fluctuate directly with alpha rhythms(53), and neuronal generated magnetic fields (cat sciatic nerve) have been measured and analyzed(54). The heart possess a magnetic vector (55,56) and electric fields (i.e., EEG, EKG) are well recognized. These are presently ascribed solely to ionic dipoles. Completely unexplained however, is the phenomenon of Kirlian photography(57,58). This technique utilizes high frequency (radio wave region) oscillating electric fields to visualize on film emanations from living organisms, as well as certain metals and crystals. Lensless photography may suggest a holographic mechanism and coherent interference may be the nature of these emanations. In human subjects, densest emanations of energy originate from acupuncture points(59).

The ancient Chinese described empirically a flow of energy through the body(60,61). The nature of the energy and the anatomical pathways through which

it flows have been unexplained, and consequently denied, by Western science. It is suggested here that Ch'i, the Chinese life energy is in fact interfering, coherent photic energy from the sun and stars which is refracted by the stratum corneum and resonant within microtubules. Tissue pathways of least resistivity to this energy have been described by the Chinese in terms of meridians. These appear to reflect embryological axes of development and, like the axes of cleavage and gastrulation(62) may be determined by MT's in the forms of neurons and non-neuronal cytoskeletal architecture. These seem to manifest primarily in the small, unmyelinated fibers mediating pain and autonomic function, both afferent and efferent. They may be embraced in a peripheral nerve, autonomic innervation of a blood vessel, or a tissue axis with no obvious neuronal axis. The relationship between the meridians and the organ systems they represent by the Chinese categorization lies presumably in the autonomic ganglia. Acupuncture therapy may be viewed as correcting an energy excess or deficiency in a given meridian system, perhaps by allowing equilibrium to be reached among the meridians or across the stratum corneum.

By holographic theory any arbitrary neuronal group, a spatially organized state, should contain the "engram" of the whole body, as measured by modulation of a pulsed function. This might hold diagnostic value and indeed, Chinese acupuncturists have claimed to do just this for thousands of years. Carefully palpating three fingerbreadths of the radial artery, subtle modulation of the pulse character by the neuronal group of autonomic innervation of this segment of the vessel is said to be diagnostic(63,54). What may be the fetal engram can be construed in the human outer ear (inverted) in which ectoderm, mesoderm, and endoderm analogues have distinct innervations(65). The many acupuncture points on the outer ear correspond to their respective body sites by this analogy(66).

Neuronal dissipation of the postulated energy might be dampened by myelin, a recognized insulator (i.e., saltatory conduction). Accordingly small unmyelinated fibers and unmyelinated ganglia would provide most efficient absorption and dissipation of energy and would be the mediators of acupuncture therapy. Myelin itself, however, might be of great significance. Myelin lamella formation, which seems to correlate with learning and development in any given fiber tract(67), consists of concentric spiral wrappings around a neuronal fiber of a lipoprotein blanket. The spacing between the lamellae is constant and corresponds to the intramicrotubular diameter. The insulating effect of myelin might include absorption and resonance into the spiral. A possible analogy is the conch shell, in which sound waves that were present during lamella formation may be reproduced later by a non specific wave. Memory, learning, and development may lie in the resonance of myelin lamellae.

Is there a microtubular forest in the neuronal tree? Did Gabor invent holography, or discover it? Physiology may follow engineering. It is reported that Casper and Klug derived their model of viral structure after studying Buckminster Fuller's geodesic domes(68). Is it that unlikely that we may holographically utilize the energy of the universe so directly, that we may, in fact be part and parcel of that energy? One need only study Eastern philosophy and Maxwell's equations to appreciate that man may have described electromagnetism no less than electromagnetism described man.

Coherence in the Cytoskeleton: Implications for Biological Information Processing

S. R. HAMEROFF [1]

1 Introduction

Fröhlich's model of coherent excitations in biological systems can provide mechanisms for long-range order and cooperativity, factors useful for biomolecular communication and information processing. Fröhlich's coherence is based on oscillating dipoles in a voltage field, and has been applied primarily to biological membranes (Fröhlich 1970, 1975, 1986). Relatively overlooked, the interiors of living cells contain parallel networks of dynamic protein filamentous polymers which organize and regulate intracellular activities and whose properties strongly suggest communication and intelligence. These networks are collectively termed the cytoskeleton because they were originally thought to provide merely structural bone-like support to living cells. It is now recognized that the cytoskeleton is a dynamic information-processing system capable of organizing cell movement, division, growth and behavior. Thus the cytoskeleton may be described as the nervous system within all cells, ranging from single cell organisms like amoeba and paramecium, to nerve cells (neurons) within the human brain. In neurons, the cytoskeleton accounts for formation and rearrangements of neuronal form and synaptic connections, factors implicated in wide ranges of cognitive functions including neural networking, learning, memory, and consciousness. Components of the cytoskeleton (microtubules, actin and intermediate filaments, microtrabecular lattice) are oriented assemblies of "polar" subunits and have been accordingly described as electrets. The characteristics of polar electrets have been considered sufficient to support Fröhlich-type coherent excitations in the cytoskeleton (Del Giudice et al. 1983c). The presence of coherent excitations within the cytoskeleton would provide an intracellular dimension of molecular cognition. Several models of information representation and processing could take advantage of coherent "clocking" mechanisms in the cytoskeleton. These include parallel switching (neural network) matrices, reaction-diffusion patterns, cellular automata, nonlinear wave propagation, and coherent interference (holography). This chapter will review characteristics of the cytoskeleton, application of Fröhlich coherence mechanisms to cytoskeletal components, and theories of cytoskeletal information processing for which coherent oscillations may be important (Hameroff 1987).

2 The Cytoskeleton

Living organisms are collective assemblies of cells which contain collective assemblies of organized material called protoplasm. In turn, protoplasm consists of membranes, organelles, nuclei and the bulk interior medium of living cells: cytoplasm. Dynamic rearrangements of cytoplasm within living cells account for their changing shape, repositioning of internal organelles, and in many cases, movement from one place to another. We now know that the cytoskeleton, a dynamic network of filamentous proteins, is responsible for cytoplasmic organization (Fig. 1).

2.1 The Nature of Cytoplasm

Nineteenth century microscopists recognized that cytoplasm had structural, contractile, motile, elastic and rigid properties which permitted elaborate and dynamic forms. They concluded that cytoplasm is not merely a liquid nor an emulsion nor an aqueous suspension of life-bearing granules. Rather, cytoplasmic architecture and contractility could be explained by the proposal of a mesh-like reticular or fibrous substructure whose interstices were filled with fluid (Burnside 1974). Biologists began to consider cytoplasm as a gel in which rod-shaped filaments formed cross-linkages. Gel aptly describes the mechanical properties of cytoplasm: an elastic intermeshing of linear crystalline units giving elasticity and rigidity to a fluid while allowing it to flow.

Development of the electron microscope through the 1960's initially did not illuminate the substructures of cytoplasm. Portions of cells which were optically empty by light microscopy persisted in being empty in electron micrographs and the cell was perceived by many to be a "bag of watery enzymes". Ironically, the fixative then used in electron microscopy, osmium tetroxide, had been dissolving filamentous elements so that their presence was observed only sporadically. Later, with the advent of glutaraldehyde fixation, delicate tubular structures were found to be present in virtually all cell types and they came to be called microtubules. Subsequent characterization of actin, intermediate filaments, microtrabecular lattice and the structure of centrioles led to the recognition that cell interiors were comprised of dynamic networks of connecting filaments and brought the cytoskeleton out of the closet.

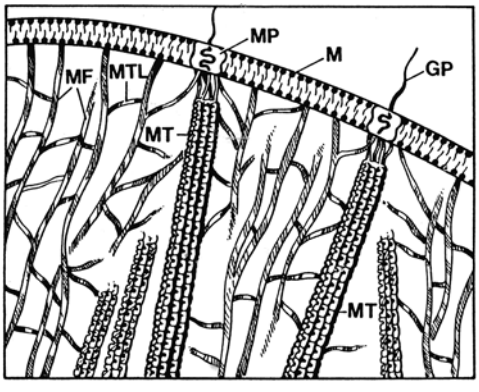

Fig. 1. Schematic of cellular cytoskeleton/membrane. *M* cell membrane; *MP* membrane protein; *GP* glycoprotein extending into extra-cellular space; *MT* microtubules; *MF* microfilaments (actin filaments or intermediate filaments); *MTL* microtrabecular lattice. Cytoskeletal proteins which connect MT and membrane proteins include spectrin, fodrin, ankyrin, and others. (Hameroff 1987)

2.2 Microtubules

Soifer (1986):

"When microtubules are required by a cell for a particular function, microtubules assemble in the appropriate part of the cell, with the necessary orientation. As microtubules are no longer needed, they depolymerize."

The most visible and widely studied cytoskeletal elements are microtubules (MT), slender cylinders intimately involved in the real time execution of important cell functions. Microtubules (MT) are hollow cylinders about 25 nanometers (1 nm = 10 Å = 10^{-9} m) in diameter whose walls are polymerized arrays of protein subunits. Their lengths may range from tens of nanometers during early assembly, to possibly meters in nerve axons within large animals. The protein subunits assemble in longitudinal strings called protofilaments; 13 parallel protofilaments laterally align to form the hollow tubules. The subunits are barbell-shaped proteins (dimers) which in turn consist of two globular proteins (monomers) known as alpha and beta tubulin (Fig. 2). Alpha and beta tubulin monomers are similar, but slightly different molecules with identical orientation within protofilaments and tubule walls. Each monomer consists of about 500 amino acids, weighs about 55 kilodaltons, and has a polarity or charge orientation. MT which grow from cell centers have a plus end (beta tubulin) which extends outward from the cell center (centrosome) into the cell periphery. The minus end (alpha tubulin) remains anchored to a microtubule organizing center (MTOC) within the centrosome. Each dimer, as well as each MT, appears to have an electrical polarity or dipole, with the negative end oriented towards the alpha monomer and cell center, and the positive end towards the beta monomer and cell periphery. The dimers are held together by relatively weak Van der Waals hydrophobic forces such as dipole coupling. Dimer neighbors form hexagonal lattices with a "leftward" tilt and several helical patterns occur in the relations among dimers (Dustin 1984).

MT from different life forms have marked similarities, but subtle differences. Comparison of MT from nerve cells of earthworms and mammals shows that the more

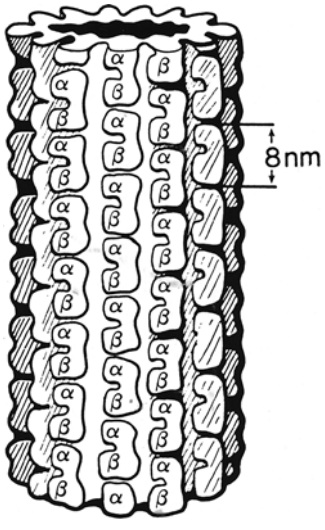

Fig. 2. Microtubules are cylinders whose walls are 13 protofilaments, each a string of 8-nm tubulin dimers. Alpha and beta tubulin monomers form the dimers. Each dimer has six neighbors. (Hameroff 1987)

primitive worm MT are more variable in geometric structure with MT ranging from 9 to 11 protofilaments, whereas mammalian MT are generally more consistent with 13. Tubulins from among different species including mammals and plants bind to common antibodies, and tubulins from different species may coassemble into hybrid MT. Despite these common traits, the diversity of tubulin gene expression has proved far greater than imagined years ago. Analysis of tubulin by amino acid sequencing and advanced electrophoretic techniques has shown that different alpha and beta tubulins exist concurrently, with the greatest diversity shown by beta tubulin. For example, Lee et al. (1986) have shown that as many as 11 different tubulin forms exist in rat thyroid microtubules and 17 different forms exist in rat brain microtubules. Thus alpha and beta tubulin are families of "isozymes," each of which may have specific functions or binding of microtubule-associated proteins (MAPs). Another tubulin variable, detyrosination, occurs in the cytoplasm subsequent to DNA transcription. Detyrosination is the removal of the terminal amino acid, tyrosine, from the polypeptide chain which comprises beta tubulin. Removal of tyrosine exposes an acidic amino acid, glutamate. Local factors in the cytoplasm beyond genetic programming determine whether or not individual tubulin subunits are "tyrosinated" or "glutamated." Thus both genetic and nongenetic coding mechanisms exist for the structure of tubulin subunits assembled within MT.

Since early electron microscopy studies, microtubules have been invariably described as being surrounded by a "clear zone" which gives the impression of a halo around them when they are viewed in cross-section. A 5-10 nanometer distance from the surface of MT is free of cytoplasmic ground substance or any other material normally seen elsewhere throughout the cell. Stebbings and Hunt (1982) have studied the "clear zone" and point out that MT surfaces are strongly "anionic" since tubulin is an acidic protein due to its high content of acidic amino acids such as glutamate and aspartate. These amino acids give up positively charged hydrogen ions to solution, leaving MT with excess electrons. Stebbings and Hunt propose that anionic, or electronegative fields at MT surfaces can explain the clear zones as well as the staining of MT by positively charged dyes, binding to MT of positively charged proteins, cations such as calcium, metals and other compounds. Electronegative fields surrounding MT may be heterogeneous or patterned due to detyrosinated subunits (exposing anionic glutamate), or other factors and act as excitable ionic charge layers (Debye layers) which are also thought to occur immediately adjacent to cell membranes (Green and Triffet 1985). Excitable clear zone charge layers and their ordered water and ions next to MT could facilitate collective communicative mechanisms occurring due to coherent excitations within the cytoskeleton.

The question of the hollow core within MT is even more mysterious; it too appears devoid of ground substance. It is unknown whether the interiors of MT are also electronegative zones, or perhaps positive ones which would create voltage gradients across MT walls. Del Giudice et al. (1986) have suggested electromagnetic focusing and possibly superconductivity within microtubule cores. Insulated from aqueous surroundings and held together by water-excluding hydrophobic forces, MT and the rest of the cytoskeleton comprise a solid state network within living cells.

What are the functions of microtubules? They do provide skeletal support, being the most rigid structures in most cells. To establish the pattern of the cytoskeleton

and the form and function of living cells, MT assemble from subunits at the proper time, place, and direction. Biochemical energy in the form of GTP plays an important role in MT assembly (and ATP for actin polymerization). Tubulin subunits bound to GTP add on to polymerizing MT; however, energy is not utilized via hydrolysis until after the GTP tubulin is incorporated. Phosphate bond hydrolysis energy from GTP and ATP may be providing energy to cytoskeletal structures for coherent excitations and/or lattice solitons, polarization waves etc.

MT are often anchored and guided by MT-organizing centers (MTOC) containing centrioles. Centrioles are cylinders comprised of nine MT triplets which exist in perpendicularly oriented pairs. Centrioles provide guidance and directional nagivation for nearly all cytoplasmic movements including cell division, or mitosis (Fig. 3). Once in place, MTOC and MT direct and participate in movement of cytoplasm, organelles and materials, growth, reproduction, synaptic plasticity, and nearly all examples of dynamic cytoplasmic activity.

The full range of MT function is achieved by the actions of various proteins which may bind in precise fashions at specific patterns of tubulin dimers in MT lattices. These *microtubule-associated proteins* (MAPs) include electromechanical enzymes which generate force and movement, communicative crossbridges to other cytoskeletal filaments and organelles, MAPs which enhance MT assembly and a class of MAPs within neurons whose functions are not understood. In many cases, the attachment patterns of MAPs to MT lattice walls have a precise geometrical configuration which appears related to the function of the MAP-MT complex (Fig. 4). Motion producing MAP "arms" which consume ATP hydrolysis energy to generate force are analogous to myosin bridges of skeletal muscle. Moving arms attached to MT are made of pro-

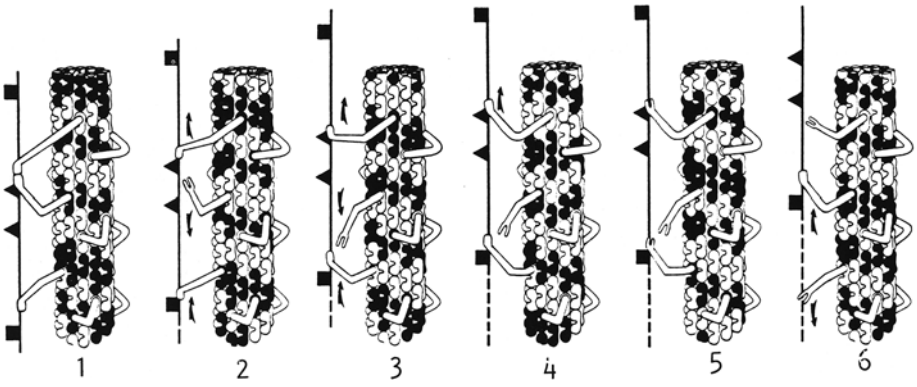

Fig. 5. Axoplasmic transport occurs by coordinated activities of microtubule attached sidearm, contractile proteins ("dynein") which cooperatively pass material in a "bucket brigade." The orchestration mechanism is unknown, but shown here as the consequence of signaling by "soliton" waves of microtubule subunit conformational states. By Fred Anderson

teins called kinesin and dynein. Dynein arms on MT which contract in organized sequences to produce collective movements were first described and characterized in cilia and flagella by (Gibbons 1968). The arms reside at periodic intervals along the outer MT within cilia and flagella and contract conformationally due to hydrolysis of ATP. Many MT-related activities generate force, locomotion and movement of vesicles and other material by a similar mechanism; axoplasmic transport is one well-studied example (Lasek 1981; Ochs 1982). Enzymes, neurotransmitter precursors, and organelles synthesized in neuronal cell bodies are transported along the lengths of axons by contractile dynein arms attached to axonal MT which act collectively to pass material in "bucket brigade" axoplasmic transport. The contractility mechanism is understood; however, the orchestration, signaling and coordination of the dynein MAPs appears to require some form of MT information processing (Fig. 5).

MT also participate in sensory perception of the cell's external environments. Many sensory receptors are modified cilia, assemblies of microtubules similar in structure to centrioles. Sensory transduction, centriole-based guidance and alignment, and axoplasmic transport are "intelligent" MT activities which are vital to biological growth, embryological development, secretion, synapse formation and many other important biological functions. MT are the scaffolding, conveyor belts, nagivators, and computers of living cells.

2.3 Intermediate Filaments, Actin and the Microtrabecular Lattice

The major filamentous components of the cytoskeleton are MT, actin filaments, intermediate filaments (IF) and a class of delicate interconnecting fibrils called the microtrabecular lattice (MTL). Actin is the most versatile component of the cytoskeleton. In conjunction with other proteins, it can polymerize in string-like filaments, form dynamic branching nanoscale meshworks or geodesic polyhedrons. Even more evanescent than labile MT, assembly of actin and associated proteins creates transient con-

figurations of cytoplasm for specific purposes. Dynamic cytoplasmic expressions such as contractile actin-based rings which divide the cytoplasm in cell division, probing amoeboid lamellipodia, and dendritic spines and synapses in neurons may be the roots of intelligence.

Interaction with a variety of other proteins (actin-binding proteins) unleash actin's full capabilities. When crosslinked by proteins such as fimbrin, actin can form rigid bundles which provide structural support. When associated with myosin (a mechano-enzyme), useful muscle-like contraction occurs. Also important are proteins such as talin, spectrin, vinculin, ankyrin and fodrin which connect the cytoskeleton with membrane proteins, and calmodulin which mediates effects of calcium ion fluxes on the cytoskeleton. Proteins such as alpha actinin, troponin, and filamin link actin in networks which cause a gelatinous consistency to cytoplasm – a "gel" (Fig. 6). In the presence of calcium ions and actin-fragmenting proteins such as villin and gelsolin, the gel network liquefies to a solution – "sol." Other actin regulatory proteins include actin capping proteins, which stabilize polymerized actin and promote a gel condition, and profilin, which binds actin subunits, prevents polymerization and maintains sol conditions (Satir 1984). Actin gel polymers, like microtubules, are structurally coherent assemblies which consume sufficient phosphate bond hydrolysis energy (ATP) to fuel coherent oscillations, depolarization waves or solitons-phenomena which would help explain the complex and dynamic functions of actin gels.

The "unknown" members of the cytoskeleton, intermediate filaments represent the most nebulous and chemically variable subgroup among the cytoskeleton. Lazarides (1980) has shown that different types associate with specific types of cells. For example, subunit structure defines five major classes of intermediate filaments: (1) keratin (tonofilaments), which are found in epithelial cells, (2) desmin filaments, predominantly found in smooth, skeletal and cardiac muscle cells, (3) vimentin filaments, found in mesenchymal cells, (4) neurofilaments, found in neurons, and (5) glial filaments, found in glial cells. Often two or more of these classes co-exist in the same cell.

MT and intermediate filaments are not the finest texture of cytoplasmic organization. Smaller, more delicate structures made of actin branch and interconnect in gel state networks which comprise the microtrabecular lattice, or ground substance of living material. Techniques in electron microscopy developed by Porter and colleagues at the University of Colorado (Porter and Tucker 1981) led to observation of an ir-

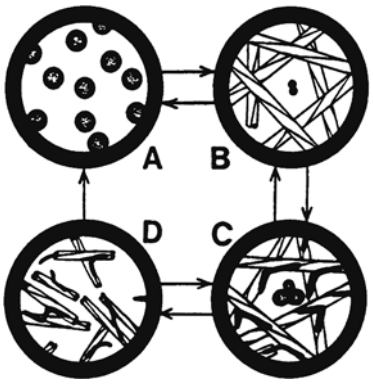

Fig. 6. Components of the cytomatrix. Assembly of actin and related proteins form cytoplasmic "gel" states. *A* monomeric actin; *B* assembled actin filaments which are helical pairs of monomeric strands; center-cross section of actin filament; *C* the presence of filamin (dark strands) causes actin cross-linking and dense "gel state;" *D* calcium and/or actin fragmenting proteins cause liquification to a "sol state." (By Paul Jablonka, from Hameroff 1987)

regular three-dimensional "trabecular" lattice of slender strands throughout the cytoplasm, interconnecting nearly everything in the cell. Slender strands of the microtrabecular lattice range in diameter from 4 to 10 nanometers with lengths of 10 to 100 nanometers and divide the ground substance of cytoplasm into two phases, a protein-rich polymerized phase and a water-rich fluid phase that fills the intratrabecular spaces.

MT, actin, intermediate filaments and the MTL comprise a dynamic cytoskeletal, solid state network within cytoplasm. Gershon et al. (1985) found that the cytoskeleton/MTL comprised from 16 to 21% of cytoplasmic volume with a surface area from 69,000 to 91,000 square microns per cell (69 to 91 billion nm^2). Biologist James Clegg (1981) has accrued evidence regarding the role of water surrounding cytoskeletal structures. Using neutron diffraction and other techniques, Clegg has found that water adjacent to the cytoskeleton is "ordered," that is aligned with polar bonds on the protein surfaces. Thus a layer of ordered water extends at least 3 nm from the billions of square nanometers of solid state surface area within each cell. This ordered water may be dipole coupled to coherent dynamics of the solid state, inhibit the thermal dissipation of protein oscillation energy from within the solid state, and shield calcium and other ions from random solid state interactions. Far from being "bags of watery enzymes," the interiors of living cell are highly ordered networks of dynamic, structurally coherent polymers.

3 Protein Conformational Dynamics

Proteins are the structural and organizational elements of the living state. Their essential functions are intrinsically linked to their structure and dynamic switching among different conformational states. Proteins such as enzymes, ion channels, receptors, cytoskeletal filaments, muscle myosin and hemoglobin undergo important conformational changes in response to a variety of stimuli. Coherent conformational states among cytoskeletal subunits may serve to represent information, exert control over routine biological functions and provide a basis for biomolecular communication.

3.1 Protein Conformation

Most protein molecules are able to shift reversibly between several different but related stable conformations due to several alternative sets of hydrogen bonds, disulfide bridges and hydrophobic Van der Waals forces of about equal energy among their constituent amino acid side chains. Thus step-like, nonlinear jumping occurs between specific conformations so that only a discrete number of alternative conformations exist for a given protein, and random switching from conformation to conformation is limited. Fröhlich (1975) proposed that dipole oscillations within water-excluding hydrophobic protein pockets were coupled to the protein's conformational state.

Different frequencies of conformational changes coexist cooperatively in the same protein (Table 1). The vast majority of processes of biological interest are in the time scale greater than 10^{-9} s, or one ns, which also lies in the collective mode realm for protein dynamics (Karplus and McCammon 1983). Protein conformational changes in the nanosecond time frame are coupled to stimuli by three fundamental features:

Table 1. Protein conformational dynamics – motions of globular proteins at physiological temperature. (After Karplus and McCammon 1983; from Hameroff 1987)

Amplitude of motions	0.001 to 10 nm
Energy	0.1 to 100 kcal
Time range	10^{-15} s (fs) to 10^{3} s (many minutes)
Time for collective functional steps	10^{-9} s (ns)
Types of motion	Local atom fluctuations
	Side chain oscillations
	Displacements of loops, arms, helices, domains and subunits
	Collective elastic body modes, coupled atom fluctuations, solitons and other nonlinear motions, coherent excitations

hydrophobic interactions, charge redistribution and hydrogen bonding. Appropriate stimuli including neurotransmitters, voltage alterations, hormones, calcium and other ions, and enzyme substrates can induce conformational changes within specific proteins (Fig. 7). Conformational transduction is the sensitive link in the mechanism of anesthetic gas molecules, and indicates that cognitive functions relating to consciousness depend in some way on protein conformational regulation. Dynamic conformational changes of proteins are the dynamics of living organisms.

3.2 Hydrophobic Interactions

The polymerization of cytoskeletal polymers and other biomolecules appears to flow against the tide of order proceeding to disorder dictated by the second law of thermodynamics. This apparent paradox is explained by the hydrophobic forces which bind protein assemblies including cytoskeletal polymers and which exclude ordered water from their protein sites. Thus the net effect is order proceeding to disorder because of the hydrophobic exclusion and disordering of previously ordered water.

The attractive forces which bind hydrophobic groups are called Van der Waals forces after the Dutch chemist who described them in 1873 (Baron 1961). At that time it had been experimentally observed that gas molecules failed to follow behavior predicted by the "ideal gas laws" regarding pressure, temperature and volume relationships. Van der Waals attributed this deviation to the volume occupied by the gas molecules and by attractive forces among the gas molecules. These same attractive forces are vital to the assembly of organic molecules, including protein assemblies and can explain cooperativity and coherent interaction among polymer subunits.

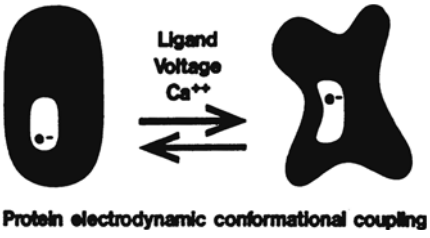

Fig. 7. Protein switching between two different conformational states induced by binding of ligand, calcium ion, or voltage change. One mechanism proposed by Fröhlich is that dipole oscillations (e^-) within hydrophobic regions of proteins may be a trigger, or switch for the entire protein. (Hameroff 1987)

Hydrophobic Van der Waals forces which are essential to the assembly and function of important biomolecules consist of dipole-dipole attraction, induction effect, and London dispersion forces.

Dipole-dipole attractions occur among molecules with permanent dipole moments. Alignments in which attractive, low energy arrangements occur are favored and net attraction between two polar molecules can result if their dipoles are properly configured. The induction effect occurs when a permanent dipole in one molecule can polarize and distort electrons in a nearby molecule so that dipole interactions are attractive. London dispersion forces explain why all molecules, even those without intrinsic dipoles, attract each other. Recognized by F. London in 1930 (Barrow 1961), the effect depends on quantum mechanical motion of electrons. Electrons in atoms without permanent dipole moments (and "shared" electrons in molecules) have, on the average, a zero dipole. However, dynamic instantaneous dipoles can be recognized which can induce dipoles in neighboring polarizable atoms or molecules. The strength of London forces can be significant only when two or more atoms or molecules are very close together (Barrow 1961). By dynamically coupling dipoles and conformational states among neighboring proteins, Van der Waals hydrophobic interactions can result in cooperativity and coherent oscillations of protein assemblies.

3.3 Electret, Piezo, and Pyroelectric Effects

Assemblies whose microscopic subunits and macroscopic whole both possess permanent electric dipoles are known as electrets. They exhibit properties known as piezoelectricity, which may help explain biological activities. In these crystals, dipolar elementary subunits are arranged in such a way that all the positive dipole ends point in one direction and all the negative dipole ends are oriented in the opposite direction. In microtubules, the positive ends of tubulin dimer subunits point away from microtubule organizing centers (MTOC) toward the cell periphery, and the negative ends point towards MTOC. Electrets can store charge and polarization and have now been identified in a variety of nonbiological materials such as ionic crystals, molecular solids, polymers, glasses, ice, liquid crystals and ceramics. Biological tissues demonstrating electret properties include bone, blood vessel wall materials, keratin, cellulose, collagen, gelatin, artificial polypeptides, keratin, DNA, cellulose and microtubules (Athenstaedt 1974). An electret effect accounts for specific properties such as anti-blood clotting in biomaterials and the non-stickiness of Teflon. Sources of polarization or charge storage in macromolecules are dipoles, ionic space charges, or ordered surface water.

Electret materials are piezoelectric (Gubkin and Sovokin 1960). Piezoelectric materials change their shape or conformation in response to electrical stimuli, and change their electrical state in response to mechanical stimuli. Koppenol (1980) has shown that the dipole moment orientation of an enzyme changes in concert with its functional activity. Electrets are also pyroelectric, in that any change in temperature alters the electrical and conformational characteristics of the molecule. The requisites for such behavior are permanent dipole moments in molecules bound in parallel alignment. Microtubules and other cytoskeletal structures appear to be appropriately configured electret, pyroelectric, piezoelectric devices.

The electret state within bone has been well studied and is able to store large amounts of polarization of the order of 10^{-8} coulombs/cm^2 (Mascarenhas 1974, 1975). The limit of charge separation (equivalent to maximal information density) has been calculated (Gutman 1986) to be about 10^{17} electronic charges/cm^3, while there may be about 10^{21} total molecules/cm^3. One cm^3 of densely arrayed parallel microtubules 100 nm apart contains about 10^{17} tubulin subunits and therefore may contain 10^{17} dipoles equivalent to the maximal density of charge! Electret and related properties can impart interesting and potentially useful coherent properties to biomolecules including cytoskeletal polymers.

3.4 Coherent Excitations (Fröhlich)

Proteins are vibrant, dynamic structures in physiological conditions. A variety of recent techniques (nuclear magnetic resonance, X-ray diffraction, fluorescence depolarization, infrared spectroscopy, Raman and Brillouin laser scattering) have shown that proteins and their component parts undergo conformational motions over a range of time scales from femtoseconds (10^{-15} s) to many minutes. The most significant conformational vibrations are suggested by Harvard's Karplus and McCammon (1983) to be in the middle of this range: nanoseconds. Such fluctuations are appropriate for conformational motion of globular proteins (4 to 10 nm diameter), consistent with enzymatic reaction rates and coupled modes like solitons.

Collective cooperativity of dynamic conformational states have been elegantly woven in a theory of coherent protein excitations by Professor Herbert Fröhlich, who has come to several profound conclusions. One is that changes in protein conformation in the nanosecond time scale may be triggered by a charge redistribution such as a dipole oscillation within hydrophobic regions of proteins (Fröhlich 1975). Another Fröhlich (1970) concept is that a set of proteins connected in a common voltage gradient field (membrane or polymer electret) would oscillate coherently at nanosecond periodicity if energy such as biochemical ATP or GTP hydrolysis were supplied. Far-reaching biological consequences may be expected from such coherent excitations, particularly when applied to the cytoskeleton.

Biomolecular excited states with very high dipole moments may, according to Fröhlich, become stabilized (metastable states) through internal and external deformations and through displacement of counter ions like calcium. Metastable states, which can correlate with functional conformations, are thus collective effects involving the molecule and its surroundings. A molecule might be lifted into a metastable state through the action of electric fields, binding of ligands or neurotransmitters, or effects of neighbor proteins. Thus rapid, nanosecond oscillations may become "locked" in specific modes which correspond to useful conformations of a protein. For example, an ion channel, receptor, enzyme, or tubulin subunit may stay in metastable conformational states for relatively long periods, on the order of milliseconds.

Expanding on Fröhlich's work, Wu and Austin (1978) concluded that coherently oscillating dipoles within a narrow band of resonance frequencies with large enough coupling constants may be expected to cause strong long-range (about 1 μ) attractive forces among dipoles. In a dense microtubule array, 1 μ^3 (one billion nm^3) would encompass about 160,000 tubulin subunits – an array sufficiently large for collective effects.

In a further extension of Fröhlich's work, a group of scientists from the University of Milan (Del Giudice et al. 1986) have viewed living matter as a sea of electric dipoles. The Milan group sees order in living systems to be induced by reduction of tridimensional symmetry to a rotational alignment along filamentous electrets such as cytoskeletal structures. In their view, quantum field theory and the Goldstone theorem require that the symmetry breaking (Bose condensation) results in long range interactions among system components (dipoles) conveyed by massless particle/waves (Goldstone bosons). The Milan group argues that the energy required to generate massless bosons is invested in the electret states of biomolecules and correlated fluctuations of their surrounding water and ions.

Celaschi and Mascarenhas (1977) showed that electret activation energy of biomolecules (0.2-0.4 eV) is equivalent to the hydrolysis of one ATP or GTP molecule and what Soviet scientist A.S. Davydov predicted for initiation of biological solitons. Consequently solitons, massless bosons, and Fröhlich's coherent polarization waves may be synonymous.

Pursuing their quantum field approach, the Milan group arrived at an astounding concept of self-focusing of electromagnetic energy within cytoskeletal filaments. Electromagnetic energy exceeding a threshold originating within, or penetrating into, cytoplasm would be confined inside filaments whose diameters depended on the original symmetry breaking (Bose condensation) of ordered dipoles. Any electric disturbance produced by thermally fluctuating dipoles or by any other source would be confined inside filamentous regions whose diameter depends on the polarization density, or ordering of biological water. The Milan group calculated a self focusing diameter of about 15 nm (precisely the inner diameter of microtubules) and argues the cytoskeleton is the material consequence of dynamic self-focusing of polarization waves in the cytoplasm. The Milan group concludes that focusing occurs in cytoplasm of living cells due to the spatial coherence and ordering imparted by cytoskeletal electret behavior.

4 Coherence and Models of Cytoskeletal Information Processing

Cooperative, collective effects of coherent protein conformational oscillations are a likely substrate for biological intelligence ranging from cytoplasmic probing to human consciousness. The activities, functions, and structures of microtubules and other cytoskeletal components have led at least a dozen author groups to publish theoretical models of information processing within MT and the cytoskeleton. The concepts include passive MT signal transduction, descriptive patterns among MT subunit states, dynamic cooperative automaton effects among coherent oscillations of microtubule subunits, and cytoplasmic/cytoskeletal sol-gel field effects utilizing holographic imagery. Coherent oscillations of cytoskeletal protein subunits such as tubulin are relevant to several of these communicative modes.

Experimental findings which support the notion of cytoskeletal communication include electrical signaling along microtubules (Vassilev et al. 1985), fluorescence resonance transfer among MT subunits and membranes (Becker et al. 1975), parallel alignment of MT in applied electric and magnetic fields (Vassilev et al. 1982) and in-

volvement of intraneuronal MT in nerve membrane excitability and synaptic transmission (Matsumoto and Sakai 1979; Alvarez and Ramirez 1979). The following models of cytoskeletal information processing are consistent with these findings and would be strengthened by coherent protein oscillations.

4.1 MT Sensory Transduction (Atema)

Biologist Jelle Atema (1973) proposed that sensory cilia transduced environmental information to the rest of the cell by propagated conformational changes in the microtubule subunits which constituted these cilia. Atema reviewed conformational changes in MT tubulin subunit dimers observed by a number of authors, and concluded that sequences of subunit conformational changes are likely to occur in microtubules coupled to wavelike or whiplike motions of cilia and flagella. Atema's microtubule theory assumed that distortion of tubulin conformation by any number of sources was sufficient to propagate a conformational wave. Thus light energy, chemical bond energy, and mechanical forces could be transduced by sensory cilia.

Atema's view of MT information processing was an all-or-none propagation of conformational changes along tubulin protofilaments. His was the first theory to look beyond the global behavior of cilia to consider conformational effects in tubulin components. Subsequent theories became more elaborate to consider localized analog functions, switching, and collective neighbor interactions among MT subunits.

4.2 MT Mechano-Ionic Transducers (Moran and Varela)

Expanding on Atema's suggestion, Harvard biologists Moran and Varela (1971) suggested that compression or bending of MT would cause release and flux of bound ions from MT subunits (16 calcium ions per tubulin). Moran and Varela saw these ionic currents capable of generating membrane depolarization much like the coordinated release of calcium ion waves by muscle cell sarcoplasmic reticulum triggers actin-myosin contractile shortening and like the calcium waves thought to regulate bending and waving of cilia and flagella as well as calcium wave coupling to sol-gel state in the cytoskeletal ground substance. Moran and Varela's contribution was to observe that MT could release ions such as calcium in a controlled and modifiable manner useful for intracellular communication.

4.3 Cytomolecular Computing (Conrad and Liberman)

Wayne State University computer scientist Michael Conrad and Soviet information scientist E.A. Liberman (Conrad and Liberman 1982) have viewed a molecular analog within the cytoskeleton as a representation of the external world.

Conrad (1985) notes that

"highly parallel signal processing and vibratory behavior on the part of microtubules and other cytoskeletal elements could play a significant role".

4.4 MT Signal Processing (DeBrabander)

Cell biologist Marc DeBrabander and colleagues (Geuens et al. 1987) have developed a method of labeling individual tubulin subunits within MT which are either tyrosinated or glutamated. Tyrosine, the terminal amino acid in tubulin, may be removed from polymerized MT to expose the more acidic glutamate as the new terminal amino acid. Thus all tubulins within polymerized MT are either tyrosinated, or glutamated which may serve as a convenient programming or memory function. DeBrabander and colleagues developed a double labeling technique in which immunogold particles bind to tubulin subunits. Large immunogold particles (10 nm) identify glutamated tubulin and smaller particles (5 nm) bind to tyrosinated tubulin. Patterns of tyrosinated/glutamated tubulin within MT show heterogenous distributions, and suggest the potential for a coding mechanism. MAP attachment, tubulin conformation, calcium binding and other factors could be coupled to MT function via such patterns. DeBrabander and colleagues have provided the first direct evidence of modifiable patterns of tubulin variability in intact microtubules. Consequently, MT appear capable of signal processing in addition to signal transduction.

4.5 Cytoskeletal String Processors (Barnett)

Brooklyn College computer and information scientist Michael P. Barnett has pursued the design of computer components suited to molecular scale devices and artificial intelligence (AI). Unlike most AI researchers, Barnett scoured the subcellular biological realm in search of molecular scale information processing concepts and "discovered" cytoskeletal microtubules and neurofilaments! He has proposed information representation as patterns in the subunits of cytoskeletal polymer subunits which may operate like information strings analogous to word processors.

In Barnett's conceptualization (Fig. 8), information strings move from right to left along processing channels which run parallel to one-dimensional memory channels in which character strings can be stored. String transformers can perform global replacements on sequences of characters like common word-processors. Barnett's model assumes the existence of processing channels (MT) along which strings of information can move, and memory channels (neurofilaments) which consist of a succession of locations, each of which can hold a single character. Parallel array and lateral interconnectedness of MT and neurofilaments could qualify these cytoskeletal elements as string processors, assuming that information may be represented in the polymers. Barnett's model is thus compatible and complementary with other models of conformational patterns within MT and the cytoskeleton. The actual implementation of Barnett's string processing would be greatly facilitated by clocking, or coherent oscillations of subunits in both MT and neurofilaments.

4.6 Microtubule "Gradions" (Roth, Pihlaja, Shigenaka)

Roth et al. (1970), and Roth and Pihlaja (1977) have considered information processing in biomolecular assemblies. Citing cooperative effects among adjacent proteins or protein subunits, they proposed that conformational gradients in microtubules and other protein arrays represent information by patterns of conformational states (gradions) among near neighbors in protein lattices.

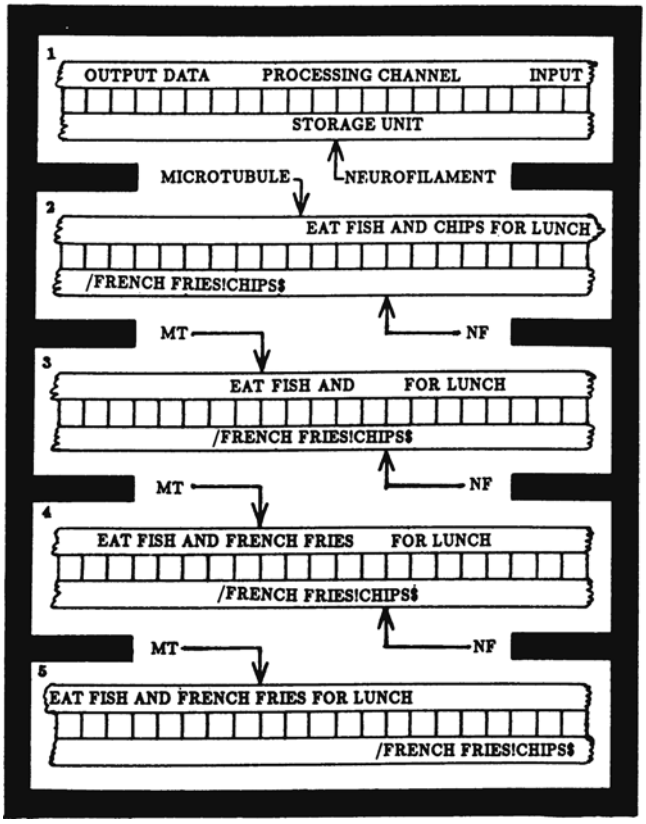

Fig. 8. Barnett's string processor model of microtubule-neurofilament memory storage. *1* a processing channel (microtubule-MT) is laterally connected to a parallel storage unit (neurofilament-NF); *2* information traverses the processing channel from right to left; on the storage channel, synonym pairs move from left to right; *3* as the word "chips" moves by its own self in storage, it is deleted; *4* "chips" is replaced by its synonym "french fries", and *5* the replacement is complete. (By Paul Jablonka, from Hameroff 1987)

Conformational states of individual tubulin subunits are thought to be controlled by factors which include ligand induced conformation, tubulin isozyme, detyrosination, or binding of MAPs including inter-microtubule bridges. Discrete gradion fields within microtubule surfaces were defined as the neighborhood areas around inter-microtubule MAP bridges. Roth, Pihlaja and Shigenaka assumed five possible conformational states for each dimer determined by inter-MT linkage sites and their cooperative allosteric effects, as well as dimer binding by a number of different native substrates or foreign molecules. The pattern of tubulin dimer conformational states in a region of MT lattice governed by attachment of inter-MT linkages (or other MAPs) is defined as a gradion, or conformational field which includes about seventeen dimers (Fig. 9). Consequently, 5^{17} different gradion patterns could exist if the conformation of each subunit were independent of all others. Such deterministic patterns would be generally useful when coupled to coherent dynamics in the cytoskeleton.

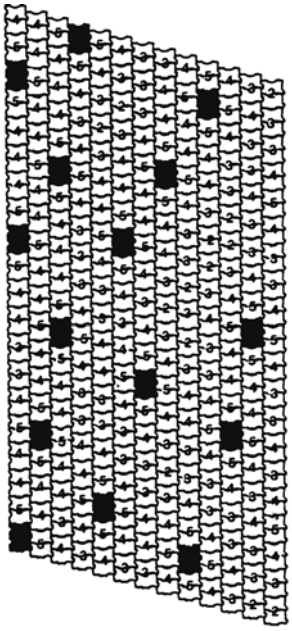

Fig. 9. "Gradions" within microtubule lattice. Dark shaded dimers are MAP attachment patterns; numbered dimers are determined by proximity to MAP attachment sites. MAP binding and other "gradionators" are thought to induce coded patterns representing information. (By Paul Jablonka from Roth 1970)

4.7 Gyroscopic Centrioles (Bornens)

French molecular biologist Michel Bornens (1979) argues for a dynamic stability based on organizational properties of centrioles (Fig. 3) and the cytoskeleton. Specifically, Bornens proposes that centrioles are animated by rapid oscillatory rotation about their longitudinal axis, which results in a dynamic stability and inertia analogous to a spinning top or gyroscope.

The rate of rotation required for gyroscopic inertia has been calculated as 2.3 million revolutions per minute (Albrecht-Buehler 1981). To account for such rapid activity, Bornens suggests a submicroscopic mechanism "allowing more independence of the centriole with respect to surrounding material." Factors which could support this contention include ordered water coupled to centriolar oscillation, some unknown property of the "pericentriolar material," ionic charge layer, or even superconductivity as suggested by Fröhlich and Del Giudice's group. Rapid rotatory oscillations in protein assemblies would be consistent with the findings of Michels et al. (1985), who found collective energy absorption in the range of 10^7 per second by protein assemblies such as virus coats. Bornens also suggests that ATP-generated centriolar rotation triggers propagating impulses along microtubules by transitory contact/stimulus of the nine rotating MT doublet/triplets in the centriole wall with their surrounding satellite bodies. This would lead to coherent rhythmic signals throughout the cytoskeleton with a frequency nine times greater than that of the centriole's rotation. Occurrence of coherent, rhythmic signals throughout the cytoskeleton would be mechanisms close to the nature of life itself.

4.8 Centriole-MT Signaling (Albrecht-Buehler)

Northwestern University biologist Guenter Albrecht-Buehler has considered the general question of intelligence in cytoplasm as well as two specific models of cytoskeletal information processing: centriole signal detection, and propagation of MT impulses.

Albrecht-Buehler (1985) has described a mechanism for impulse propagation along microtubules. He considers that each MT protofilament is a chain of alpha-beta tubulin dimers: AB,AB,AB,...,AB. Within the wall of a microtubule, each monomer is in contact with other monomers of the same protofilament and with those of adjacent protofilaments. Each monomer is consequently subject to attractive Van der Waals forces from surrounding tubulin monomers which hold together the protofilaments and MT cylinders. Albrecht-Buehler proposed that each of these interactions must weaken the A-B dimer bond; consequently the wall of a microtubule exists in a "state of resonance as to the relative strengths of the intermonomeric bonds. For example, (A-B)(A-B)...(A-B)(A-B) could resonate with (A)(B-A)(B-A)...(B-A)(B). Such a resonating chain could propagate information at close to the speed of light".

Albrecht-Buehler is suggesting a coherent communicative resonance among protein conformational states within MT assemblies.

4.9 Dynamic Tensegrity (Heidemann and Jarosch)

Buckminister Fuller proposed an interesting architecture he called tensegrity, constructed from an assembly of tension and compression members (Fuller 1975). The compression members of solid struts are isolated from each other, held together by the tension members. Joshi et al. (1985) have shown that cytoplasm has both compressive and tensile elements. Semi-rigid microtubules are under compression, presumably due to tension generated by actin filaments and actin based microtrabecular lattice. In general, MT do not contact each other so that the self-supporting capability of cytoplasm may indeed stem from tensegrity.

Robert Jarosch (1986a,b) has published a series of papers describing actin-MT interactions which suggest that (1) contractile actin filaments are spirally wound around microtubules, (2) coordinated contraction of the actin filaments imparts a rotational torque to MT, somewhat like a spinning top, (3) actin filaments wound in opposite directions on the same MT can cause rotational oscillations of the MT. These two models fit together to provide a picture of a dynamic cytoplasmic tensegrity network in which the cytoskeletal elements may be coherently twisting back and forth. Perturbation of any part of such a tensegrity network could have dynamic consequences throughout its domain. Transient changes in tension, compression, or oscillatory rhythm caused by a variety of factors would be transmitted and possibly amplified throughout the cytoskeleton.

4.10 Dynamic MT Probing (Kirschner and Mitchison)

Strong evidence supports the concept of dynamic instability in microtubule assembly. Kirschner and Mitchison (1986) ask: "how can a peripheral clue lead to reorganization deep within a cell?" One possibility is that a signal is relayed to the microtubule-organizing center leading to a change in its structure, orientation, and directed nuclea-

tion of microtubules. This would be consistent with a primary role for information integration and decision-making within the MTOC. A simpler non-hierarchical idea is that a signal at the periphery affects distribution directly. Since the whole cytoskeletal array is very dynamic, it would only be necessary to stabilize or destabilize a particular subset of microtubules for the entire cytoskeleton to rapidly transform.

4.11 Sphere Packing Screw Symmetry (Koruga)

There are 32 possible symmetry arrangements of packed spheres in a cylindrical crystal. Erickson (1973) used hexagonal packing of protein monomers to explain the form and patterns of viruses, flagella and microtubules. Djuro Koruga (1986) of the University of Belgrade's Molecular Machines Research Unit has analyzed the symmetry laws which describe cylindrical sphere packing and the structure of microtubules.

Koruga (1986):

"The sixfold symmetry and dimer configuration lead to screw symmetry on the cylinder: a domain may repeat by translocating it in a spiral fashion on the cylinder. From coding theory, the symmetry laws of tubulin subunits suggest that 13 protofilaments are optimal for the best known binary error correcting codes with 64 code words. Symmetry theory further suggests that a code must contain about 24 monomer subunits or 12 dimers".

Koruga's symmetry arguments may be compared with the gradion concept of Roth, Pihlaja, and Shigenaka in which a field of about 17 monomers is thought to represent a basic information unit. Koruga concludes that microtubule symmetry and coherent structure are optimal for information processing.

4.12 Cytoskeletal Self-Focusing (Del Giudice)

Starting from Fröhlich's model of coherent excitations, Del Giudice and colleagues (Del Giudice et al. 1983a,b, 1986; Del Giudice 1986) have used quantum field theory to describe the electret state of biological systems (ordered water surrounding linear biomolecules) and determined that there exists a strong likelihood for the propagation of particle-like waves in biomolecules. Further, the ordering of water should lead to self-focusing of electromagnetic energy into filamentous beams excluded by the ordered symmetry. For ordered cytoplasm, they calculate the diameter for the confinement and propagation of particle-like waves (massless bosons, polarization waves, or solitons) in biomolecules to be about 15 nanometers, exactly the inner diameter of microtubules.

Cytoskeletal polymers may thus be capable of capturing and utilizing ambient or biologically generated electromagnetic energy. One possible example is infrared energy which is routinely generated by dipoles in biological molecules. This energy is generally believed to be dissipated into heat within the aqueous cytoplasm, however self-focusing within a solid-state cytoskeleton could utilize this energy productively in a communicative medium.

4.13 MT Automata, Holography (Hameroff, Watt, Smith)

The self-focusing of electromagnetic energy described by the Milan group is thought to occur by an electret induced increase in the refractive index of cytoplasm. A similar concept was proposed (Hameroff 1974) in which microtubules were thought to act like dielectric waveguides for electromagnetic photons. It was also proposed that the periodic array of MT subunits leaked or diffracted energy with 8 nanometer periodicity, resulting in a source of coherent energy (or calcium ions) from MT. Cytoplasmic interference of the coherent sources from among multiple MT could lead to holographic imaging in cytoplasm. Coupling of calcium concentrations to cytoplasmic sol-gel states could "hardwire" holographic interference patterns into the microtrabecular lattice. In parallel arrays of MT within nerve fibers, graded potentials or traveling action potentials were suggested to activate planes of cytoplasm perpendicular to the long axis of the MT and nerve fibers (Fig. 10). These traveling planes may be likened to image screens as in TV sets. In a TV picture tube, the screen is motionless and electron beams move to create a pattern by their intersection with the screen. Perhaps imaging within neurons occurs on travelling screens generated by action potentials moving through parallel MT arrays. The content of such images would depend on programming mechanisms in the conformation of tubulin subunits which comprise the MT walls, and which would update with each successive action potential. Hameroff and Watt (1982) described a method of MT tubulin programming in which charge carriers (calcium ions, electrosolitons) or conformational waves such as phonons or solitons were steered through MT lattices by genetically or cytoplasmically programmed tubulins and specific MAP-binding sites.

Hameroff et al. (1984, 1986) have utilized principles of cellular automata to explain information processing in MT. Cellular automata are dynamical systems which can generate and process patterns and information, and are capable of computing. Cellular automata require a lattice structure of like neighbors with discrete states and neighbor rules, and a universal clock to which all neighbors are timed. Adopting Fröhlich's model of coherent nanosecond dipole oscillations coupled to conformational

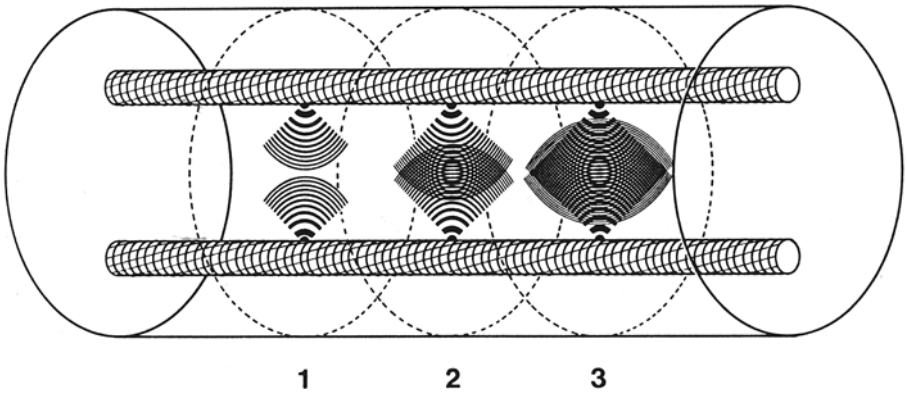

Fig. 10. Interference patterns in cytoplasm caused by coherent waves (e.g. Ca^{2+}, sol-gel state, MTL) generated by dynamic activities in microtubules may be a basis for holographic information imagery. (Hameroff 1987)

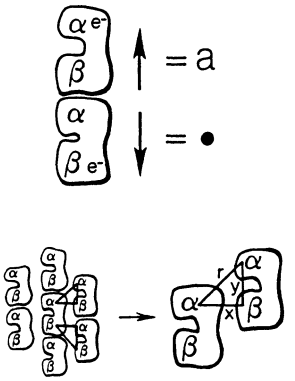

Fig. 11. *Top* MT-tubulin dimer subunits comprised of α and β monomers. Relative electron occupancy of either monomer may correlate with coherent dipole oscillations in the nanosecond time domain. *Bottom* screw symmetry hexagonal packing leads to unequal neighbor rules based on lattice distances and Van der Waals dipole interactions. For dimers shown at right, x = 5 nm, y = 4 nm, r = 6.4 nm. The relative strength of each neighbor dimer dipole state is y/r^3

states as a clocking mechanism, the authors calculated MT lattice neighbor Van der Waals dipole interactions as neighbor rules for an MT-automaton computer simulation. Each tubulin dimer was considered in one of two possible states at each nanosecond generation. The two states were related to Fröhlich's concept of dipole oscillation so that the dipole can be oriented either toward the alpha tubulin end (a, Fig. 11) or toward the beta tubulin end (represented by a dot in Fig. 11). The polarity and electret behavior of MT indicate that in the resting state, tubulin dimer dipoles should be oriented toward the beta monomer.

Dimer states at each "clock tick," or generation were determined by neighbor states at the previous generation.

$$\text{state} = \alpha, \text{ if } \sum_{i=1}^{n} f(y) > 0, \text{ state} = \beta, \text{ if } \sum_{i=1}^{n} f(y) < 0 ,$$

where n = 7 as the number of neighbors, and f(y) the force from the *i*th neighbor in the y direction.

$$f(y) \propto \frac{\sin\theta}{r^2}, \sin\theta = \frac{y}{r}; f(y) \propto \frac{y}{r^3} .$$

The dipole state of any particular dimer at each clock tick thus depends on the summation of the dimer's neighbor dipole states (including its own) at the previous clock tick. The neighbor influences are unequal because of the screw symmetry of the MT lattice. Distant dimers (more than one neighbor away) would be expected to have little influence because of the dropoff in force intensity (y/r^3) with distance. However, collective influences from many like oriented dimers could augment long-range cooperativity. Using only near neighbor influences, computer simulation of an MT automaton yields interesting patterns and behavior of dipole/conformational states. These include both stable and traveling interactive patterns capable of computing and regulation of cytoskeletal activities. For example, Fig. 12 shows such patterns traveling through MT lattices, leaving altered wakes, or memory. Assuming nanosecond generations, these traveling patterns would travel at 8 nm per ns (8 m/s), a velocity consistent with propagating action potentials, or solitons. Variability in individual tubulin dimer isozymes, ligand binding, or MAP attachments could program and read out information in routine cellular functions. As one example, propagation

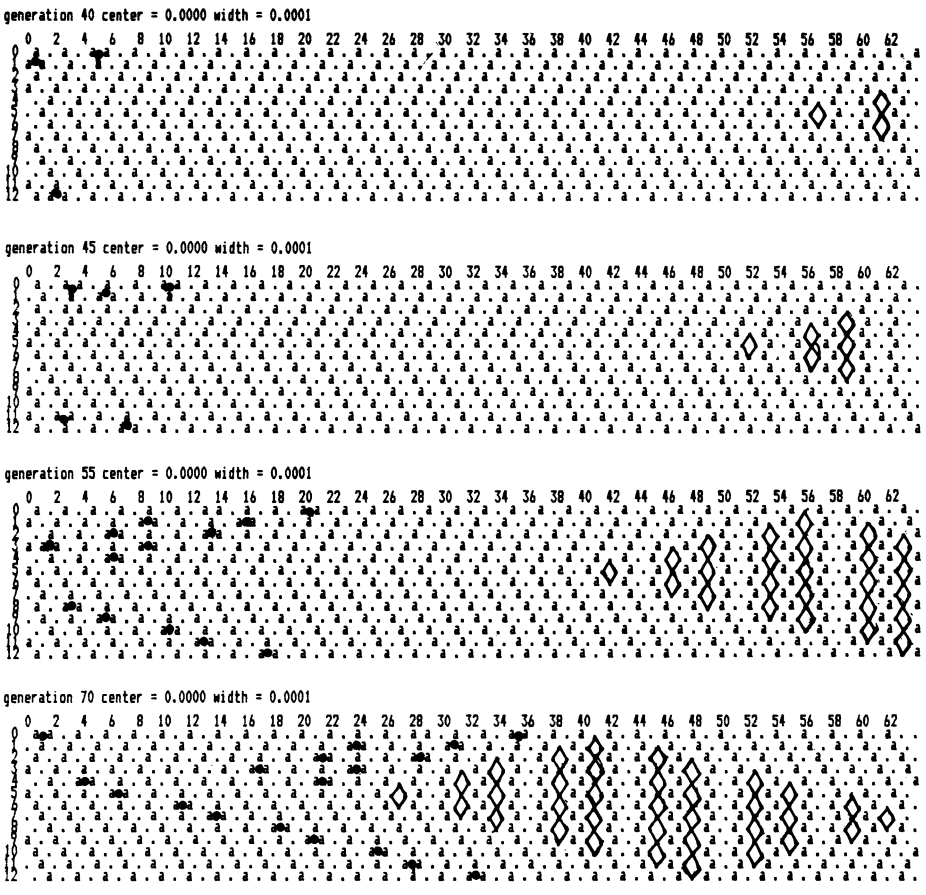

Fig. 12. 30 "nanoseconds" of computer simulation of MT cellular automaton based on Fröhlich coherent oscillations and tubulin subunit neighbor rules based on dipole-dipole interactions. Thirteen protofilaments are arranged horizontally, 64 rows are shown vertically yielding a flat MT lattice. "Alpha" states of tubulin (Fig. 11) are shown by "a," beta states by a *dot*. Four contiguous beta states are highlighted by *diamond patterns*. Four contiguous alpha states by *darkened dots*. The stimulation sequence (generations 40, 45, 55 and 70) shows movement of patterns at velocity of 8 nm/ns (8 m/s). (Hameroff et al. 1984)

of MT conformational patterns could coordinate the activities of contractile MAP sidearms in axoplasmic transport (Fig. 5). In a general sense, MT automata may be the information substrate for biological activities ranging from ciliary bending to human consciousness. Specific automata patterns distributed throughout wide volumes of cytoskeletal arrays within the brain could lead to cooperative resonance and collective effects resulting in images, thoughts, or ideas similar to coherence-induced phase transitions in certain metals yielding emergent collective properties such as superconductivity.

5 The Cytoskeletal Connection

The current prevalent model of brain function and artificial intelligence is the neural network, a collective dynamical system whose output is determined by the states of component neuronal synapses. In turn, the state of each synapse is determined by other neurons, modulated by the interneuronal cytoskeletons. In turn, the cytoskeleton is a collective dynamical system whose net activity is determined by the states of its component subunits. Their states, in turn, are determined by another level of organization including cytoplasmic factors, ordered water and ions, genetic isozymes of individual subunits, other cytoskeletal elements such as the microtrabecular lattice, and cooperative effects – coherence – from among collective assemblies of subunits. Cognitive processes which have been ascribed to neural net concepts may be more accurately interpreted as fractal hierarchies of dynamical systems which are highly parallel, highly interconnected, and of increasing capacity as they become more microscopic. Coherent oscillations of these subunits would permit collective effects to occur at each level and at successively more macroscopic levels with a net effect of consciousness.

Coherent Electric Vibrations in Biological Systems and the Cancer Problem

H. FRÖHLICH

Abstract—**The existence of coherent electric vibrations in the 5×10^{10}–3×10^{12} Hz region has now been established experimentally for biologically active microorganisms. It is shown that such vibrations might play a decisive role in the control of growth of tissues and, hence, in the cancer problem.**

I. Survey

SEVERAL YEARS AGO, it had been proposed [1] that electric vibrations with frequencies of the order of 10^{11}–10^{12} Hz should be excited coherently in active biological materials through metabolic processes. The given frequency range is to be considered as a very rough order of magnitude. It thus borders closely on the now accessible microwave range. Excitations of the proposed type could have far-reaching biological consequences, for they would lead to selective long-range interactions which probably are required to control growth in normal tissue and whose absence might lead to cancer.

Verification of the theoretical conjecture posed considerable experimental difficulties. During recent months, however, conclusive experimental evidence for their existence has been obtained in bacteria [2], [3] and in yeast cultures [4]. This latter followed and extended earlier work [5] on the action of coherent millimeter waves on biological systems for which it was found difficult to obtain detailed experimental information.

Existence of such extraordinary physical properties in biological systems must be the result of long evolutionary processes. It may be hoped, therefore, that such vibrations exist not only in the monocellular systems for which their existence has been verified, but also in higher systems and particularly in tissues.

While the stimulus for this work has arisen from theoretical considerations, it must be emphasized that the role of the theory must first be the introduction of relevant concepts—coherent electric vibrations in the present case. Model calculations are useful (Section IV) in that they may further specify such concepts. More detailed predictions, however, require experimental corroboration. For, in contrast to the physics of materials where, from their structure, many properties can be derived theoretically through the theory of linear response, biological systems are largely characterized through nonlinear response.

Manuscript received June 24, 1977. This work was supported in part by the Leverhulme Trust.

The author is with the Department of Physics, Oliver Lodge Laboratory, The University, P.O. Box 147, Liverpool L69 3BX, England.

II. The Model and Its General Consequences

Membranes of biological systems usually have a thickness of about 10^{-6} cm across which an electric potential difference of the order of 100 mV is maintained. An enormous electric field of the order of 10^5 V/cm thus acts on the membrane which, therefore, is strongly polarized electrically. The only generally accepted role of this field refers to nerve conduction, but membranes of other than nerve cells also maintain such a field. A possible role of such fields may refer to proteins dissolved in a membrane which, under the influence of the field, may undergo configurational changes, particularly if they possess metastable states with high electric dipole moments as has been discussed on other occasions [6]–[9].

For the present purpose, it will be noted that a section of the membrane oscillating (with displacement) perpendicular to the surfaces represents an electric wave with half-wavelength of the width of the membrane, and (in view of its polarization) an oscillating electric dipole. Assuming elastic properties corresponding to a velocity of sound of 10^5 cm/s this yields a frequency of one-half 10^{11} Hz. Proteins built into the membrane and possessing a high dipole moment may, of course, also oscillate, probably with higher frequency. Sections of giant molecules such as DNA or larger complexes might oscillate with lower or higher frequencies. All this assumes that the damping of such oscillations is not unduly high. In each such case, harmonics which no longer represent dipolar oscillations—with appropriately higher frequencies—should exist.

Oscillating polar systems of this type interact with each other, and their resulting oscillations can usually be presented in terms of normal modes. It will now be assumed that the lowest of these modes is excited very strongly (coherently) through the supply of energy from metabolic processes. In general, this will involve nonlinear features. A mathematical treatment for a possible model will be presented in Section IV, but much more complex features than these considered may be at work. The existence of such vibrations, however, will have consequences which

0018-9480/78/0800-0613$00.75 © 1978 IEEE

are far reaching and largely independent of the manner in which they are excited, provided they involve oscillating electric dipoles.

The most important of these consequences refers to a long-range attractive selective interaction [8], [10]. It should be noticed first that, in biological systems, static charges are usually screened at relatively short distances in contrast to electric vibrations in the frequency region of 10^{11} Hz which have a range much larger than the dimensions of a cell. Consider now two such oscillating systems with frequencies ω_1 and ω_2, respectively, at a distance R, large compared with their linear dimensions. In this case, dipolar terms in the interaction only need be considered, leading to normal mode frequencies $\omega_\pm$

$$\omega_\pm^2 = \frac{1}{2}(\omega_1^2+\omega_2^2)\left[1 \pm \left\{\left(\frac{\omega_1^2-\omega_2^2}{\omega_1^2+\omega_2^2}\right)^2 + \frac{M^2}{R^6}\right\}^{1/2}\right]. \quad (1)$$

Here, for given displacements of the oscillators, M/R^3 measures the ratio of the interaction energy between the dipoles and of their individual potential energies. Thus as long as the { } bracket is small compared to unity,

$$\omega_\pm = \left(\frac{\omega_1^2+\omega_2^2}{2}\right)^{1/2}\left[1 \pm \frac{1}{2}\left\{\left(\frac{\omega_1^2-\omega_2^2}{\omega_1^2+\omega_2^2}\right)^2 + \frac{M^2}{R^6}\right\}^{1/2} - \frac{1}{8}\left\{\left(\frac{\omega_1^2-\omega_2^2}{\omega_1^2+\omega_2^2}\right)^2 + \frac{M^2}{R^6}\right\} + \cdots\right]. \quad (2)$$

The energy of interaction between the two systems is now obtained by subtracting from the free energy at distance R the free energy as $R \to \infty$. In thermal equilibrium, both ω_+ and ω_- contribute, and the result is the well-known van der Waals interaction $\alpha 1/R^6$, whether or not $\omega_1 = \omega_2$. In our case, when ω_- is very strongly excited, say with $n_- \gg 1$ quanta, the thus defined interaction energy I becomes (let $\omega_1 \geqslant \omega_2$)

$$-I \simeq \hbar n_- \left(\frac{\omega 2_1+\omega_2^2}{2}\right)^{1/2}\left[\frac{1}{2}\left\{\left(\frac{\omega_1^2-\omega_2^2}{\omega_1^2+\omega_2^2}\right)^2 + \frac{M^2}{R^6}\right\}^{1/2} - \frac{1}{2}\frac{\omega_1^2-\omega_2^2}{\omega_1^2+\omega_2^2} - \frac{1}{8}\frac{M^2}{R^6} + \cdots\right]. \quad (3)$$

When $\omega_1 \simeq \omega_2$, an attractive interaction $\alpha 1/R^3$ thus arises in contrast to the case $\omega_1 \neq \omega_2$ when the attraction is again $\alpha 1/R^6$ at large distances.

Furthermore, since the magnitude of the interaction depends on the strength of excitation, such interaction will be switched on or off depending on whether or not metabolic energy is supplied. This might apply to the attraction of an enzyme and a substrate at certain stages of cell development [6].

The case of a whole assembly of such pumped equal systems which should be of particular interest for the control of tissue growth has not yet been treated in detail but general theorems concerning normal modes do, of course, apply although such theorems usually refer to regular arrangements of the individual oscillating systems, frequently though not necessarily with nearest neighbor interaction only. In our case, e.g., in an assembly of cells pumped metabolically to oscillate with equal frequency, interaction with more distant neighbors will be relevant and, in the lowest normal mode, each individual oscillator will exhibit a definite phase relation to the phase of the mode so as to make the total (negative) interaction energy a minimum. This will cause certain contractions and in this way, will very likely involve nonlinear terms. The total interaction energy may thus be expected to become size and shape dependent.

An individual cell in the neighborhood of this assembly may then be expected to be attracted to it much more strongly when its frequency is the same as that of the assembly than when it is different. Assuming that this frequency is different for differently differentiated cells [11], this would explain the great attraction that equally differentiated cells exert on each other.

The possibility of switching on or off the collective mode through metabolic processes might give rise to changes in the configuration of larger regions such as required prior to cell division. The supply of metabolic energy, in turn, would have to be regulated so as to be available at the correct time. A whole temporal succession would thus arise.

Models for such processes could be treated mathematically in some detail. At the present stage of development, it seemed to be more important to find conclusive experimental proof for the existence of the conjectured vibrations.

III. Experimental Evidence

If vibrational states with frequencies of the order one-half 10^{11}–10^{12} Hz (or higher) are strongly excited by metabolic processes, then corresponding Raman lines should be found when the system is metabolically active but not when it is nonactive. The excitation, moreover, should be much stronger than thermal excitation.

An alternative approach would be to attempt interfering with the biological processes by exciting the systems from outside.

A. Raman Effect

Careful investigation of the Raman spectrum of an enzyme (lysozyme) in aqueous solutions yields broad bands in the region of 100 cm^{-1}(3×10^{12} Hz) [12]. Such broadening indeed should be expected from the high friction with water.

The Raman spectrum of resting (not metabolizing) bacterial cells was found to be of a similar nature [2]. If synchronized cells (i.e., they are all in the same stage of development) are supplied with an appropriate nutrient (which on its own also shows a broadband), then a number of relatively sharp strong Raman lines appear in a

range between 7×10^{10} and 5×10^{12} Hz. They thus fall into the expected membrane frequency region and may well be due to the predicted excitations. In principle, however, they might also arise from intermediate chemical products which for unknown reasons are not subject to the friction with water. The crucial experiment consists in the measurement of the ratio R of the intensities of anti-Stokes and Stokes lines. If the lines (frequency ν) arise from an intermediate chemical, then this ratio should be

$$R_0=\exp(-h\nu/kT) \tag{4}$$

for their excitation would, in a very short time, reach the thermal equilibrium value (temperature $T\simeq300$ K). If the excitation arises from metabolic pumping, however, and is very large compared with thermal excitation, then $R_0\simeq1$ must be expected.

Experiments on active synchronized E coli B bacteria conclusively proved the existence of strong excitations [3]. A Raman line which, during the life cycle of the bacteria, shifts from 118 to 125 cm^{-1} (3.75×10^{12} Hz) showed $R_0=1.01\pm0.09$ for 118 cm^{-1} and $R_0=0.93\pm0.13$ for 125 cm^{-1}, while the respective thermal equilibrium values (3.1) are $R_0=0.57$ and $R_0=0.55$. When the thermal value of R_0 is larger, such tests would, of course, require much higher accuracy.

Experiments to date showed that a multiplet near 40 cm^{-1} appeared during a short period in the cell cycle only; many more such temporary lines may be anticipated since nonsynchronized cells show many more lines though they are of much lower intensity than those of synchronized cells. The hope thus exists that these excitations may be attributed to definite cell activities as suggested in Section II.

Lines also seem to exist near 5 cm^{-1} (1.5×10^{11} Hz) or possibly lower, though this was beyond the available resolving power.

B. Action of Coherent Millimeter Waves

Already several years ago, it had been observed that electromagnetic (EM) radiation of 7.1 and 7.3×10^{10} Hz depresses the growth of E coli bacteria [13]. These findings were confirmed recently [14].

A series of most startling results on the influence of coherent millimeter waves on various properties of biological materials was presented in the U.S.S.R. Academy of Sciences [5]. According to this report, irradiation in the range of 5–8 mm ($4–6\times10^{10}$ Hz) can influence certain properties of biological objects ranging from microorganisms to higher organisms. It is claimed that in almost all cases, sharp frequency resonances in the biological effects are found while only optically broadbands have been observed. Also, the dependence on intensities exhibits threshold properties. A critical value S_0 of the rate of energy supply exists such that no effect is observed when $S<S_0$, while for $S>S_0$ the effect is nearly independent of S. These findings confirm our general conjecture of the biological importance of frequency selective vibrations [15].

Details of these experiments are not available, and it was decided, therefore, to repeat one of the experiments with the greatest care aiming at the highest possible accuracy [4]. The influence of the radiation on the rate of growth of yeast was selected where, in [5], results at four frequencies had been reported: one showing an increase and three showing a depression of this rate. The culture was different in the two cases so that one could not expect exactly the same results. The reproducibility of the measured rate was ±3 percent; the long-time frequency stability was ±3 MHz (a single rate determination takes about 10 hours). Yeast was suspended in a stirred aqueous nutrient medium and the growth was measured optically. A frequency range between 4.14 and 4.19×10^{10} Hz was investigated. About 40 values with 20 control (absence of microwaves) were measured. Power (a few milliwatts) and temperature in and near the sample were monitored. The finite penetration depth of the waves in water implied that at most 20 percent of the suspension was illuminated at a time. The results show five minima with growth rates between 70 and 85 percent of the control within 4.65 and 4.79×10^{10} Hz, separated by maxima of rates between 100 and 115 percent of the control, and no noticeable effect outside this range. Thus the effect is largely negative and exhibits extremely sharp biological frequency resonances. The dependence on the intensity of the radiation has not yet been investigated.

These findings strongly support the conjecture that coherent electric vibrations play an important role in biological activities. The extremely narrow frequency resonances pose most interesting problems whose answers demand further investigation. A model for the predominantly negative effects might arise from the assumption that the active biological system excites certain frequencies in terms of limit cycles. Application of radiation at slightly different frequencies might then destroy the original limit cycle and, hence, reduce the biological activity connected with it.

In conclusion, we have evidence for the biological importance of vibrations in the region of 5×10^{10} Hz from experiments with coherent millimeter waves. The strongest evidence from the Raman effect is at about 3×10^{12} Hz, but it extends to lower frequencies, possibly to about 10^{11} Hz. The interconnection of these various frequencies is unknown at present.

IV. A Model Calculation

The original proposal of coherent excitation of electric vibrations (polarization waves) through supply of metabolic energy was supported by the calculation of a model [13] which can be generalized in the following manner. Consider a band of z polarization waves with frequencies $\omega_k(k=1,2,\cdots,z;\omega_1<\omega_2\cdots<\omega_z)$ in strong interaction with a heat bath at temperature T, referring thus to the interaction of our vibrations with the rest of the system. In lowest order, this can be described in terms of emission of quanta $\hbar\omega_k$ from the polarization waves into the heat bath and of the corresponding absorption. To obtain interest-

ing effects, it will be necessary to consider the lowest nonlinear processes involving two quanta. Suppose that energy is supplied to the k mode at the rate S_k. Then, if this mode contains n_k quanta $\hbar\omega_k$, the following kinetic equation holds:

$$\dot{n}_k = S_k - \phi\left(n_k \exp^{(\beta\hbar\omega_k)} - (n_k+1)\right) - \chi\sum_l \left\{n_k(1+n_e)\exp^{(\beta\hbar\omega_k)} - n_e(1+n_k)\exp^{(\beta\hbar\omega_e)}\right\} - \lambda\sum_e \left\{\dot{n}_k n_e \exp^{(\beta\hbar(\omega_k+\omega_e))} - (n_k+1)(n_e+1)\right\}. \quad (5)$$

Here $\beta = 1/kT$ and the exponential factors arise from the condition of detail balancing. The transition probabilities ϕ, χ, λ are averages depending on temperature and a possible dependence on frequency is neglected. They are largely connected with the interchanged energy with nearly free ions and dipoles in the cell media.

Under stationary conditions then, $n_k = 0$, so that

$$\sum S_k = \phi\sum_k \left(n_k \exp^{(\beta\hbar\omega_k)} - (n_k+1)\right) + \lambda\sum_k\sum_l \left\{n_k n_e \exp^{(\beta\hbar(\omega_k+\omega_e))} - (n_k+1)(n_e+1)\right\} = \sum_k \left(n_k \exp^{(\beta\hbar\omega_k)} - (n_k+1)\right) \cdot \left\{\phi + \lambda\sum_e \left(n_e \exp^{(\beta\hbar\omega_e)} + (n_e+1)\right)\right\} \quad (6)$$

and

$$n_k = \left(1 + \frac{S_k}{\phi + \chi\Sigma n_e \exp^{(\beta\hbar\omega_e)} + \lambda\Sigma(n_e+1)}\right)\frac{1}{\exp^{(\beta\hbar\omega_e-\mu)}-1} \quad (7)$$

where

$$1 - e^{-\beta\mu} = \frac{(\chi-\lambda)\Sigma\left(n_e \exp^{(\beta\hbar\omega_e)} - (n_e+1)\right)}{\phi + \chi\Sigma n_e \exp^{(\beta\hbar\omega_e)} + \lambda\Sigma(n_e+1)}. \quad (8)$$

Thus unless $\chi = \lambda$ (requiring $\mu = 0$), ω_k represents a modified Bose distribution with chemical potential μ.

Now, for most more specific models, $\lambda \ll \chi$ holds ([16]). If this inequality holds to the extent that λ is negligible, then the above equations reduce to

$$\Sigma S_k = \phi\Sigma\left(n_k \exp^{(\beta\hbar\omega_k)} - (n_k+1)\right) \quad (9)$$

$$n_k = \left(1 + \frac{S_k}{\Sigma S_e}\frac{\phi}{\chi}\left(1 - e^{-\beta\mu}\right)\right)\frac{1}{\exp^{(\beta(\hbar\omega_k-\mu))}-1} \quad (10)$$

and μ satisfies

$$\hbar\omega_1 > \mu \geqslant 0. \quad (11)$$

The upper limit $\hbar\omega_1$ follows from the condition $n_k \geqslant 0$.Thus from (10) and (11)

$$\Sigma n_k \leqslant \left(1 + \frac{S_0}{\Sigma S_e}\frac{\phi}{\chi}\left(1 - \exp^{(-\beta\hbar\omega_1)}\right) \perp \Sigma \frac{1}{\exp^{(\beta(\hbar\omega_k-\mu))}-1}\right) \quad (12)$$

where S_0 is the largest of the S_k.

Now, from (9) it follows that Σn_k must increase proportionally to ΣS_k if this quantity is sufficiently large. This can be achieved only if μ comes very close to $\hbar\omega_1$ so that n_1 becomes much larger than the other n_k.

Thus the pumped system exhibits a phenomenon very well known for massive particles in thermal equilibrium: Einstein's condensation of a Bose gas; but, while in this case, the corresponding order arises when the temperature is decreased below a critical value, our case requires that the energy supply is raised above a critical value.

It should be emphasized that these results rest on a large magnitude of the nonlinear χ interaction. Other terms such as nonlinear direct interaction between the polarization waves could have been introduced. Such terms would tend to increase the temperature of the polarization waves above that of the heat bath and thus counteract Bose condensation.

Calculations of this type thus demonstrate the possibility of Bose condensation, i.e., of strong excitation of the lowest mode, provided certain material conditions are satisfied. This, one would conclude, has arisen through long evolutionary processes.

Even so, it seems difficult to expect excitations as narrow as those found experimentally and reported in Section III. Quite possibly, a second stabilizing agent will have to be found. If, for instance, the hypothesis of a limit cycle mentioned in Section III would hold, then the amplitude x would have to satisfy an equation of the type

$$\ddot{x} + \omega_1^2 x + \gamma\dot{x}(x^2 - a^2) = 0 \quad (13)$$

in the absence of an external field; γ and a^2 are constants. The missing agent would then replace ordinary friction terms $\alpha\dot{x}$ by the appropriate nonlinear terms which depending on the amplitude can extract or supply energy to the oscillator.

V. Coherent Vibrations and the Cancer Problem

While bacterial cells divide as long as nutrient and space are available, cell division in normal tissue is subjected to a control which is absent in cancer. It is required, therefore, to find the origin of this control.

We shall show that, in principle, this control could rest on the coherent electric vibrations discussed in the previous sections. In microorganisms, these vibrations have been found to exhibit quite extraordinary properties with regard to the sharpness of frequency resonances (Section III). It will be assumed then that they also exist in active normal tissue, though it will be for future experiments to verify this.

Suppose the coherent vibration in the assembly of cells forming a tissue to be excited as discussed in Section II. This requires each cell to oscillate with appropriate phase and with correct frequency. Changes in a cell that alter this frequency lead to the loss of most of its (negative) interaction energy with the coherent mode. Such changes can, therefore, occur only if sufficient energy is supplied. Now cell division may at certain stages lead to alteration of the relevant frequency. This step is, therefore, con-

trolled energetically by the interaction of the coherently excited mode with the particular cell. The magnitude of the required energy will depend on the strength of excitation of the mode. The availability of the required energy will depend on the available amount of nutrient though, to some extent this should also influence the strength of excitation.

Clearly, the oscillating system of cells exhibits a certain stability. Not only does it attract cells in the neighborhood if they have the correct frequency (Section II), but also an influence will be exerted on cells that for some reason have lost the correct frequency to reinstall it, for this gains free energy.

Now a cell that has lost the correct frequency will no longer contribute to the collective vibration and, hence, weaken it so that the potential barrier controlling cell division in other cells is reduced; but this will be a small effect. If a number of cells, however, will be so affected, then the strength of the collective vibrations will decrease more significantly, and a critical number of such cells should thus exist at which the control becomes ineffective. A phase transition into an uncontrolled state will thus take place.

Clearly, ideas of this type can give rise to many different specific situations in which the coherent vibration in conjunction with the available nutrient controls cell division. A more specific model [18] would, e.g., assume that the DNA protein complex of the cell nucleus of a differentiated cell is responsible for the vibration. Prior to cell division, this complex must unfold and would then loose the correct frequency which, as shown above, would require an appropriate supply of energy which may only rarely be available. Cancer would arise when, from external reasons, the frequency of a sufficient number of cells is changed. This might be caused through the invasion of the nucleus by foreign molecules. It might also arise through the transfer of a sufficient number of electrons to the conduction band of proteins, e.g., by sufficiently short-wave ultraviolet light. For the arising plasma oscillation would interact with our mode and alter its frequency [1].

VI. Proposed Experiments

The most important task should be experimental establishment of the conjectured vibrations in active (growing) tissues. Naturally, one would use the methods that have been successful in the cases of bacteria and other microorganisms, i.e., Raman effect and use of coherent millimeter waves to influence properties. In normal growth, one would expect sharp lines with some of the frequencies depending on the nature of differentiation. In cancer growth, some of these lines would either be absent or broadened.

If monolayers of cells are used, then the strength of the collective mode will not necessarily be the same as in bulk because of the contributions of other layers. The observed contact inhibition in normal tissue, i.e., the absence of growth in three dimensions, should then be understood in terms of the control by the collective mode which is absent in cancer tissues which do not exhibit contact inhibition. Another factor in such investigations must also be the amount of nutrient available. A certain amount of nutrient will be required to establish our mode and, hence, the energy barrier which a normal cell will have to overcome in cell division. The energy available to overcome this barrier might, however, also depend on the amount of available nutrient so that a fairly complex situation could be expected.

Spectroscopy with coherent millimeter waves might also be successful although it must be realized that individual cells will most likely oscillate with phase shifts such that the whole system will only be very weakly optically active. This also implies that the excited coherent vibration will emit only minute amounts of EM radiation.

In conclusion, it is hoped that coherent electric vibrations in the 5×10^{10}–3×10^{12} Hz region whose existence has been established in microorganisms also exist in growing tissues and play an important role in the control of growth. If the low frequency side, i.e., the range of millimeter waves is relevant, and if this relevance shows resonant effects similar to those discussed in Section III, then one should expect important nonthermal effects of millimeter waves of correct frequencies on cancer tissues.

Note Added in Proof

Recently S. J. Webb, R. Lee, and M. E. Stoneham (*J. Quantum Chem: Quantum Biology*, vol. 4, pp. 277–284, 1977) have demonstrated the existence of several (Stokes-) Raman lines in the region of 50–200 cm^{-1}. These were found to be broadened and split in the case of mammary carcinoma. If confirmed, and if strong anti-stokes lines also exist, then this finding is in accordance with the suggestion (1) that cancer cells contain unattached electrons such that their plasma frequency is close to the frequency of the coherent vibrations discussed in the present paper; interaction between the two vibrations will then lead to a splitting of lines.

Coherent Excitation in Active Biological Systems

H. Fröhlich

ABSTRACT: The principal types of coherent excitations: metastable state with high electric dipole moment, and coherent high-frequency electric vibrations are derived from simple models. Far-reaching consequences for biological systems are discussed. The conjecture is supported by a great variety of experiments.

1. General

From the point of view of atomic and molecular physics (and chemistry), biological materials are extremely complex and complicated systems. Yet they function in a most systematic way. Molecular biology succeeded in establishing the structure of the relevant giant molecules. Thus, e.g., it was found that enzymes possess an active site where the relevant processes can take place according to the laws of chemistry. Yet, this fails to explain their enormous catalytic power. Clearly, function must be treated in terms of dynamic, rather than static, properties. As a next step one may be tempted to introduce the known interaction between the atoms and ions of the system and, based on the known structure, calculate their dynamical properties. Such a procedure would be relevant in the range of linear displacements from a rigid structure like a solid. Enzymes, however, do not form such a rigid structure. Attempts to carry out the appropriate calculation have been discussed recently.[1] Even for small enzymes they

F. Gutmann et al. (eds.), *Modern Bioelectrochemistry*
© Plenum Press, New York 1986

require quite considerable computer time. Such endeavors, thus, while useful as a demonstration of the importance of dynamic properties, will not result in a general theory of the relevant processes, if such a theory exists.

One might then try an approach that emphasizes the common features of various systems—enzymes in the above example—and treat them in a general way thus creating a framework into which the individual cases will fit. To take an example from pure physics, consider the dynamic properties of fluids. Here we do not proceed by first considering the structure of a particular fluid, a most formidable task, and then, based on this knowledge, investigate the dynamic properties. If this were possible then we would obtain the motion of individual atoms or molecules which constitute the fluid, a result which is not very interesting. What is interesting is the space-time dependence of the mean density, $\rho(x, t)$ and of the mean current density, $j(x, t)$. Both are connected by a set of differential equations, the Navier–Stokes equations, from which their space-time dependence can be derived in terms of certain parameters like compressibility, frictional constants, which define the particular fluid. These Navier–Stokes equations can be derived exactly from the basic multiparticle equation, the Schrödinger equation,[2] not by solving it in terms of the multiparticle coordinates, but rather by first expressing ρ and j in terms of individual particle properties, and then finding the differential equations satisfied by them, which essentially arise as symmetry properties of the multiparticle system.

The success of this procedure rests in the definition of the two multiparticle quantities ρ and j, which describe the essential properties of hydrodynamic flow. Derivation of the actual values of the various parameters entering the equations of flow would require, of course, deeper investigation of the basic multiparticle equation. Could we not apply a corresponding method in the treatment of the dynamic properties of biological systems? The answer is no, not for the time being, for we do not yet know the quantities that would take a role corresponding to ρ and j in the previous case, though later in this chapter we shall make proposals in this respect and discuss their experimental verification. The difficulty arises from the enormous number of states of which excited multiparticle systems, like the biological ones, are capable and which make a systematic investigation and inspection impossible. Thus the lowest energy state of a system of N particles, the ground state, usually—though not always—is a crystal. Small displacements of the particles from their equilibrium positions can be treated in a systematic way as linear excitations. In biological systems, however, we are very far from these states, in the realm of nonlinear excitation. The number of states then rises exponentially with the number N of particles—in some particular case say as 10^N. Quite clearly it is impossible, even with a supercomputer, to evaluate and

investigate all these states. Hence we must find a way of deciding on "interesting" properties, usually connected with some kind of order. This order need not, however, be of a spatial nature. In a machine, for instance, this order consists in its way of functioning. Normally we treat this with the laws of macrophysics, which, in turn, follow from the laws of microphysics.

Early microbiologists were tempted to consider spatial order as the only order existing in physics. Thus, after no spatial order had been found in the arrangement of amino acids in an enzyme, Monod[3] says that knowing the arrangement of 199 amino acids would not permit us to predict the 200th. He concludes that the arrangements are random. Actually, however, the whole chain must function as an enzyme; replacing the "correct" 200th amino acid by a "wrong one" disturbs this function.

In looking to physics for guidance to find a concept capable of describing biological "order" we are led to the concept of coherence, which applies to cases as different as superconductors, superfluids, lasers, and masers. Roughly speaking it implies that if a certain property is known at a space-time region near (x, t) it is also determined at another, (x', t'). Thus in a coherent wave, for instance, amplitude and phase at (x, t) determine their values at another, (x', t'). Considering now biological systems, periodic processes are very common among them with periods ranging from that of life cycles to very high-frequency electric vibrations. In contrast to most physical periodic processes, periods of biological processes often vary from case to case. Thus the periods of the life cycles of cells grown under exactly the same conditions vary within certain limits, i.e., each cell exhibits a certain amount of personality. Also, if an apparent cause for a certain biological process is removed, another takes over because biological processes are frequently multicausal.

We shall presently describe the derivation of certain coherent excitations on the basis of definite physical models. Such developments show that random energy supplied to a certain system need not lead to heating but may result in the excitation of ordered (coherent) states. This need not imply that other models could not lead to similar excitations, i.e., that a multicausal situation exists—in other words that experimental verification of the excitation need not necessarily be considered as proof of a particular model. Clearly a situation then arises which requires close collaboration between theory and experiment. Thus, e.g., theory has predicted certain coherent excitations and experiment verifies their existance. This presents a development from the point of view of physics. From the point of view of biology, however, we may ask a question that is prohibited in physics: what is the purpose of these excitations? Evidence will be presented later in this chapter for the first (physical) stage, but the second, biological question has hardly been touched yet. Its solution will, of course, lead back again to physics, i.e., a certain process has certain consequences.

If these consequences are vital biologically then multicausal possibilities must be considered again, i.e., what other processes could have the same consequences.

2. Coherent Excitations

In looking for a physical characteristic common to most biological systems, one is at once led to their dielectric properties.[4] Most startling among these is the high electric field of about 10^5 V/cm present in biological membranes. This field acts in the range of nonlinear response. Materials inside membranes are, therefore, strongly, nonlinearly polarized. Furthermore, the many ions contained in biomolecules make an essential contribution to their stabilization through their interaction[5] as well as through their interaction with the surrounding medium, e.g., water.[6] On the other end biological systems are capable of reacting to extremely weak external impulses as reported in Section II of Ref. 7. Hence, by appropriate arrangements and excitations, biological systems may form most sensitive instruments that in normal technology would be devised in completely different ways with very different materials.

As a first case of coherent excitation, a metastable state with very high electric polarization (ferroelectric state) will be shown to exist in materials with high polarizability, combined with elastic softness, as discussed in Section III B of Ref. 7, and Ref. 8. Such excitation is coherent as the polarization at a point x determines the value at another, x'. The metastability of this excitation arises from the shape dependence of the electrostatic energy of a material. Thus, e.g., the ratio of the energies of a slab and that of a sphere both having equal volume and polarization is $3\varepsilon/(\varepsilon+2)$, where ε is the dielectric constant (cf. p. 168 of Ref. 9). To the electrostatic energy must be added the elastic energy arising from a deformation of the material.

Thus consider a sphere with polarization P and electrostatic energy $\frac{1}{2}\gamma P^2$. If deformed into an ellipsoid with excentricity η, this energy is changed by terms proportional to η, and higher powers, as the electrostatic energy does not have an *extremum* for the sphere, $\eta = 0$. The elastic energy arising from the displacement will, however, have no linear term in η but be proportional to η^2, as elastically the sphere is the equilibrium state. The total energy U, therefore, for small η will have the form

$$U = \tfrac{1}{2}\gamma P^2(1 + c_1\eta + \tfrac{1}{2}c_2\eta^2) + \tfrac{1}{4}C\eta^2 \tag{1}$$

where $C > 0$ and $\gamma > 0$, and the C_2 term has been inserted as it might influence the C term. Minimizing with regard to η yields

$$\eta = -c_1\gamma P^2/(C + c_2\gamma P^2) \tag{2}$$

and hence

$$U = \tfrac{1}{2}\gamma P^2 - (c_1 \tfrac{1}{2}\gamma P^2)^2/(C + c_2 \gamma P^2) \tag{3}$$

Thus U rises more slowly than it would without the deformation ($\eta = 0$), and it reaches a maximum beyond which it decreases with increasing P^2, provided $c_2 > 0$, and $2c_2 < c_1^2$. For still larger P^2, higher-order P^2 terms will be relevant, so that U goes through a minimum. Should that be at negative U, then this represents the ground state and the material is ferroelectric. Otherwise this minimum represents a metastable state with very high polarization, a quasi-ferro-electric state.

On a more formal basis we may consider a homogeneous polarization field P, energy density $\frac{1}{2}\omega^2 P^2$, interaction with an elastic field with potential energy density $\frac{1}{2}s^2\rho^2$ for longitudinal elastic displacements yielding a density ρ. Their interaction must be proportional to ρP^2, to provide the effect discussed above.

The total potential energy has then the form

$$W = \tfrac{1}{2}\omega^2 P^2 + (\tfrac{1}{2}s^2\rho^2 + cP^2\rho)(1 - d^2P^2) \tag{4}$$

where c and d are constants and the d^2P^2 term has been included to take care of nonlinearity required to stabilize the material. Minimizing with regard to ρ yields

$$\rho = -\frac{c}{s^2} P^2 \tag{5}$$

and hence

$$W = \frac{1}{2}\omega^2 P^2 - \frac{1}{2}\frac{c^2}{s^2} P^4 + \frac{1}{2}\frac{c^2 d^2}{s^2} P^6 \tag{6}$$

Thus this potential energy increases proportional to P^2 for small P^2, and proportional to P^6 for large P^2. In between it has a maximum, followed by a minimum provided a parameter λ satisfies

$$\lambda = 3s^2 d^2 \omega^2 / c^2 < 1 \tag{6a}$$

and this minimum represents a metastable state when $\frac{3}{4} < \lambda < 1$, while for $\lambda < \frac{3}{4}$ this highly polar state is the ground state. This confirms our previous results, and (6a), moreover, indicates the conditions the material must satisfy. They are, in particular, elastic softness (small s) and high polarizability (small ω) in conjunction with large coupling between the fields (large c^2).

Existence of highly polar metastable states should thus be a general property of biological materials. One would expect this to hold in less sim-

plified models, introducing particular structures together with anisotropy. One would expect then to find more than one metastable state. A small generalization of the above is possible, in fact, if the various parameters s, ω, c slowly depend on space coordinates, provided derivatives of P and s need not be introduced into the expression for the potential energy.

Most generally, of course, small excitations in materials with definite molecular structure are described through frequency–wave number bands, which can be classified as polar or nonpolar. Introduction of nonlinear features, as required here, must then be investigated for various particular cases, though our above treatment should always be correct as a limiting case. From the structural point of view, metastable excited states would then be classified as arising from conformational changes.

A candidate frequently mentioned in this respect is the displacement of H^+ in an H bond (e.g., Refs. 10–12 and related papers), for which also evidence from an analysis of dielectric properties in the millimeter region is available.[13,14] Displacement of various H^+ ions does, of course, yield electric polarization, though this need not be homogeneous. It is important, however, to realize that this polarization necessarily is connected with electric polarization of the rest of these molecules, which in turn leads to elastic displacements in it, as follows from our general model. Within this frame, polarization of the H bond represents a subsystem which enhances the stability of the metastable state. Detailed calculations have not been carried out yet. P= polarization state

So far we have considered the potential energy W of our system only, and found it to have a minimum at $P=0$ and at $P=\pm P_0$ if P_0^2 is the value of P^2 at which the metastable state occurs. The system can of course oscillate harmonically if the displacement from $P=0$ or $P=\pm P_0$ is small. More generally, however, the system will carry out anharmonic oscillations. In fact it is shown in Ref. 8 that to a good approximation P satisfies the equation of motion

$$\ddot{P}+\frac{\partial V(P)}{\partial P}=0 \tag{7}$$

where

$$V=A+\tfrac{1}{2}BP^2+CP^4 \tag{8}$$

i.e., as long as P^4 can be neglected, the oscillations are harmonic. Yet even then the system possesses highly nonlinear properties as A, B, C are not constant but depend on the time average p of P^2,

$$p=\overline{P^2} \tag{9}$$

by

$$A = \frac{1}{2}\frac{c^2}{s^2}p, \qquad B = \omega^2 - 2\frac{c^2}{s^2}p - \frac{d^2c^2}{s^2}p^2, \qquad C = \frac{c^2d^2}{s^2}p \tag{10}$$

Thus each amplitude of P defines its own potential V. Clearly for small amplitudes when p can be neglected in B, and the P^4 terms are also negligible, the frequency is ω. For growing amplitude, but when P^4 is still negligible, the frequency of oscillations is softened, i.e., B becomes smaller until finally it changes sign; V then has a maximum at $P=0$ and a minimum further outside.

Near the metastable state, P may, of course carry out small, harmonic oscillations again, but with a frequency different from ω.

The coherent excitation considered so far is essentially static; its establishment requires a supply of energy larger than the energy of the metastable state above the round state $P=0$. A dynamic, very different type of coherent excitation may exist whose maintenance requires a continuous supply of energy at a rate larger than a critical s_0. The model is again based on polar oscillations of a large biological system, forming a band of modes with frequencies ω_1, ω_2,..., ω_z. Metabolic energy is considered to be supplied at a rate s_j to mode ω_j. This systems of polar modes is considered to interact with a heat bath which is kept at a constant temperature T. In cells, this will largely consist of cell water with its ions. Linear interaction will then impose a Planck distribution for the excitation of the polar modes. This interaction is described in terms of emission and absorption of single quanta $h\omega_j$ between the modes and the heat bath. When nonlinear interactions are taken into account, however, then energy exchange in terms of two quanta will occur. Most important among these are simultaneous emissions and absorption of quanta $h\omega_j$ and $h\omega_l$. If n_j represents the number of quanta by which mode ω_j is excited, then the following equation arises for the rate of change, n_j (cf. Section III C of Ref. 7):

$$\begin{aligned}\dot{n}_j = s_j - \phi_j(n_j e^{\beta\omega_j} - (1+n_j)) \\ - \sum_l \chi_{jl}[n_j(1+n_j)\, e^{\beta\omega_j} - n_l(1+nj)\, e^{\beta\omega_l}]\end{aligned} \tag{11}$$

where $\beta = h/kT$, and the ϕ and χ are transition probabilities. The ratio of absorption and emission terms, proportional to n and $1+n$, respectively, follows from the principle of detailed balance. Note that after further summation over j, the χ terms vanish so that in the stationary case when $\dot{n}_j$ vanishes, the total number $\sum n_j$ of quanta that arises from the total rate of supply $\sum s_j$ is determined by the first-order terms only through the ϕ. The

actual distribution will, however, be largerly determined by the χ terms, provided that they are relatively large. In the stationary case then they must vanish so that

$$n_j = \frac{1}{\exp[\beta(\omega_j - \mu)] - 1} \tag{12}$$

follows where μ must be determined from the already known total number of quanta $\sum n_j$. When this number exceeds a critical one, i.e., when $\sum s_j$ exceeds s_0, then μ must approach the lowest ω_1, yielding a large n_1, as in Bose condensation. This frequency is then very strongly, i.e., coherently, excited. Detailed considerations[7] show that in certain circumstances other frequencies might be strongly excited.

To understand the possibility of this type of coherent excitation, the strong interaction with the heat bath must be emphasized. It endeavors to impose its temperature on the distribution which is demonstrated by the form (12), which represents a Bose distribution at temperature T. But while in a Bose gas the number of particles is fixed so that the Einstein condensation arises only when the temperature is sufficiently lowered, in our case the temperature is fixed, but the number of particles (quanta) increases with increasing rate of energy supply.

It must also be emphasized that this type of coherent excitation arises from the strong nonlinear coupling with the heat bath (χ terms). Other terms could be introduced, in principle, which would counteract this effect. Thus a very strong nonlinear interaction among the quanta of the polar modes, without the use of the heat bath, would simply tend to increase the temperature. We thus have found a particular example of the two different ways energy supply to a system may act, resulting in either an increase in temperature, or in the creation of a new order, that may be dynamic. Our considerations have emphasized the second possibility. Experiment must decide whether biological systems make use of it.

Finally, in this section, possible frequencies for the excitation of coherent vibrations should be considered. Originally special reference was made to membrane oscillations as their high polarization will then yield coherent electric oscillations (cf. Ref. 7, with earlier literature). Since the thickness of a membrane is about 10^{-6} cm and its elastic constant is equivalent to a velocity of sound of about 10^5 cm/s, a frequency of the order of 10^{11} Hz was expected, corresponding to electromagnetic waves in the millimeter region. When based on proteins or DNA, however, both higher and lower frequencies may be expected.

It must be emphasized at this point that most of the polar modes of a system interact only weakly with electromagnetic waves of the same frequency, as usually the wave lengths do not match. Thus, e.g., excitation of

sections of the outer membranes of a cell may result in a very high multipole electric oscillation, and hence in small interactions with electromagnetic waves of the same frequency.

3. *Consequences*

The two coherent excitations, metastable highly polar states, and coherent electric vibrations, may have far-reaching consequences arising from the forces exerted by the respective fields which are absent in the nonexcited states. The electric field in the metastable state is static; it thus acts inside and near the excited system, while at larger distances it is screened by the ions in the surrounding medium. For molecules, e.g., proteins, surrounded by cell water, the screening distance naturally is much shorter than for proteins dissolved in membranes. In the case of excitation of coherent vibrations, on the other hand, screening is negligible once the frequency exceeds a critical one.

Forces arising from the excitation of the metastable state may then be employed to reduce activation energies in enzyme processes.[15,4] The system enzyme + substrate will change with the motion of ions in it and, hopefully, the direction and magnitude of the internal field will change as required by the process. The whole system, enzyme + substrate, while active, possesses a high electric dipole moment which, in principle, could be measured by standard dielectric methods. Such measurements have not been attempted yet; they face difficulties arising from the presence of unattached ions in the medium in which the enzyme reaction occurs.

For a protein dissolved in a membrane the possibility arises that it may act as a switch element. For if μ is the dipole moment in the metastable state, and F is the electric field in the membrane, then if the directions of μ and F are appropriate the interaction lowers the energy by $(\mu - \mu_0)F$, where μ_0 is the dipole moment in the ground state. If this energy equals the energy of excitation of the metastable state, then the system is degenerate with two equal energy states. They then can be switched by the addition of relatively weak fields.

It should also be noticed that in proteins, aligned in a membrane, the excitation energy may be transferred from a particular excited protein to its neighbor, thus providing transport of energy that is nearly loss free.

Solitons, furthermore, represent a particular case of excitation to a metastable state.[16,17] In the Davydov soliton, in particular, stretching of the C = 0 bond forms the polar excitation, stabilized by the surroundings which play the part of the elastic field. This soliton, too, provides a loss-free transport of energy.

Excitation of a metastable state requires a certain minimum amount of energy. Excitation of the coherent polar mode, on the other hand, requires supply of a minimum rate of energy, s_0; its maintenance thus requires biological pumping. Its excitation results in a long-range, frequency-selective interaction that may lead to attraction between two, or many molecules, provided they oscillate with equal frequency. In particular cases this may also result in selective repulsion. In the case of the enzyme–substrate system, in the first stage the (frequency) correct substrate is attracted to the enzyme (long-range selectivity); in the second stage the usual short-range chemical processes take place—an example of a multicausal process.

As indicated in connection with Eq. (11), the energy supply s_j may occur at any, or all, frequencies of the polar modes. The subsequent excitation of a particular mode, e.g., ω_1, then requires some time even when the total rate of supply exceeds s_0. The system thus possesses storing ability. One would expect, however, that this time is particularly short if the energy is supplied at the frequency of the mode that will be excited coherently. Furthermore, arising from the considerations of mode softening, this mode, when excited, may be detached from the band and hence provide a very frequency-sensitive target for further energy supply. Detailed calculations on this question have not been carried out yet.

Consider now biological processes that make use of coherent excitation of a particular polar mode, requiring pumping at a rate $\sum s_j > s_0$. Let (cf. Section IV C of Ref. 7) t_1 be the time required for this process; then, we expect it to be the faster the larger $\sum s_j$; but it will never occur ($t_1 = \infty$) as long as $\sum s_j < s_0$. Thus if a and n are positive numbers we may assume

$$t_1 = a \Big/ \left(\sum s_j - s_0 \right)^n, \qquad \sum s_j \geqslant s \tag{13}$$

If we now consider a complex biological process consisting of many steps, only one of which depends on the excitation, i.e., on s_j, then if t_2 is the time required for all these s_j-independent processes, the total time for the process is

$$t = t_1 + t_2 \tag{14}$$

i.e., the total rate is

$$\frac{1}{t} = \frac{(\sum s_j - s_0)^n}{\alpha + t_2 (\sum s_j - s_0)^n}, \qquad \sum s_j > s_0 \tag{15}$$

It thus depends in a steplike manner on the rate of supply $\sum s_j$.

We must assume now that the biological system is controlled in such a manner that the rate of energy supply is switched on at a period that integrates the particular process considered here with the whole biological development. External supply of energy, e.g., by microwaves at a rate say s_e, will then influence the rate $1/t$ and hence interfere with the general development. The effect of even a small outside s_e can be very big at a stage when the biological $\sum s_j$ is close to s_0, because replacing $\sum s_j$ by $\sum s_j + s_e$ in Eq. (15) is equivalent to replacing s_0 by $s_0 - s_e$, i.e., it shifts the steplike curve Eq. (15). At particular times in the biological development, small s_e hence may cause large effects, in particular when s_e is supplied at the "correct" frequency, which involves little time for the reaching of the required quasistationary distribution of the excitation of modes.

In considering now candidates that may act as carriers for the electric vibrations arising in the coherent excitation of a particular mode, recent results on the structure of cells must be presented. It has been found[18] that an intricate network of protein structures known as the cytoskeleton exists, among which the so-called microtrabecular lattice extends from the cell surface throughout the cytoplasm. It has also been proposed[18] that enzymes do not float in the cytoplasm but are attached to this lattice, which may act as carrier of the coherent electric vibrations that provide frequency-selective interaction between appropriately excited molecules. Supporting this conjecture is the conclusion that "microtubules $\cdots$ form a vectorial framework upon which some other force generating component is organized."[19] This also is supported by theoretical investigations on self-focusing.[20] To avoid misunderstandings it should be repeated again that while the relevant frequencies might be in the range of electromagnetic millimeter waves, interaction with such radiation will be weak as the wavelengths will not be in the millimeter region, but probably will be less than the cross section of the tubules, possibly of the order of molecular distances.

It will now be shown that combination of our two coherent excitations may result in low-frequency periodic enzyme reactions giving rise to corresponding electric vibrations—another coherent electric vibration (Ref. 21 and Section IV E of Ref. 7). Consider an enzyme process consisting of the interaction of a substrate and an excited enzyme and assume the energy thus made available to excite a nonexcited enzyme. Then if N, Z, S are the respective numbers of excited enzymes, nonexcited enzymes, and substrates, the rate of change of N is proportional to NZS with a rate constant α. Also if there exists a spontaneous decay of excitation of an enzyme, rate constant β, then

$$\frac{dN}{dt} = \alpha NZS - \beta N \tag{16}$$

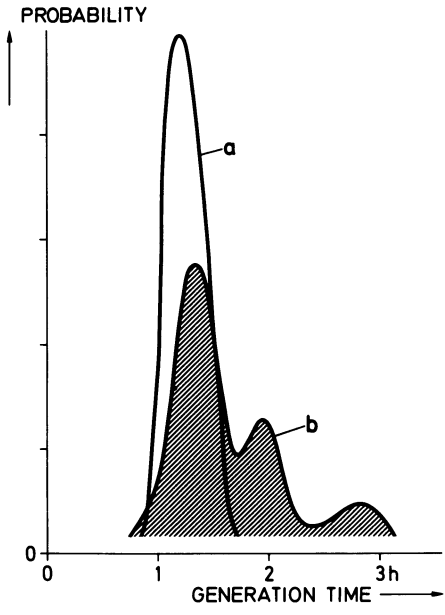

FIGURE 1. Probability of time of cell cycle when irradiated (a) with 83800 MHz or without irradiation, (b) with 83835 MHz (W. Grundler, personal communication).

and the number of substrates decreases at the rate αNZS. Consider now that during this process substrates are coherently excited to a frequency that attracts other substrates to the region (rate constant γ); then

$$\frac{dS}{dt} = -\alpha NZS + \gamma S \tag{17}$$

Consider the case that Z is so large that it can be treated as time independent; then time-independent solutions N_0, S_0 exist,

$$N_0 = \gamma/\alpha Z, \qquad S_0 = \beta/\alpha Z \tag{18}$$

Hence if

$$N = N_0 + v, \qquad S = S_0 + \sigma \tag{19}$$

then

$$\dot{v} = \gamma\sigma + \alpha Z\sigma v, \qquad \dot{\sigma} = -\beta v - \alpha Z\sigma v \tag{20}$$

These are the well-known Lotka–Volterra equations that have periodic solutions. In the limit that σ and v are small so that the σv term can be neglected, $(\beta\gamma)^{1/2}$ represents the frequency of oscillation, which thus is determined by the rate γ of spontaneous decay of enzyme excitation, and

by the rate β of attraction of substrate molecules. According to our first type of coherent excitation, the excited enzyme carries a large electric dipole moment, which thus also will oscillate with the frequency $(\beta\gamma)^{1/2}$. Outside electric observation will normally integrate the contribution of all enzymes and thus will also depend on their spatial disposition.

This scheme was originally derived for brain waves, and extended by taking into account a possible short-range interaction between excited enzymes, which then tends to organize them into a ferroelectric system. This results in an extension of Eqs. (19) and (20) into a complicated set of equations whose solutions are limit cycles; this means that the system will then tend to oscillate with a fixed amplitude.

This case has been investigated in detail[22] and it has been shown that a weak, appropriate, external perturbation may cause the collapse of the limit cycle and hence lead to the liberation of the considerable energy stored in it. This was intended as a model to demonstrate how weak electric perturbations can cause large effects in the brain (e.g., a nerve impulse).

The considerations given here are of a very general nature, and modifications of the theory can easily be performed without altering the principal result of coherent excitations. One will expect the excitation of a polar mode to be relevant whenever long-range coordination is required, as in cell division, tissue growth, and the cancer problem; cf. Section IV D of Ref. 7 and Ref. 23.

The theoretical derivation of the existence of a coherently excited polar mode following from (11) can also be phrased in a field theoretical model, or in a more exact way be supported by numerical work as quoted in Ref. 7, as well as by more recent work—the present chapter is not meant to provide a complete review. It is of importance, however, that other models involving nonlinear coupling of oscillations can lead to coherent excitation of a single mode.[24,25]

It has also been suggested that the assembly of biological oscillators may be modeled as parameter tunnel diode memory system with couplings. The frequencies of such a system can include values very much lower than the "design" frequency, which thus supports our prediction of mode softening.[26]

4. *Experiments*

A great variety of experiments support the conjecture of coherent excitations in biological systems. The complexity of biological materials might permit different interpretations in a number of these experiments. The possibility of understanding them from a common point of view gives strength, however, to our interpretation. In fact the conclusions of a recent

meeting[27] were "that coherent excitation had now been shown to be an intimate feature of biological activity; further progress would rely on detailed studies...." The proceedings of this meeting were published in the "Green Book."[28]

A number of these experiments require subtle preparation of the biological material, which is not always described in detail and hence may lead to failure of reproducibility. As a first example consider the Raman spectrum of life algae. If certain frequencies are nonthermally excited, as required in coherent excitation, then the ratio of anti-Stokes to Stokes lines should be larger than in thermal equilibrium. This was actually found.[29] A repetition of the experiment showed no such effect.[30] The authors forgot, however, to supply CO_2, which is required to maintain the biological activity, giving rise to the excitation.

A great number of investigations on the Raman effect in active bacteria have been carried out.[31] To be active, considerable dilation must be maintained, and it has been estimated that an enhancement of excitation by a factor of 10^5 is required to obtain sufficient intensity to be noticiable.[32] Such enhancement cannot be expected for a single cell. A number of cells must, therefore, be assumed to oscillate coherently because the scattering intensity then is proportional to the square of the number of scattering units. While thus, seeing the lines at all already provides an indication for coherent excitation, measurement of the ratio R anti-Stokes: Stokes intensity, carried out in one case, gives a more direct proof. Thus at about 120 cm^{-7}, in *E. coli* B bacteria, $R \simeq 1$ was measured while in thermal equilibrium $R \simeq 0.55$. Note that $R = 1$ is the largest possible value.[33] To maintain the required synchronization is a task that so far has not been properly documented. Adverse influences may arise from the laser beam, or from turbulance that may develop in a flow instrumentation, used to avoid destructive action of the laser beam on bacteria.

To avoid some of these difficulties a special method of synchronization has been used, whereby appropriate nutrients are provided, suddenly, after a period of starvation.[34] It was found that a nutrient line at 980 cm^{-1} is highly excited, the enhancement above thermal being by a factor between 8 and 15; and it showed a slow periodicity of about 10 min. For a tentative interpretation we assume that nutrient molecules in or near an active cell (the measurements integrate excited and nonexcited molecules) are very highly excited and attract outside nutrient molecules to the cell, or to a particular region in it. This would then correspond to the term γS in Eq. (17). The periodicity, then, might follow in a similar way. By further investigation of the activity of this system, it should be possible to separate the diffusion part of the molecules from the region in which they are subjected to forces, and hence, possibly, determine the relevant biochemical process.

While this separation of movement due to forces, from diffusion, remains to be carried out, a very thorough separation of this type has been performed in connection with the formation of so-called rouleaux of red blood cells, i.e., stacks of cells that form in their plasma.[35,36] It had been observed that when such cells approach to a certain distance they seem to rush towards each other. Analysis with the help of the Smoluchowski theory of diffusion revealed, quantitatively, the existence of a long-range attractive force. Its properties were found to agree with the requirements of the theory of long-range interaction arising from coherent excitation of electric vibrations in the membrane. Thus on removal of the membrane potential, the interaction disappears, but is restored when the potential is restored. Similarly it is found that the interaction disappears when the metabolism, required to maintain the excitation [terms s_j in Eq. (11)] is inhibited. Furthermore the interaction is specific in that a mixture of red blood cells from different animals segregate into rouleaux of equal origin.

It was also found that the interaction is carried by long molecules which, inside cells, corresponds to the role attributed[18,20] to the microtrabecular lattice as discussed in Section 3. Furthermore it has been shown[37] that albumin, a globular protein, does not transmit the interaction at physiological concentrations. Albumin can, however, be converted into a transmitter by a treatment that unravels the tertiary structure and allows it to polymerize.

The frequencies for the excitation discussed here have not been measured directly, but the involvement of the membranes suggests a region near 10^{11} Hz, though both lower frequencies (mode softening) and higher frequencies (proteins dissolved in the membrane) may be contemplated. In addition, much lower frequencies arise from periodic enzyme reactions, discussed in Eqs. (16)–(20). Among other experiments that support the existence of coherent excitation[38] are the attraction of particles of a dielectric powder to active cells,[39] by the method of "microdielectrophoresis." Investigations have been carried out on a great variety of living cells. They show that an oscillating electric field with minimum frequency of about 10 kHz exists near the surfaces of living but not of dead cells. This can be suppressed by metabolic inhibitors and is maximal (order 100 V/cm) near mitosis (in yeast).

Since the dielectric particles used in these experiments are much smaller than the cells to which they are attracted, they do not give much information about the relative phase on various sections of the cell surface. Thus a dipolar oscillation would interact strongly with electromagnetic waves of the same frequency, and the field will then decrease slowly with the distance from the cell, in contrast to the case of a high multipole whose electric field will be significant near the cell surface only. Nevertheless, within this region it will give rise to a secondary magnetic field, which

might result in the attraction of small magnetic particles, as has been observed recently.[40] While thus observation of emission of electromagnetic radiation would present a useful identification, lack of such observation does not imply absence of electric vibrations; for this might require measurement instruments to be placed very close to the cell surface.

An enormous literature has accumulated on the action of microwaves on biological systems, much of it, however, at single frequencies or single intensities only, which makes it difficult to analyze the results. An exception is formed by investigation of the action of coherent millimeter waves on biological systems. These wavelengths are strongly absorbed by cell water, and great care has been taken, therefore, to eliminate thermal effects by using low intensities. In this case direct action of the electromagnetic field is excluded as this would require intensities many millions of times stronger than those used in the relevant experiments.[41] Early experiments are discussed in Section V B of Ref. 7. Their results are best summarized as follows[42]: "(a) the effect of irradiation depends strongly on the frequency of the microwaves; (b) in certain microwave-power ranges, the effect of exposure depends weakly on variation of the power through several orders of magnitude; (c) the effects are observed to depend significantly on the time of irradiation."

These results seem to confirm all theoretical predictions first made in 1968[43]: As shown in previous sections, the excitation of coherent membrane oscillations should be in the 10^{11} Hz region at very sharp frequencies; the response should be steplike as a function of the supplied energy [cf. Eq. (15)], and the system has storing capability. However, the supplied energy, in the theory, is largely of metabolic nature—this has to be so as the energy supplied externally alone would be much too small to cause big effects. It has been pointed out, however, in the discussion following Eq. (15) that at an appropriate instant of the development of the biological system, a small external energy supply s_e may shift the position of the step in the response function, i.e., it will act strongly at a very sensitive stage of development. This may be compared to a phase transition in the development of the whole biological system; the externally supplied energy then changes its timing of this process relative to other processes, and the consequences for the whole system may be specific in particular cases.

It seems obvious that such subtle interference might be influenced by the natural fluctuations present in highly excited systems, like biological ones. This is in particular so as it has been shown that noise may cause phase transitions in nonlinear systems.[44] It might be suggested, therefore, that details of the experimentation are relevant for the outcome of the investigation.

Consider now, in particular, the sharp resonances in the rate of growth of yeast under the influence of microwaves in the 42-GHz

region.[45,46] A great number of very sharp maxima and minima in the rate of growth versus frequency curve was found. The experiment emphasizes high-frequency stability and provides the use of two very different electrodes to supply the radiation to the yeast cultures that grow in liquid suspension. Cross correlation between the two geometries in the range between 41700 and 41800 MHz reveals a central line of about 10 MHz width with three side bands on each side, separated by about 18 MHz. The effects are relatively small, about $\pm 10\%$, but very well resolved and reproducible. Another feature, apart from the extremely sharp resonances, lies in the absence of a difference in magnitude between the two electrodes, although their surfaces differ by a factor of 10, and the radiation penetrates from the surface only a fraction of a millimeter. The suspension is constantly stirred, and it can be concluded that a single yeast cell is at most affected once during its life cycle, and then only in a particular state of development.

Clearly one would expect such extraordinary effects to arise from important, highly sensitive properties which will not reveal themselves in population effects, though these have the property of high reproducibility.

An investigation of the time of a life cycle of individual cells, and the influence of millimeter waves on it, was therefore undertaken. Frequencies in the 83-GHz region were used—for organizational reasons different from those of the source used in the experiments described above. The cell cycle time was not influenced by radiation of 83800 MHz, but very strongly so by the neighboring 83835 MHz, as shown in Figure 1. Remarkably, however, about half of the cells are not affected, whereas the others are affected very strongly. This leaves the question open whether cells show a "personality" by responding to one or another frequency, or whether a secondary effect, like a particular fluctuation at a critical time, is required to produce the effect, as suggested above.

Further experimentation should result in a more detailed knowledge of the particular cell processes involved. The sharpness of the resonances makes it quite clear, already at the present stage, that coherent excitations must be involved, and the fine structure of 18 MHz might arise from periodic enzyme reactions, Eq. (20).

While the above results are highly reproducible, it is not yet quite clear which particular items in the instrumentation, and the handling of the biological materials, are vital. Thus, at the same laboratory, a similar instrumentation has been produced which shows no effect. Up to the time of writing, the reason for this had not yet been discovered.

Other investigations in the field are published in Ref. 28. It should be expected that multicellular systems might show a larger effect. In fact[47] the growth of cress roots can be completely stopped within 100 seconds after irradiation with low-intensity 56-GHz microwaves, provided the

polarization is parallel to the root. From the theoretical discussion it can be concluded that the process, which owing to the effect of external energy supply is started at an inappropriate time, completely disrupts the growth. Further biological and physical investigations are required to find this process. Clearly it must, at its own time, make use of coherent excitation.

Other biological systems exist, however, whose dynamic properties are much better known than those of cress root. Among these, properties of the membranes systems of electron transport phosphorylation have been studied from the point of view of bioenergies.[48] This requires energy transport over relatively long distances, and other concepts that can all be supplied by various coherent excitations. Measurements to confirm this are now planned.

Finally, to return to the metastable highly polar state of individual molecules, it should be possible, in sufficiently strong external fields, to lift the molecules into this state. Transitions into a metastable state were actually discovered when strong fields were applied to so-called Langmuir–Blodget multilayers and the low-frequency dielectric response was then measured.[49] Haemoglobin and some other molecules were investigated. When the applied field reached about 10^5 V/cm, characteristic changes in the dielectric response were observed. They are maintained even when they are remeasured in low fields, i.e., the layers have been transferred into a metastable state. This state persists for up to six weeks. The gradual reversion to the initial characteristics can be accelerated by heating for short periods to about 40°C. It is to be expected that, owing to the presence of water and ions, the high polarization is screened. The fact, however, that the metastable state is reached through the application of very high fields indicates its basic high polarity.

Another support for the existence of a highly polar metastable state arises in the so-called electret method. Here the material is polarized in strong fields, and the polarization is frozen in by cooling to very low temperatures. Gradual increase in temperature then releases polarization at characteristic temperatures. In our metastable state, the release should begin at temperatures above physiological ones. Both investigated enzymes, trypsin and urease, show this effect,[50] though the polarizing field amounted to only 25000 V/cm.

In a very different kind of experiment it was found that laser irradiation increases the activity of chymotrypsin by a factor of up to 3.[51] This was investigated as arising from lifting the enzyme into the active, metastable state through the Raman effect. Detailed investigations of the dependence on the density of molecules and on laser power support this interpretation. For other possibilities see Ref. 52.

In summary it is seen that a variety of different experiments support the conjecture of two types of coherent excitation: a metastable state with

large electric polarization, and existance of coherent electric vibrations. It should be emphasized again that the theoretical models show that such excitations should be possible. They are not unique; other models might achieve similar results. In fact if, as we think, biological activity makes great use of these excitations, the manner of establishing them need not be unique.

Abstract

Following the conjecture of Fröhlich that the Bose condensation of phonons is the dominant biological effect, Wu and Austin derived from the Fröhlich Hamiltonian an expression for the relaxation time which is inversely proportional to the temperature by using the technique of Green's function. In this paper, we have generalized the Wu and Austin expression by improving their approximations with the superconducting canonical transformation and obtained the relaxation time depending exponentially on the inverse temperature. Moreover, we have checked our expression by using a different method based on the "continued fraction expansion" and also employed this technique to derive the dielectric constant for this system.

Introduction

Fröhlich [1–6] proposed that the phonon condensation may be possible in the biological systems because of their extraordinary dielectric properties. The dipoles of the biosystem generate longitudinal coupled oscillations to produce a narrow phonon energy band. Fröhlich [1–6] showed from the rate equation that such a phonon system will undergo Bose Condensation if it is coupled to a thermal bath system and an energy pump with a pumping rate exceeding a critical value. Wu and Austin [7] showed that this phenomenon of Bose condensation in the biosystem can be demonstrated from the fundamental quantum mechanical arguments. Furthermore, Wu and Austin [8] derived an expression for the relaxation time in terms of the phonon-bath coupling coefficient and estimated the numerical value for it.

In this paper we have derived an expression for the dielectric constant in terms of the same phonon-bath coupling coefficient. The calculations have been based on the "continued fraction expansion" technique developed by one of the authors (Paul [9]), and provided an estimate of this coefficient from the available experiment data.

Theory

Wu and Austin [7] assumed for the biosystem the following Hamiltonian of the

© 1983 John Wiley & Sons, Inc. CCC 0020-7608/83/020709-04$01.40

superconductors introduced by Fröhlich [10]:

$$H = \sum_i \hbar\omega_i a_i^\dagger a_i + \sum_k \hbar\Omega_k b_k^\dagger b_k + \sum_p \hbar\Omega_p P_p^\dagger P_p + \sum_{ijk} \hbar(\chi a_i^\dagger a_j b_k^\dagger + \chi^* a_j a_i^\dagger b_k) + \sum_{pi} (\xi P_p a_i^\dagger + \xi^* P_p^\dagger a_i), \quad (1)$$

where each of the normal modes of the oscillation of the biosystem is represented by the creation and the destruction operators $a_a^\dagger$ and a_i, respectively. Similar operators $(b_k^\dagger, b_k)$ and $(P_p^\dagger, P_p)$ are assigned for the rest of the biosystem which are the bath and the pump, respectively. The χ is the coupling coefficient which is responsible for the interaction between the phonons and the bath.

Rate of change of the number of quanta in the ith mode N_i is given by the Heisenberg equation

$$\frac{dN_i}{dt} = \frac{1}{i\hbar}[N_i, H]; \quad (2)$$

and the expectation value of Eq. (2) is

$$\left\langle \frac{dN_i}{dt} \right\rangle = \left\langle \psi(t) \middle| \frac{dN_i}{dt} \middle| \psi(t) \right\rangle. \quad (3)$$

Using the perturbation method and the commutation relationship of the boson operators, Wu and Austin [7] derived the rate equation given by

$$\left\langle \frac{dN_i}{dt} \right\rangle = S_i - \Phi(T,\omega_i)[\langle N_i \rangle e^{\beta\omega_i} - (1 + \langle N_i \rangle)] - \sum_j \Lambda(T,\omega_i,\omega_j)[\langle N_i \rangle (1 + \langle N_j \rangle) e^{\beta\omega_i} - \langle N_j \rangle (1 + \langle N_j \rangle) e^{\beta\omega_j}], \quad (4)$$

where we have $\beta = \hbar/kT$, S is the rate of supply of energy from external source to the ith mode, and Φ depends on the coupling coefficients other than χ.

For the stationary state, we have

$$\left\langle \frac{dN_i}{dt} \right\rangle = 0. \quad (5)$$

Using Eqs. (4) and (5) one may solve for the average occupation number of each phonon state and obtain an expression of the form

$$\langle N_i \rangle \approx (e^{\beta(\omega_i - \mu_i)} - 1)^{-1}, \quad (6)$$

where μ_i is defined as

$$e^{-\beta\mu_i} = (\Phi(T,\omega_i) + \sum_j \Lambda(T,\omega_i,\omega_j)(1 + \langle N_j \rangle)) \times (\Phi(T,\omega_i) + \sum_j \Lambda(T,\omega_i,\omega_j)\langle N_j \rangle e^{\beta\omega_j})^{-1} \quad (7)$$

and

$$\Lambda(T,\omega_i,\omega_j) = (2\pi/\hbar)|\chi|^2 e^{-\beta(\omega_i-\omega_j)} \tag{8}$$

So if we have $\chi = 0$, $\mu_i = 0$, no condensation can take place.

Bose condensation is possible, however, if and only if

$$\omega_i > \mu_i \geq 0. \tag{9}$$

From the rate equation it is obvious that the Bose condensation in the biosystem depends upon the coupling coefficient χ. Wu and Austin [11] have shown that this coupling coefficient dominates the other ones that appear in Eq. (1). Therefore, they employed Green's function technique [8] to derive an expression for the relaxation time τ_1 in terms of χ only

$$\tau_1 = \hbar^3\pi\nu'^3/|\chi|^2 kT\gamma\Delta, \tag{10}$$

where ν' is the speed of sound, k is the Boltzman constant, T is the absolute temperature, Δ is the width of the energy band, and γ is a positive quantity less than 1. From Eq. (10) we estimated a numerical value for $|\chi|$ as 4×10^{-2} by using $\tau_1 \approx 10^{-10}$ s, $\nu' \approx 300$ m/s and $\gamma\Delta \approx 10^6$ as given in Ref. 8.

Measurement of χ from the Dielectric Constant

Since oscillators involved are dipolar in nature it is easy to see that they should leave a remarkable effect upon the dielectric properties of the system. If a medium composed of dipolar entities is subjected to a rapidly changing electromagnetic field the dipoles will oscillate with the field but if they are coupled to a bath, then the response will be modified by this coupling. This modification will appear in the form of a phase lag which is related to the imaginary part of the dielectric constant $\epsilon''(\omega_0)$ and therefore $\epsilon''(\omega_0)$ is related to the parameter χ. The precise details of this calculation are based upon the continued fraction technique developed by Paul [9] involving a two-body Green's function. These details will be published elsewhere but for the present we are providing a simplified version of the final equation in order to estimate χ from experimental measurement of the dielectric constant.

The expression for the dielectric constant derived by us is given by

$$\epsilon''(\omega_0) = \frac{4\pi^3\hbar^2\rho|\mu|^2\omega_0(N_i - N_j)^2}{|\chi|^2 kT\Gamma(\omega_0)}, \tag{12}$$

where ρ is the density of the material, $|\mu|$ is the mean dipole moment, ω_0 is the resonant frequency, and $\Gamma(\omega_0)$ is the linewidth. Since the relaxation time is inversely proportional to $\Gamma(\omega_0)$ and in our derivations the latter contains exponentials of $(-h\omega_0/kT)$, thus the relaxation time will be proportional to the exponent of temperature's inverse.

Discussion and Results

Supekar and Bandopathyaya [12] provided some experimental data for cholesterol

at and around two resonant frequencies which are given below in the SI units

$$\rho = 7.5 \text{ kg/m}^2, \quad T = 300°\text{K},$$
$$\omega_{01} = 0.63 \text{ MHz}, \quad \Gamma(\omega_{01}) = 0.92 \text{ MHz},$$
$$\epsilon''(\omega_{01}) = 0.270 \text{ F/m},$$
$$\omega_{02} = 2.19 \text{ MHz}, \quad \Gamma(\omega_{02}) = 3.16 \text{ MHz},$$
$$\epsilon''(\omega_{02}) = 0.265 \text{ F/m}.$$

Using the above values, we obtained from our equation (12) $|\chi/\hbar| = 5 \times 10^{-3}$ (experimental accuracy is 2%) for both resonant frequencies. This shows that the coupling coefficient indeed does not depend on the frequency. This value of $|\chi/\hbar|$ agrees satisfactorily with the value found from formula (10) of Wu and Austin which is $|\chi/\hbar| \approx 4 \times 10^{-2}$.

Detailed measurement of the dielectric constant of the biosystem in microwave frequencies are in progress in our EPR laboratory.

Acknowledgments

This work was supported by research grants awarded by NSERC to two of the authors (R.C. and R.P.). The other author (J.A.T.) acknowledges the award of a graduate student research assistantship of the Physics Department, The University of Calgary.

"Neural network" models of brain function assume neurons and their synaptic connections to be the fundamental units of information processing, somewhat like switches within computers. However, neurons and synapses are extremely complex and resemble entire computers rather than switches. The interiors of the neurons (and other eucaryotic cells) are now known to contain highly ordered parallel networks of filamentous protein polymers collectively termed the cytoskeleton. Originally assumed to provide merely structural "bone-like" support, cytoskeletal structures such as microtubules are now recognized to organize cell interiors dynamically. The cytoskeleton is the internal communication network for the eucaryotic cell, both by means of simple transport and by means of coordinating extremely complicated events like cell division, growth and differentiation. The cytoskeleton may therefore be viewed as the cell's "nervous system". Consequently the neuronal cytoskeleton may be involved in molecular level information processing which subserves higher, collective neuronal functions ultimately relating to cognition. Numerous models of information processing within the cytoskeleton (in particular, microtubules) have been proposed. We have utilized cellular automata as a means to model and demonstrate the potential for information processing in cytoskeletal microtubules. In this paper, we extend previous work and simulate associative learning in a cytoskeletal network as well as assembly and disassembly of microtubules. We also discuss possible relevance and implications of cytoskeletal information processing to cognition.

1. Cognition: emergent computation in the brain

1.1. Connectionism

The use of connectionist models of functional brain organization has advanced understanding of cognition and linked neuroscience to computer science. "Neural networks", which approximate cortical neurons as parallel processors with variable lateral interconnections, may be simulated on computers and can provide a working model of some aspects of brain function [32, 41]. A key concept relating neural network dynamics to neuroscience was introduced by Hebb [40]. He hypothesized that spatially organized neural networks called "cell assemblies" function as reverberatory circuits which constituted elements of thought. Gazzaniga's [30] "modules", Minsky's [55] "agents", Freeman's [26] "cartels" and other conceptualized functional entities are examples of more recent, comparable proposals for anatomic neural networks. In Hebb's view, an individual neuron could participate in many cell assemblies just as an individual member of society may participate in many social groups. By strengthening or reinforcing repeatedly used connections ("synaptic plasticity"), Hebb suggested that recognition, learning and problem solving occurred

through lowered thresholds of specific loops. By assigning energy levels to threshold loop patterns ("landscapes"), mathematical solutions could be applied to neural net configurations [41].

There are, however, at least two inconsistencies in the analogy between neural nets and brain function. The first is that neurons and their synapses are extremely complex and by themselves resemble computers more than fundamental switches. Accordingly, further attempts to approach mechanisms of brain cognition need to consider dynamic regulatory activities within each neuron. The second is that a number of important artificial neural networks require "back propagation": tuning of internal parameters from output conditions. Both of these inconsistencies may be resolved by consideration of the cytoskeleton, an intracellular parallel network of protein polymers which regulate synapses and performs other important functions.

We contend that rudimentary information processing occurs within and among intraneuronal cytoskeletal elements such as microtubules (MTs) (fig. 1). By subserving synaptic connectionism, such information processing can provide a lower level in a hierarchy of cognitive processes from whose highest level emerges consciousness. Further, retrograde patterns travelling through the cytoskeleton could serve a role analogous to back-propagation in some artificial neural networks. In sections 4 and 5, we describe simulation of such retrograde patterns travelling through microtubules.

In the cytoskeleton, filamentous bridges among parallel MTs and/or neurofilaments could serve functions comparable to the recognition automata of Reeke and Edelman [61]. To take maximal advantage of parallelism, these authors have modelled two parallel automata which communicate laterally and have distinct and complementary personalities. One model automaton ("Darwin") is highly analytical, keyed to recognizing edges, dimensions, orientation, color, intensity, etc. The other ("Wallace") is more "gestalt" and attempts to merely categorize objects into preconceived

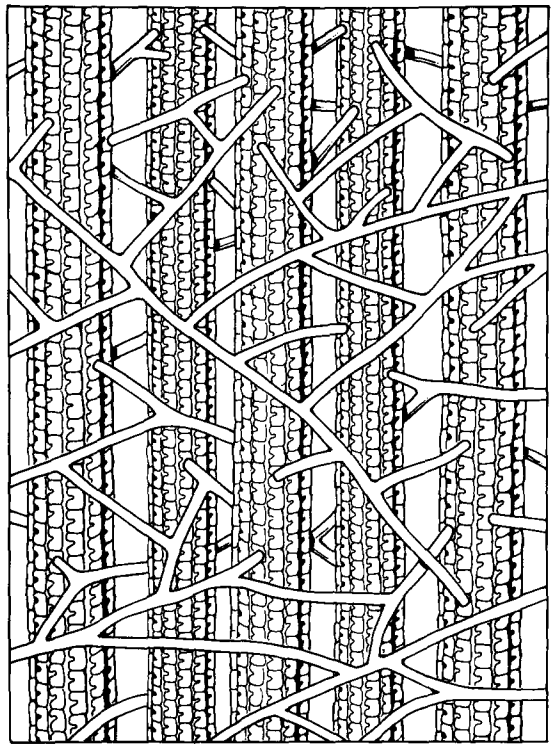

Fig. 1. Connectionist network of five parallel arrayed microtubules (MTs) interconnected by lateral crosslink filaments. Drawn by Fred Anderson from electron micrograph of neuronal dendrite cytoplasm (Aoki and Siekevitz [5]).

classifications. Lateral communications between the two parallel automata resolve conflicting output and form an associative memory. In the cytoskeleton, filamentous bridges among parallel MTs and/or neurofilaments could serve comparable functions.

Multi-level nets are consistent with connectionist brain models in which neural net "assemblies", "modules", etc. fit in an overall cognitive hierarchy of parallel layers of brain/mind organization [13, 20]. The highest cognitive level in such models is global brain function which correlates with awareness, thought, or "consciousness" (although some would argue for even higher-level social consciousness among people, political parties, societies, etc. [42, 59]). The second level appears to be comprised of anatomically and functionally recognizable brain systems and centers (i.e. respiratory

center, satiety center, etc. [66]). At intermediate levels, maps such as the motor and sensory homunculi represent the body and outside world. Finally, the lowest level is thought to be the neural synaptic network, module or cartel which may operate cooperatively by utilizing dense interconnectedness, parallelism, associative memory and learning due to synaptic plasticity.

The lowest level of brain/mind organizational hierarchy, and potential correlate of the binary switch in computers, is generally considered to be the neuronal synapse. However, we suggest that information processing in the cytoskeleton could provide a basement level to the cognitive hierarchy. The cytoskeleton is a parallel, interconnected network of microtubules, actin, and intermediate filaments which also connects to membrane proteins, cell nuclei, centrioles and other structures. Capabilities for dynamic organization coupled with the cytoskeleton's grid-like lattice structure have prompted at least a dozen author groups to model microtubules and other cytoskeletal structures as information processing devices [35]. In neurons, synaptic connectionism and regulation (plasticity) depend on cytoskeletal functions as do other cognitive processes. Information representation, transduction, translocation (including retrograde signaling suitable for "back-propagation") and computation in the cytoskeleton may function just below synaptic neural networks in a cognitive hierarchy.

The next sections will describe: (1.2) evidence linking the cytoskeleton to computation, (2) a biochemical overview of microtubules and other cytoskeletal elements, and (3) models of cytoskeletal information processing. In section 3.3, our previously published model of molecular automata in microtubules [39] is reviewed. Section 4 describes a network model of connected microtubule automata capable of learning and association and section 5 covers an assembly/disassembly microtubule automata model relevant to cell division, growth and plasticity. Section 6 concludes with a discussion of the potential implications of cytoskeletal computation.

1.2. Cytoskeleton and computation

The concept of cytoskeletal computation is based on the observation that cytoplasmic interiors of living cells, particularly nerve cells, are not watery soups. The current picture of cell interiors is one of a highly organized network in which cell water is bound and governed by cytoskeletal structures rather than a freely diffusing solution of macromolecules. Two lines of evidence support this concept. The first is the cytoskeleton which interpenetrates the cytoplasm and defines its architecture and function. Some cytoskeletal components are in polymerization equilibrium, interconverting cytoplasm between "sol" (liquid, solution) and "gel" (gelatinous, viscous) states. This "sol/gel" equilibrium (mediated by Ca^{2+} and Mg^{2+} effects on cytoskeletal actin and other proteins) indicate that the interiors of living cells operate very close to the solid–liquid phase transition. Theoretical findings predict optimal computational capabilities for distributed dynamical systems near this phase transition [47, 58].

Another line of evidence supporting the possibility of a computational cytoplasm includes data from nuclear magnetic resonance (NMR), neutron diffraction and other techniques which show a high degree of bound water in the cytoplasm. Water molecules abutting cytoskeletal (and other) cytoplasmic surfaces are attracted to these surfaces and are restricted in their motions. As a result, a greater proportion has four (rather than three or less) hydrogen bonds with their neighbors. Such water is called "vicinal" water, and has unusual properties compared to "bulk" water: lower density, greater heat capacity and greater viscosity. Further, such vicinal water may cooperatively oscillate with coherent excitations in cytoskeletal proteins (section 3.2).

Further circumstantial evidence for cytoskeletal computation and communication stems from the spatial distribution of discrete sites/states in the cytoskeleton. For example, subunits in microtubules have a "density" of about 10^{17} per cm^3, very close to the theoretical limit for charge sepa-

ration [34]. Thus, cytoskeletal arrays have maximal density for information storage via charge, and the capacity for dynamically coupling that information to mechanical and chemical events via conformational states of proteins (i.e. Fröhlich's mechanism of dipole excitations coupled to conformational state).

The dynamic complexity of neurons and their synaptic connections suggest that they utilize "lower" layers which may include dendritic processing, branch point conductance and molecular dynamics [14, 63]. Lynch and Baudry [51] have studied long-term potentiation ("LTP") of synaptic efficacy in glutamate–NMDA hippocampal neurons, a correlative model of learning. They find that LTP depends on rearrangement of subsynaptic cytoskeleton – a dynamic network of parallel arrayed, interconnected proteins including microtubules, actin, and intermediate filaments. Desmond and Levy [21] have studied dendritic spine structural changes during a synaptic learning paradigm. They find mechanical shape changes in spines mediated by cytoskeletal actin connected to microtubules in dendrites. Aoki and Siekevitz [5] have studied dendritic spine synaptic plasticity in development and find that synaptic down-regulation occurs in conjunction with depolymerization of microtubules in the main dendrite. They find also that signaling and regulation for dendritic spine synapse function depends on phosphorylation of a cytoskeletal protein: MAP2. Microtubule associated proteins (MAPs) attach to and connect microtubules to other microtubules, actin, intermediate filaments, organelles, membrane proteins and cell nucleus. MAP2 is found only in neuronal dendrites, and consumes a large proportion of phosphorylation energy. MAP2 phosphorylation is regulated by cyclic AMP-dependent protein kinase and calcium–calmodulin protein kinase. Theurkauf and Vallee [68] have found MAP2 to be "the major substrate for endogenous cyclic AMP-dependent phosphorylation in cytosolic brain tissue", and concluded that MAP2 phosphorylation "may be an important reaction in response to neurotransmitter stimulation". Thus, numerous mechanisms exist for coupling membrane synaptic events and cytoskeletal activities.

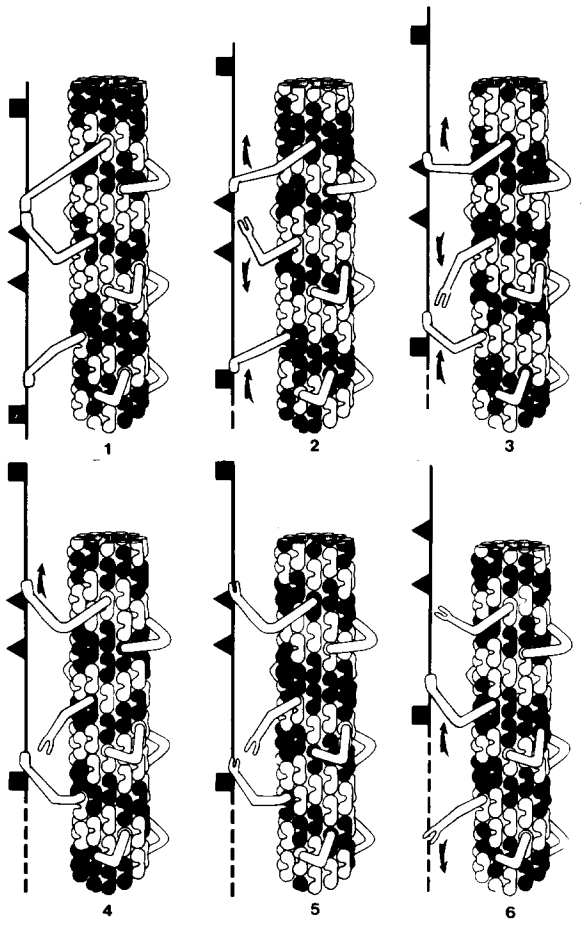

Fig. 2. Axoplasmic transport by coordinated activities of microtubule attached contratile (MAP) proteins ("dynein"). The orchestration mechanism is unknown, but shown here as the consequence of traveling conformational patterns on the MTs. By Fred Anderson.

Maintenance and modulation of synaptic function also depend on axoplasmic transport, an MT based conveyor system which supplies structural components to synapses [48, 57]. Contractile "sidearm" MAPs attached at specific sites on microtubules pass materials in a cooperative bucket brigade which achieves a velocity of 400 mm/day (fig. 2). The contractile sidearms hydrolyze ATP for energy, but the mechanism of orchestration and signaling is unknown. Material can travel in

opposite directions along a single microtubule. Other organized activities in cytoskeletal structures help control the molecular machinery of cell division, growth, differentiation, formation of synapses and dendritic spines, as well as relatively complex functions within single cell organisms like amoeba and paramecium which occur without benefit of brain, neuron, or synapse [22, 65].

Evidence for direct cytoskeletal involvement in cognitive processes comes from Mileusnic et al. [54], who have correlated production of MT subunit protein ("tubulin") and microtubule activities with peak learning, memory and experience in baby chick brain. Cronly-Dillon and co-workers [16] have shown that when baby rats first open their eyes, neurons in visual cortex begin producing vast quantities of tubulin. When the rats are 35 days old and the critical learning phase is over, tubulin production is drastically reduced. Other studies have shown that cytoskeletal proteins directly link to nerve membrane ion channels and receptors [46, 70] and that the intra-neuronal cytoskeleton is linked to nerve membrane excitability and synaptic transmission [2, 53]. Direct evidence for signal propagation in MT has been generated by Vassilev et al. [71], who suspended parallel excitable membranes in ionic solution. Only when two membranes were connected by MTs, excitation in one membrane provoked excitation in the other. The authors suggested that similar communication signals occurred routinely within the cytoskeleton. Also, Becker et al. [10] studied energy resonance transfer among fluorescent groups separately attached to different MT subunits or to membranes. They showed energy resonance transfer occurs both among MT subunits and among MT subunits and membrane proteins.

The intra-neuronal, sub-synaptic cytoskeleton is important to neural function including synaptic plasticity. In assessing cognition, low-level processing may be important. Because the cytoskeleton comprises a connectionist network within each branching neuron, it may be described as a cytoskeletal forest within each dendritic tree.

2. Microtubules and the cytoskeleton

2.1. Cytoplasm

Neurons and other cells are comprised of protoplasm, which in turn consists of membranes, organelles, nuclei, and the bulk interior medium of living cells: cytoplasm. Nineteenth century light microscopists described cytoplasm as containing or consisting of "reticular threads", "alveolar foam", or "watery soup". Development of the electron microscope through the 1960's did not initially illuminate the substructure of cytoplasm because the commonly used fixative (osmium tetroxide) was dissolving fine structure and the cell was still often perceived to be a "bag of watery enzymes".

In the early 1970's, with the event of glutaraldehyde fixation, delicate tubular filamentous structures were found in virtually all cell types and they came to be called microtubules. Originally thought to provide merely structural, or bone-like support, MTs and other filamentous structures such as actin, intermediate filaments and centrioles were collectively termed the "cytoskeleton". Recognition that complex dynamic activities of microtubules and other cytoskeletal elements were essential for organization, movement and growth of cellular cytoplasm finally brought the cytoskeleton out of the closet.

2.2. Cytoskeletal networks

Bulk cytoplasm contains networks of individual microtubules, arrayed in parallel and interconnected by filamentous strands. Other interconnecting networks of smaller filamentous proteins (actin, intermediate filaments, microtrabecular lattice, etc.) intersperse with MTs to form a dynamic gel whose activities in all types of cells (i.e. mitosis, growth and differentation, locomotion, food ingestion or phagocytosis, synapse modulation, dendritic spine formation, cytoplasmic movement, neurotransmitter release, etc.) are essential to the living state [18]. Orientation and directional guid-

ance of these cytoskeletal functions depend on centrioles: assemblies of nine pairs or triplets of microtubules arranged in replicating super-cylinders always found in pairs oriented perpendicular to each other. To initiate cell mitosis, centriole pairs migrate to opposite poles of the cell from where MT "mitotic spindles" separate chromosomes and establish orientation and architecture for the next generation cells [17, 19].

2.3. Microtubules

Of the various filamentous structures which comprise the cytoskeleton, microtubules are the most prominent, best characterized and appear best suited for dynamic information processing [22, 65].

MT are hollow cylinders 25 nm in diameter whose lengths may span meters in some mammalian neurons. MT cylinder walls are assemblies of 13 longitudinal protofilaments which are each a series of subunit proteins known as tubulin (fig. 3). Each tubulin subunit is a polar, 8 nm dimer which consists of two slightly different classes of 4 nm, 55 kilodalton monomers known as α and β tubulin. Genes for α and β tubulin are complex, multi-gene families which give rise to varying tubulin isozymes. During evolution some tubulins have been highly conserved for basic cell functions. However, extensive microtubule heterogeneity exists in complex cells due to genetic diversity, expression, post-translational modifications, MAPs, and assembly patterns [24, 31]. For example, two-dimensional gel electrophoresis has shown 17 different β tubulin isozymes exist in mammalian brain MTs, whereas fewer exist in other tissues [49].

The tubulin dimer subunits within MTs are arranged in a hexagonal lattice which is slightly twisted, resulting in differing neighbor relationships among each subunit and its six nearest neighbors (fig. 4).

MT self-assembly and disassembly are dynamic, complex processes which depend on various factors including temperature and calcium ion concentration. Oriented by centrioles, MT polymerization determines the architecture and form of cells which can quickly change by MT depolymerization and reassembly in another direction [45]. GTP, an energy-providing analog of ATP, binds to polymerizing tubulin; GTP hydrolysis energy is subsequently delivered to assembled MTs. MTs whose ends are GTP tubulin are stable and will continue to grow. After the GTP is hydrolyzed to GDP, GDP tubulin is exposed at MT ends and unless stabilized by MAPs, centrioles or other structures, MTs rapidly disassemble with their component subunits being utilized by assembling MTs. This dynamic instability results in a "selectionist" activity in which MT networks can probe or retreat in cellular appendages including dendritic synapses. The precise mechanism of consumption of GTP hydrolysis energy in MTs is not understood, although one possible utilization is the production of solitons or coherent lattice excitations as proposed by Fröhlich [27–29]. It is known that GTP tubulin and GDP tubulin have different conformational states [8].

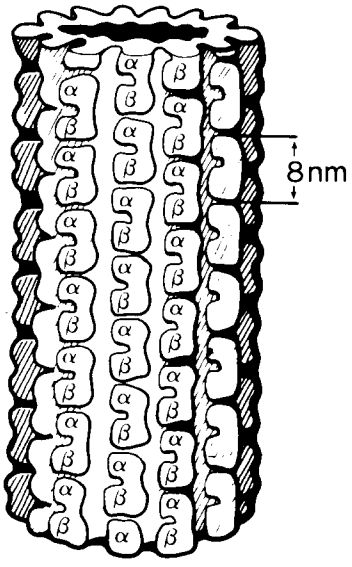

Fig. 3. Microtubules (MTs) are cylinders whose walls are 13 protofilaments, each a string of 8 nm tubulin dimers. Alpha and beta tubulin monomers form the dimers; each dimer has 6 neighbors. Drawn by Fred Anderson from X-ray crystallographic data of Amos and Klug [4].

When viewed in cross section by electron microscopy, MT outer surfaces are surrounded by a "clear zone" of several nm, which apparently represents an electronegative field due to excess electrons in tubulin and may also serve to organize cytoplasmic water and enzymes [67]. MTs, as well as their individual dimers, have dipoles with negative charges localized toward α monomers [17]. Thus MTs are "electrets": oriented assemblies of dipoles which are predicted to have piezoelectric properties [7, 52]. Contractile or enzymatic MAP proteins may be attached to MTs at specific dimer sites and MAP attachments can result in various helical patterns on MT surface lattices [12]. Contractile MAPs participate in axoplasmic transport while other MAPs form bridges which laterally connect specific subunits on parallel arrayed MTs.

3. Models of microtubular information processing

3.1. Cytoskeletal signal processing

The lattice polymer structure of MTs have suggested capabilities for information processing, and numerous author groups (some of which are mentioned below) have published theoretical models of MT/cytoskeletal information processing.

Atema [6] proposed that cellular sensory transduction occurred by propagated conformational changes in MT subunits. His view was an "all or none" propagation in which entire MTs were essentially trigger switches.

Barnett [9] proposed that filamentous cytoskeletal structures operated like information strings analogous to word processors. He proposed that MTs are processing channels along which strings of information can move, and that neurofilaments (intermediate filaments within neurons) are parallel arrayed memory channels. While not specifying the mechanism of pattern representation within MTs or neurofilaments, Barnett's model emphasizes the potential utility of parallel arrays of laterally interconnected molecular structures.

A model which does address patterns within MTs was proposed by Roth and Pihlaja [62]. They suggested conformational states of tubulin subunits within MTs were regulated by binding of inter-MT linkages of MAPs. They assumed five possible conformational states for each tubulin subunit (based on drug binding studies) could be induced by proximity of MAP binding and cooperative allosteric effects.

Hameroff and Watt [36] proposed that conformational states of tubulin within MTs were coupled to charge or dipole states, and interacted cooperatively with neighbor tubulin states. Such interactions were thought to be based on "molecular automata" in which the conformational states of individual tubulin dimer subunits represent "bits" of information subject to dynamic influence by neighboring subunits [36–39, 64]. The control of protein conformation is, by itself, an interesting enigma. Before considering molecular automata as a specific model of MT information processing, some aspects of protein conformational regulation theory will be mentioned.

3.2. Coherent protein dipole excitations

Proteins are vibrant, dynamic structures in physiological conditions. A variety of recent techniques have shown that proteins and their component parts undergo conformational motions over a range of time scales from 10^{-15} s to many minutes with the functionally most significant conformational vibrations appearing in the "nanosecond" range of 10^{-9}–10^{-11} s. Biologically relevant motions of globular proteins in this time scale are thought to include collective elastic modes, e.g. solitons and other nonlinear motions, and coherent excitations [43, 44, 60]. These motions are global changes in protein conformation rather than more rapid thermal fluctuations of side chains or local regions. Such global protein conformations appear suitable for computation: finite states which can be influenced by dynamic neighbor interactions.

need to include these

Collective conformational states near the nanosecond time domain have been woven into a theory of coherent protein excitations by Fröhlich [27–29]. Changes in protein conformation, according to Fröhlich [28], are triggered by charge redistributions such as dipole oscillations within specific hydrophobic regions of proteins. Another concept of Fröhlich [27] is that a set of proteins connected in a common physical structure and electromagnetic field such as within a polarized membrane (or polymer electret like a microtubule) may be excited coherently if chemical energy such as ATP or GTP were supplied. Coherent excitation frequencies of the order of 10^9–10^{11} Hz are deduced by Fröhlich, who cites as evidence sharp windows of sensitivity to electromagnetic energy in this region by a variety of biological systems [33]. Circumstantial evidence for Fröhlich's activities in microtubules include the apparent electronegative field surrounding MTs, and the unexplained consumption of GTP hydrolysis energy by MT lattices. Other aspects of Fröhlich's model include metastable states (longer-lived conformational state patterns stabilized by local factors) and polarization waves, i.e. travelling regions of conformational states slightly out of phase with the majority of coherently excited states.

3.3. *Molecular automata in microtubules*

Conrad and coworkers [15] introduced the idea of "molecular" automata within neurons as a basis for intracellular information processing related to cognition. We believe molecular automata activities in cytoskeletal structures such as microtubules could explain much of their organizational activities.

introduction for automaton behavior

Automaton behavior including dynamic patterns and capabilities for computation require a lattice whose subunits can exist in two or more states at discrete time steps, and transition rules which determine those states among lattice neighbor subunits. Fröhlich's [27] model of coherent excitations and cooperative coupling among proteins arrayed in an electromagnetic field may be applied to tubulin subunit dimers within MTs to serve as a "clocking" mechanism and define discrete generations for automaton behavior. We can obtain an estimate for the clocking frequency assuming one coherent "sound" wave across the MT diameter ($\Phi \simeq 25$ nm). A crude calculation, assuming that $V_{\text{sound}} \simeq 10^3$ m/s, yields a clocking frequency of approximately 4×10^{11} Hz for one wave across the MT diameter. This is in the predicted range and correlates with a clocking generation time of 2.5×10^{-11} s. However, faster and slower automata are possible, depending on the type of MT excitation being considered.

Orientation or phase of any tubulin subunit dimer relative to the coherently oscillating majority at any excitation period would depend on factors such as initial conformational states, binding of water, ions, or MAPs, bridges to other MTs, tyrosinated/glutamated state, energy-providing phosphate nucleotides (i.e. GTP) and associated proteins, genetically determined subunit factors and electrostatic dipole interactions among neighboring subunits. Many of these factors may be considered programming modes (either hereditary or environmental) whose net effects would serve to alter phases of particular subunits in coherently excited arrays. To simulate MT molecular automata, we will focus solely on electrostatic dipole interactions among MT subunits.

Our derivation of automaton neighborhoods and neighbor dynamics for computer simulation are illustrated in figs. 4 and 5. The MT cylinder (25 nm in diameter) has a circumference of 13 tubulin subunit dimers and the pitch pattern (angle from horizontal) of the leftward helix is one and one-half dimers. For automaton simulation we consider seven-member neighborhoods of tubulin dimers: a central dimer surrounded by a tilted hexagon of six neighbor dimers. Taking the cylinder axis of the MTs to define the y-axis, the dimer neighborhood is defined as follows (fig. 4): "C" is the center dimer and "N" (north) is the nearest-neighbor dimer in the positive direction of the y-axis. Similarly, dimers labeled "NE" (northeast), "SE" (southeast), "S" (south), "SW" (southwest),

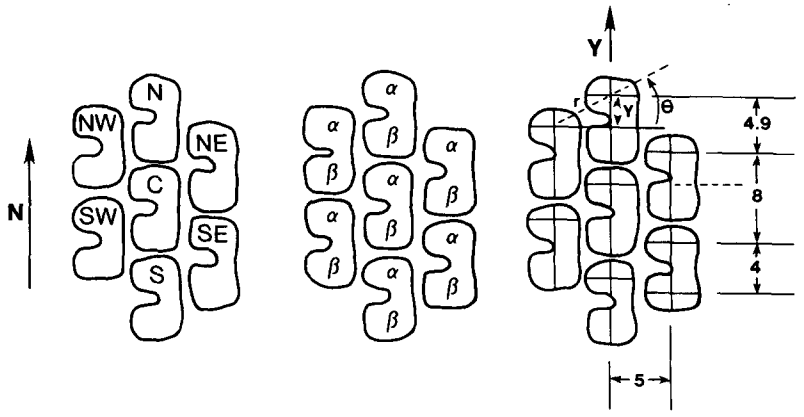

Fig. 4. Microtubule automata (MTA) neighborhood. Left: Definition of neighborhood dimers. Center: α and β monomers within each dimer are labelled. Right: Distances (in nm) and orientation among lattice neighbors. Interaction forces are calculated using $y_i = r_i \sin\theta$.

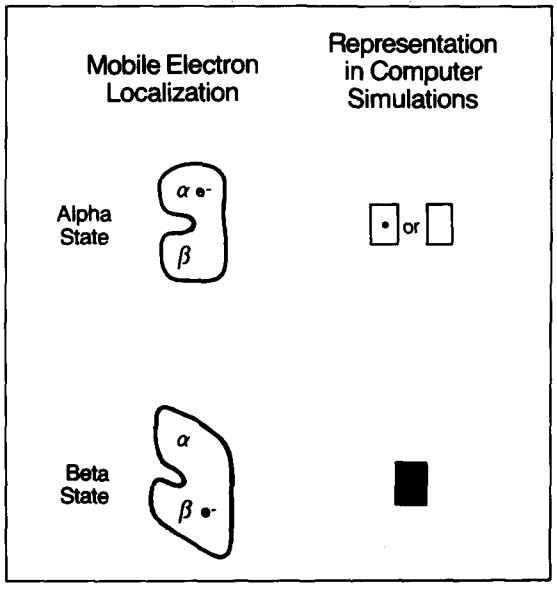

Fig. 5. Switching between conformational states in microtubule (MT) dimers. Top row: α states, bottom row: β states. Left: dimer conformation coupled to mobile electron localization, Right: representation of states in computer simulation.

and "NW" (northwest) are appropriately oriented around the "C" dimer. Within each dimer the α monomer is north of its β partner. The helical twist yielding an offset along the y-axis for NW, SW, NE, and SE neighbors leads to neighbor dimer distances and dipole interaction forces which differ among the six neighbors surrounding the C dimer.

To calculate the neighbor dipole interaction forces as a basis for automaton transition rules, each dimer may be viewed as having a mobile electron shared by the two monomers (fig. 5). At each time step the electron's average position is considered to be oriented either more toward the α monomer ("alpha state") or more toward the β monomer ("beta state") with associated changes in dimer conformation. Experimental evidence [69] suggests that a conformational shift of 29° from vertical may occur. Because MT net dipoles are negative toward the α ends, oscillations need not necessarily change direction totally to effect a conformational change. For example, a relative dipole reorientation toward the α monomer may be sufficient to induce a tubulin dimer conformational state. For our calculations, however, we have assumed that electrons localize in the centers of the two monomers.

Considering the MT lattice geometry, the y-component of the resulting electrostatic force acting on an electron in a central dimer can then be calculated as:

$$f_{\text{net}} = \frac{e^2}{4\pi\epsilon} \sum_{i=1}^{6} \frac{y_i}{r_i^3}, \qquad (1)$$

Table 1
Relative forces ($= -1000y/r^3$) for neighbor configurations. Net forces are summation of six neighbors.

Neighbor position	Central dimer α		Central dimer β	
	neighbor α	neighbor β	neighbor α	neighbor β
north	+15.625	+62.500	+6.944	+15.625
northeast	+15.205	−7.022	+9.635	+15.205
southeast	−14.250	−8.338	−7.022	−14.250
south	−15.625	−6.944	−62.500	−15.625
southwest	−15.205	−9.635	+7.022	−15.205
northwest	+14.250	+7.022	+8.338	+14.250

where y_i and r_i are defined as illustrated in fig. 4, e is the electron charge, and ϵ is the average permittivity for MT proteins, typically 10 times the vacuum permittivity [50]. We have assumed that only the y-component of the interaction forces are effective and have neglected any net force around the MT circumference.

Relative neighbor dipole coupling forces calculated from eq. (1) and MT geometry are shown in table 1. These relative forces, which we use for transition rules, may be multiplied by 2.3×10^{-14} N to obtain calculated absolute values of intersubunit forces.

To simulate MT automata, we represent MT structure as a two-dimensional grid in which the cylindrical MT has been fileted open and flattened (figs. 6 and 7). The grid consists of MT subunit dimer loci which can exist in either an α state (blank or blank with dot) or β state (solid black). At each time step (generation), resulting neighbor forces are calculated for each dimer in the grid. The extent to which each dimer is influenced by neighbor forces acting upon its mobile electron is represented by a "threshold" parameter. The higher the threshold, the greater are the summated neighbor forces necessary to induce a transition. For example, a threshold of ± 9.000 means that net neighbor forces greater than $+9.0 \times 2.3 \times 10^{-14}$ N will induce an α state, and negative forces of less than $-9.0 \times 2.3 \times 10^{-14}$ N will induce a β state.

Biological factors which might affect the threshold include temperature, pH, voltage gradients, ionic concentration, genetically determined vari-

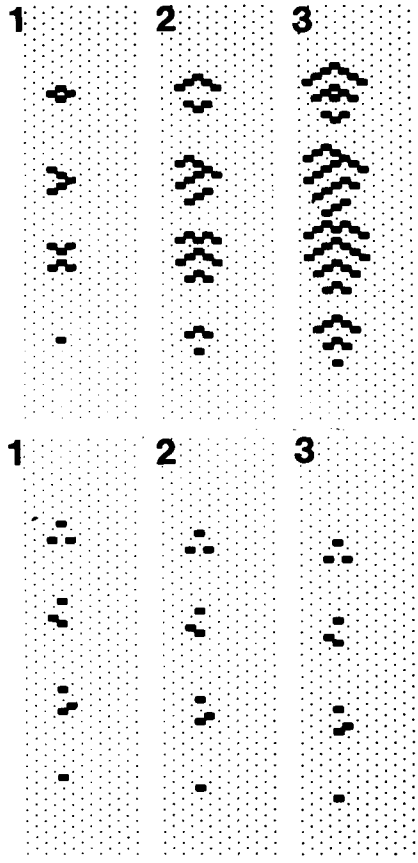

Fig. 6. Some virtual microtubule automata existing for two different threshold values. Top: objects in left panel are labelled (top to bottom) as diamond blinker, triangle glider, spider glider and dot glider. The middle and right sided panels in the top show the next two generations at threshold ± 1.000. The objects either blink or move and leave "wakes" which lead to travelling wave structures. Bottom: the first three generations of some other gliders with threshold ± 9.000. At this higher threshold, the gliders travel without creating a wake or travelling waves.

ability in individual dimers, and binding of molecules including MAPs and/or drugs to dimer subunits. In nerve cells, travelling membrane depolarizations could induce transient waves of lowered threshold along parallel arrayed MTs. Consequently, the frequency of depolarization for a particular nerve cell would directly influence the elaboration of patterns within that nerve cell's MT automata.

In the MT automata of Smith, Watt, and Hameroff [64] and Hameroff, Smith and Watt [37, 38] boundary conditions were chosen in which reflection of automata patterns occurred at each end of simulated MTs. In more recent studies using toroidal boundary conditions [39], we have investigated effects of varying thresholds on MT automata behavior as well as the effects of asymmetrical thresholds in which α and β transition thresholds differ. The simulations have demonstrated behaviors of both a general nature (e.g. virtual automata, gliders and blinkers) similar to behavior in other automata systems, and of a specific nature (e.g. perturbation stable gliders, wedge patterns, NE–SW orientations) derived from unique MT properties. Threshold-dependent behaviors include gliders (dot, spider, bus and giant gliders), travelling and standing wave patterns, blinkers, linearly growing patterns ("bean sprouts"), bidirectional gliders, and frozen patterns. The bifurcations found in the automata dynamics are summarized in fig. 8.

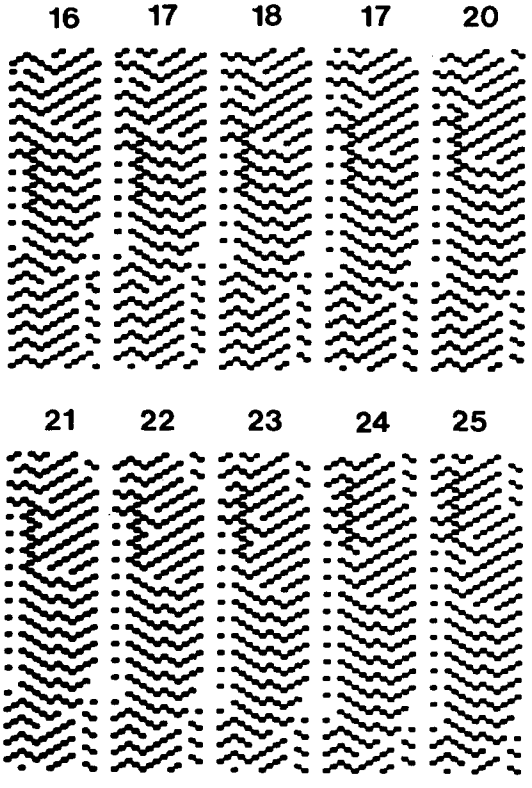

Fig. 7. Time steps 16 through 25 of a microtubule automata simulation with asymmetric threshold, demonstrating localized bilateral information transformation. The initial condition was few randomly scattered α seeds on a β background. The threshold from α to β is −20.000. From β to α the threshold is 2.000. Note that as the β bus (black line of dimers) moves north a new α glider (white line of dimers) is developed in the western region of the neighborhood. This new glider continues to expand until generation 22 when it is "released" from the β bus and starts to travel south together with the other α glider. This dynamical phenomenon may account for the observed bilateral transport on MTs as well as processes related to "back-propagation" in neural networks.

Having demonstrated the potential capability of MT automata for information processing in single MTs, in the present study we have begun to model simple MT networks as well as MT assembly and disassembly.

4. A cytoskeletal connectionist network

The largest portion of free energy used in neuronal dendrite cytoplasm is consumed by MAP2, which actively interconnects dendrite MTs and other structures [68]. A number of empirical studies have also shown that cytoskeletal structures within dendrites change during learning. The relation between cognitive structural changes within neurons and among neurons is enigmatic: which is cause and which is effect? In "true" neural networks (i.e. the brain), the formation of new connections, as well as the breakdown of old ones, is presumably a function of both internal neuronal states (configuration and states of the cytoskeleton, membranes, membrane proteins, second messengers, etc.), as well as signals received from other neutrons. Thus, a multi-level hierarchy of information processing is suggested in biological

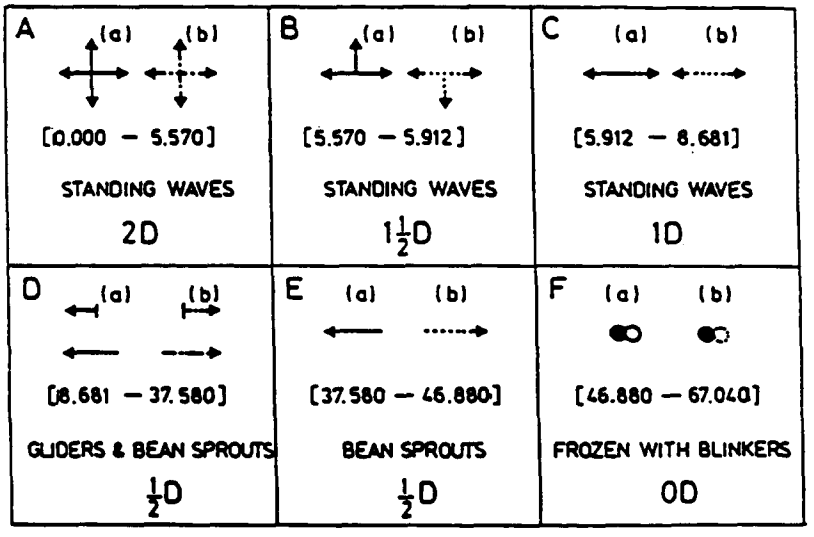

Fig. 8. Bifurcation table for toroidal microtubule automata dynamics with symmetrical dipole coupling thresholds. The upper items in each sector (A)–(F) indicate the dominant global behavior for: (a, solid arrows) β seeds on an α background, and (b, dashed arrows) α seeds induced on a β background. Below the dominant behaviors are the threshold intervals, how we describe each type of dynamic phenomena, and the dimensionality of the growth patterns.

neural networks. To explore this possibility, we have devised an adaptive network based on cytoskeletal structure and function.

Present technologies cannot yet address nanoscale actions of individual protein subunits (although scanning tunnelling microscopy and related techniques may soon be capable). Consequently, there are currently insufficient data to directly test or accurately model such actions and their collective properties.

To merely explore some possibilities, we have used what is known about cytoskeletal structure to serve as the basic architecture for a new connectionist computer. The result is an adaptive dynamical system having certain similarities with the cytoskeleton.

Parallel arrays of MT automata (MTA) are interconnected via MAP-like connections enabling different MTA to communicate with one another. The MAP connections are themselves modeled to be simple automata (MAPA) capable of transmission of signals (sequences of α and β states) from one MTA to another. In the simplest case, this transmission is unidirectional, only transferring signals from a predefined input area on one MTA to a predefined output area on another. Consequently, any tubulin dimer state (α or β) from the MAPA origin on the "input" MTA1 is transmitted to the MAPA target area on the "output" MTA2 (fig. 9).

Conditions which can contribute to dynamic behavior of the MTA network (MTAN) system include MTA thresholds as well as number, attachment locations, and directionality of MAPA. By defining inputs and outputs for each MTA (fig. 10), together with a recursive procedure for updating subunit states, we are able to construct a simple adaptive network.

To model a computationally efficient connectionist network via a feedback between connection topology, internal automata dynamics and automata rules, we use an optimization process often used by Nature: *variation* combined with *selection*. Several systems compete in parallel with respect to a given set of tasks. At each step in the optimization process the most efficient system is selected as the "mother system". At the next step in the optimization process a population of other systems is created as "daughters" or random offspring from the mother system. When one of the offspring begins to perform better than the original system, this offspring is turned into the mother

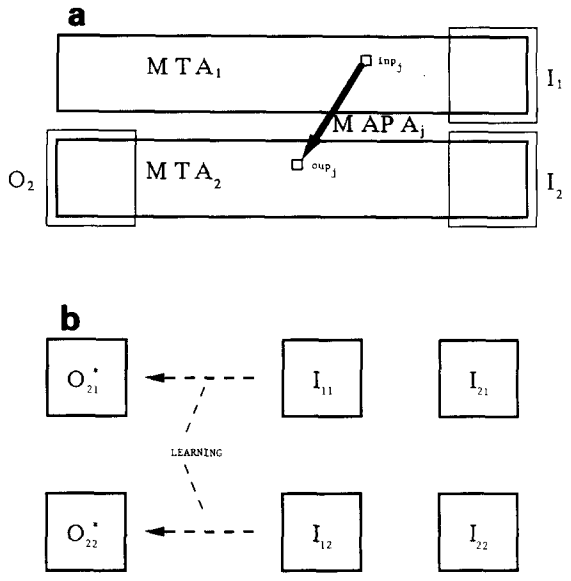

Fig. 9. (a) The simple microtubule automata network, the MTA net, consists of two toroidal MTA of length l dimers, coupled via microtubule associated protein automata, MAPA. The output for the MTA net is defined at the left end of the lower MTA indicated by O_2, and it is taken when the system is updated $l-(13+1)$ times after the input patterns are set at locations I_1 and I_2 at time 0. Input and output areas occupy a matrix area of $13 \times 13 = 169$ dimers. The jth MAPA transmits the dimer states from the input area inp_j at the upper MTA to the output area oup_j at the lower MTA. For each pair of input patterns, I_1 and I_2 at the upper and lower MTA, there exists a desired output pattern O_2^* at the lower MTA. (b) By means of the learning algorithm, the mappings $(I_{11}, I_{21}) \rightarrow O_{21}^*$ and $(I_{12}, I_{22}) \rightarrow O_{22}^*$ are generated.

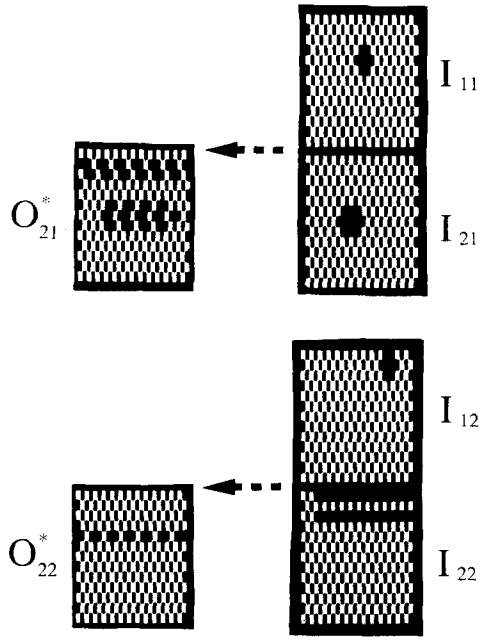

Fig. 10. A MTA network with start configurations (I_{11}, I_{21}) and (I_{12}, I_{22}) and corresponding desired output patterns O_{21}^* and O_{22}^*. These two maps have been chosen from the learnable set for the MTA network. The structure of this set is as yet unknown. The present realization of the MTA network is not able to satisfy every input–output pattern combination.

system as the next step in the optimization process. In this way it is possible to evolve efficient networks with respect to different computational tasks.

In our initial efforts to model a cytoskeletal network, two parallel MTA are capable of being interconnected by MAPA at any subunit loci. Each MTA has an input area at the right end, and output area at the left. Output area states are compared to desired output states using their Hamming distance. For the system to recognize inputs to produce desired outputs, we have random MAPA connections between the two MTA. The learning algorithm for our network is represented both by the threshold parameter for the individual MTA and by the interconnections between the different MTA. A detailed description of the learning algorithm is given in the appendix.

The MTAN obtains truly distributed computation since it is only governed by low-level, neighborhood interactions mediated by intermolecular forces. Such a spatial locality is usually not found in other connectionist models. Another important difference is that the learning algorithm for the MTAN does not use a local learning rule as most artificial neural networks do; rather, MTAN uses an *evolutionary search* to accomplish learning. However, our current MTAN system needs input/output learning in the same sense as most artificial neural net systems do.

In the following example we have fixed the threshold parameters for the upper and the lower MTA at ± 5.900 and ± 9.000 respectively. The corresponding input–output maps used for learning are shown in fig. 10. The connection topology

$C_j = C_2$ for the first accepted input–output map is shown in fig. 11 together with the dynamics for the MTA net at time 0, 43, and 66. The Hamming distance between the desired and the actual map is $H_d = 0$. In fig. 12 the connection topology $C_k = C_4$ for the second input–output map is shown together with the dynamics at time 0, 23, and 66 ($H_d = 0$). It turns out that C_4 also satisfies the first input–output map. We had to redo pass (5) and (6) in the learning algorithm a number of times before the system found a correct C_k satisfying both the maps $(I_{11}, I_{21}) \rightarrow O_{21}^*$ and $(I_{12}, I_{22}) \rightarrow O_{22}^*$.

In the situations where the two pattern combinations can be memorized, there always seem to be several C_k's satisfying the two maps. However, the present realization of the network is not able to memorize every pattern combination at the same time. Some maps cannot coexist.

The MTA net is also able to "associate" or generalize patterns. In figs. 13a and 13b the system tries to associate or recognize the first input pattern, and in 13c and 13d the system tries to associate the second pattern. Note that H_d may be quite high due to a simple horizontal offset, even though the patterns seem very similar. The basis for this associative ability is the existence of relatively perturbation-stable virtual automata in this system. The dynamics of the system is more

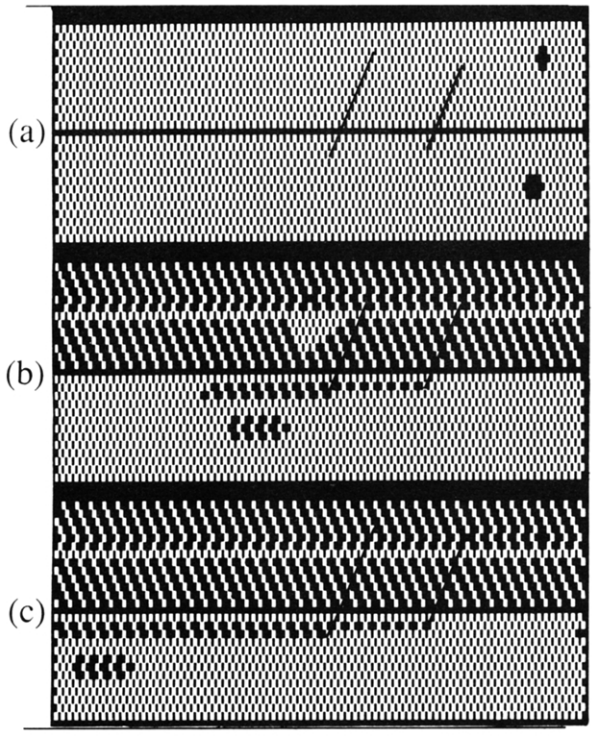

Fig. 11. MTA net at stage (3) in the learning process. The parameters for this net are $l = 80$ and $\text{inp}_j = \text{oup}_j = 1$. The connection topology $C_j = C_2$, with MAPA at the dimer locations $(60,6) \rightarrow (55,2)$ and $(47,4) \rightarrow (41,3)$, turns out to satisfy the first input–output map. The Hamming distance $H_d = |O_{21}^* - O_{21}| = 0$. The dynamics is shown at time: (a) 0, (b) 43, and (c) 66. The thresholds for the upper and lower MTA are ± 5.900 and ± 9.000 respectively.

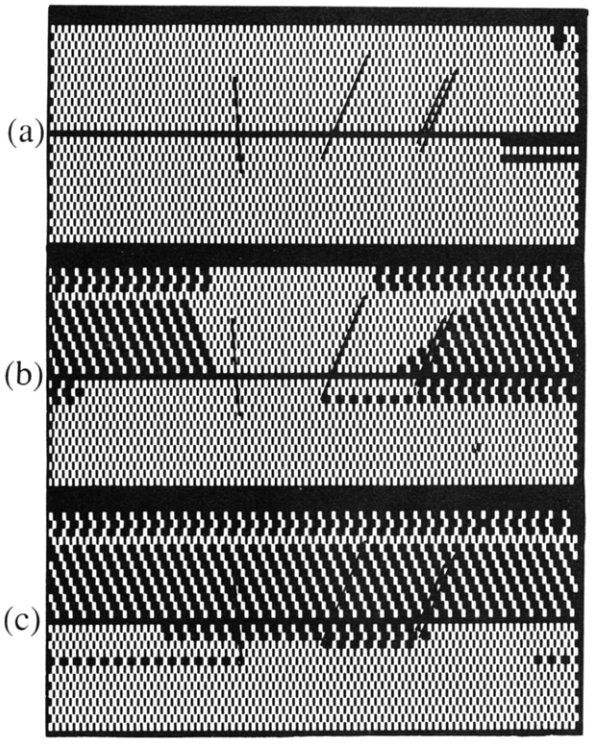

Fig. 12. The same MTA net as shown in fig. 11 at stage (5) in the learning process. $C_k = C_4$ is here given by: $(60,6) \rightarrow (55,2)$, $(47,4) \rightarrow (41,3)$, $(59,7) \rightarrow (55,1)$, and $(28,7) \rightarrow (29,5)$. The dynamics is shown at time: (a) 0, (b) 26, and (c) 66. It can be shown that C_4 both satisfies the first and the second input–output map ($H_d = 0$). However, pass (5) and (6) had to be repeated a number of times, with $D = 10$, before a correct connection topology was found. The thresholds for the upper and lower MTA are still ± 5.900 and ± 9.000 respectively.

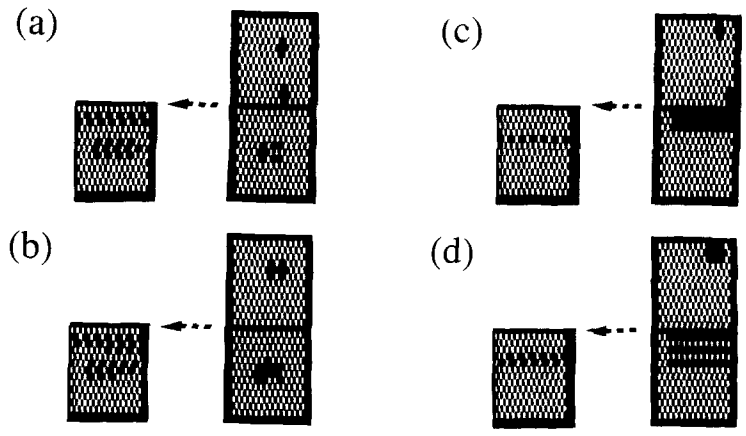

Fig. 13. Association of patterns in the MTA net with connection topology C_4. (a) and (b) are related to the first map, and (c) and (d) are related to the second map. In (a) $H_d = 26$ and in (b) $H_d = 6$ although (a) looks more right than (b). (c) is perfectly associated. In (d) we see a less correctly associated pattern, $H_d = 26$. Compare with fig. 10.

resistant to perturbations in the longitudinal (north–south) MTA direction than in the east–west direction. This property appears due to chosen threshold values which mainly support communication along the north–south axis on the MTA (see the bifurcation table in fig. 8). The reason for the preferred north–south communication for higher thresholds is due to the geometry of the MT lattice. The east–west interactions between most of the dipole configurations are simply cut off for higher thresholds. For example, table 1 shows relative forces for the 24 configuration pairs occurring. None of the pairwise east–west interactions exceed an absolute value of the relative force larger than $15.205 \times 2.3 \times 10^{-14}$ N. The pairwise north–south interactions have absolute values up to $62.500 \times 2.3 \times 10^{-14}$ N.

Selection of specific asymmetric threshold values which differ between the two connected MTA as well as selection of different background states in the two connected MTA can lead to significant behavior. For example, a larger absolute positive threshold in MTA1 and a larger absolute negative threshold in MTA2 cause north → south direction gliders in MTA1 which induce, by MAPA connections, south → north gliders in MTA2. Another example of retrograde information transport is a system with MAPA connections between MTA in different ground states. This is possible since β-gliders always travel south on an α background and α-gliders always travel north on a β background (for details on the dynamics in a single MTA, see ref. [39]). Such retrograde signaling could implement "back-propagation" within neural net neurons. MTs from separate dendritic branches merge and interconnect in the dendrite; thus dendritic MTA nets can merge information from multiple dendritic branch synapses. "Up-regulation" due to increased activity in one synaptic area could thereby "down-regulate" relatively inactive synapses on separate dendritic branches.

Although our system presently is able to adapt to certain dynamics, the learning process is not optimal for several reasons. These include the basis on which the daughter systems are both constructed and chosen, and because of an inefficient use of the MTA patterns. Also, the Hamming distance is probably not the best index for selection of a connection topology because two identical patterns shifted just for one dimer often result in a huge Hamming distance. This behavior also limits the associative properties.

Several potential improvements could be implemented in the MTA net system. The resolution of

different maps on the same MTA net would increase significantly if the system were able to use "coded" MAPA. A coded MAPA could be an automaton which only transmits if a certain α/β sequence ("an initiator pattern") passes the input area for the MAPA. Similarly, the MAPA should stop the transmission whenever a certain stop pattern passes the input area; thus the system would have properties very similar to the DNA transcription system. Alternatively, the MAPA could be coded to transmit a signal averaged over a certain area in the input zone. Another possible improvement which could reflect true biological activity involves MAPA connection patterns. Rather than random connection topologies, MTA patterns could determine where the MAPA connections should be located. For example, connection sites could be determined by the location of a persistent diamond blinker or some other pattern occupying roughly $2 \times 2 = 4$ dimer subunits. These possibilities have yet not been tested, but indicate a potential for adaptation and learning in structures based on cytoskeletal networks. Future work will explore these areas.

Assembly and disassembly of MTs, MAPs, centrioles and other cytoskeletal structures determine cell division, differentiation, movement, transport, and (in neurons) synaptic connectivity. Coupling between MTA dynamics and MT assembly/disassembly could explain the orchestration of these elegant and delicate functions. In section 5, we investigate this area.

5. Assembly and disassembly of microtubules

Experimental results of studies on assembly and disassembly of MTs both in vivo and in vitro are summarized in ref. [11]. In order to grow, the microtubule must have dimers containing exchangable GTP at the end. Without this GTP "cap", depolymerization occurs unless the MT is stabilized by other factors such as binding to other cytoskeletal structures. Thus, free MTs tend to either grow or shrink. These results support the dynamic instability model of MT assembly and disassembly [45]. In a simple cellular automaton model for such a process, each boundary site can be considered to be in one of five different states: as polymerized tubulin dimers with either GTP or GDP, as free tubulin with either GTP or GDP, or as water. The possible transitions are shown in fig. 14.

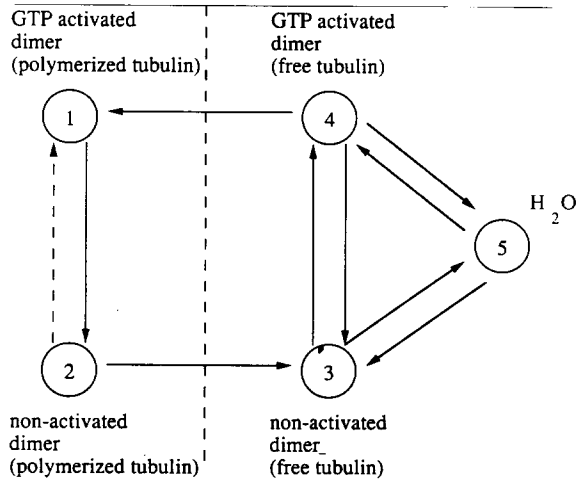

Fig. 14. State diagram for a simple model of assembly/disassembly of microtubules. State 1 is GTP activated tubulin dimer in polymerized form (microtubule geometry), state 2 is microtubule tubulin is non-activated form (GDP), state 3 is non-activated free dimer (in solution), state 4 is GTP activated free dimer, and state 5 is water. The transitions are discussed in the text. Note that this model is formulated partly as a Markov chain, and partly as a cellular automaton.

In the present study, we are concerned with the elongation of already existing tubules, since formation of initial fragments is governed by complex nucleation processes and interactions with centrioles.

We assume that the GTP hydrolysis to form GDP tubulin occurs through a process $(1 \rightarrow 2)$ described by some probability P_{12} at each update of the system (fig. 14). The disassembly $(2 \rightarrow 3)$ of the MTs occurs through dissolving of the non-activated dimers. This process is assumed to depend on the concentration of activated free tubulin [11]: a polymerized boundary dimer will

get free if a major part (three or more) of its neighbors is of the non-GTP free form (including water). Thus, the lower the GTP-activated free dimer concentration, the faster the disassembly. In this model both the concentration of the activated GTP tubulin and the non-activated GDP tubulin are determined by a stochastic process involving internal transitions between the three states: 3, 4, and 5. The higher the overall probability for the presence of an activated dimer among the free states, the more likely is a polymerization process in the system. Polymerization ($4 \rightarrow 1$) takes place if an activated free dimer is aligned with at least two activated polymerized dimers. A necessary condition for polymerization is that the fractional occupation time for activated dimer among the free states is significantly higher than the decay probability P_{12} for the activated microtubule dimer. The transition $2 \rightarrow 1$ is not modeled at this point, but will be discussed later.

Simulations of microtubule assembly and disassembly with the simple model are shown in fig. 15. The clocking frequency in this model is significantly lower than the assumed clocking frequency for signal propagation on the microtubule (10^9–10^{11} Hz). Elongation of existing dentrite MTs in vivo may result in a MT growth of 1 mm/day corresponding to 1 nm/s (or one dimer row per 8 s), although in vitro assembly under physiological conditions may elongate at least two orders of magnitude faster. The simulation in figs. 15d–15f shows an elongation rate of approximately 6 times 8 nm for each 50 generations. This corresponds to approximately 1 nm/s. Therefore the updating of the assembly/disassembly model does not demand nearly the same frequency as the signal propagation model does (10^9–10^{11} Hz). In the present simulation we update with a real time of only 1 Hz.

If specific dynamics on the MTA are able to activate dimers at certain locations, for instance at the free ends (the $2 \rightarrow 1$ transition), there exists an internal mechanism for determining whether a microtubule in the network should start growing. Introducing to the simple cytoskeletal model from

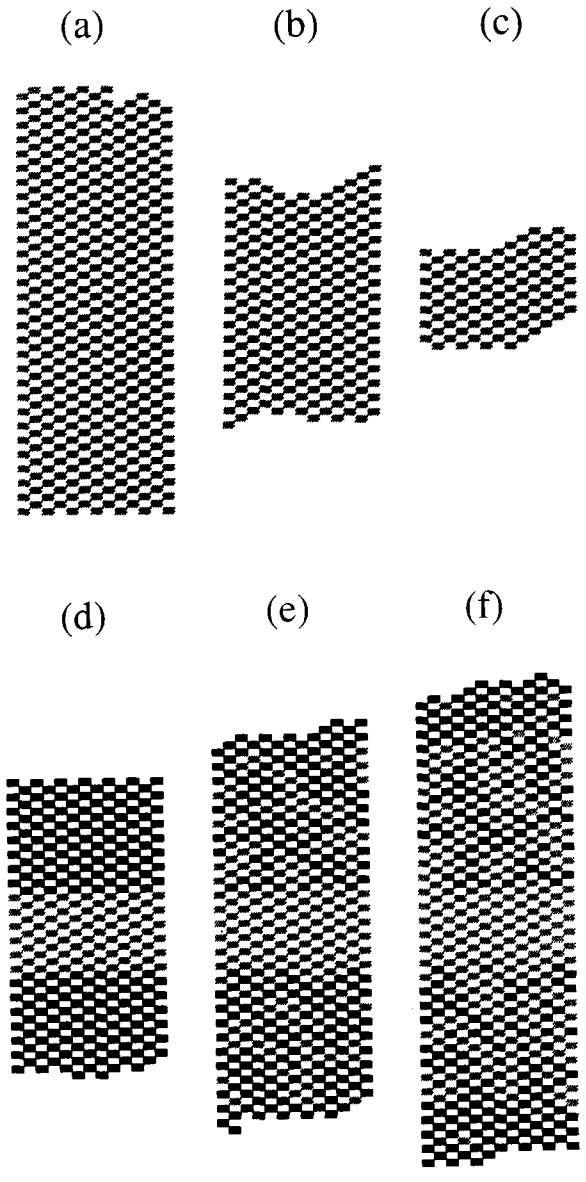

Fig. 15. (a)–(c) disassembly of a microtubule shown at time 0, 21, and 49, with hydrolysis probability $P_{12} = 0.05$ per generation, and an overall probability of 0.091 that the free states are visited by an activated dimer during the automaton generation time. Non-activated microtubule tubulin dimers (state 2) are represented by shaded squares, whereas the free tubulin and water are blank (states 3, 4, and 5). (d)–(f) Assembly of a microtubule with GTP activated caps (state 1 shown as dark squares), shown at time 0, 20, and 50, with hydrolysis $P_{12} = 0.05$ per generation, and an overall probability of 0.987 that the free states are visited by an activated dimer during the automaton generation time.

section 4, such a mechanism adds another feedback between local dynamics and meta-dynamics of our network. Relevant to section 4, selecting the sites of MAPA connections by means of MTA dynamics would also be consistent with this type of feedback.

In vivo assembly/disassembly of MTs may actually be controlled by signals transmitted on the cytoskeleton.

6. Discussion: connectionism in the cytoskeleton

Deciphering of the genetic code in DNA and RNA has led to many technological applications. The existence of a "real-time" processing code in the cytoskeleton could be comparably useful because of the important functions which could be controlled or regulated (mitosis, differentiation, aging, growth, immune function, etc.).

In the neuronal cytoskeleton, MTA can be relevant to brain/mind cognitive function. For example, MT automata may be utilized for guidance and movement of cells and cell processes (axon growth cones, dendritic spines) during morphogenesis of the brain's network architecture. In learning, axoplasmic transport and other mechanisms orchestrated by MT automata could regulate synaptic plasticity. Threshold-dependent bidirectional MT automata patterns indicate that a "back-propagation" type of synaptic regulation could occur because rapid information transport in directions opposite to the nerve impulse is possible. Combined with possible retrograde information flow across synapses ("trophism", pre-synaptic modulation) the cytoskeleton could support "neural-net" type phenomena in the brain. Beyond these morphological roles, MT automata could themselves directly participate an imprinting, pattern recognition, memory and other cognitive functions. MT automaton gliders (8 to 800 m/s) may exist as traveling waves, coupled to nerve membrane depolarizations. Coupling between membrane events and MT automaton behaviors may occur via ionic fluxes or direct connection through specialized sub-membrane cytoskeletal proteins such as ankyrin, fodrin and spectrin to the cytoskeleton. This coupling can lead to a view of the brain as a hierarchy of networks with a cytoskeletal basement level. MT automata would then comprise the "fine grain" of cognition, the "roots of consciousness".

Relegating cognition function to the level of protein conformational dynamics is supported by efforts to understand the mechanism of general anesthesia. Anesthetic gas molecules erase consciousness (while sparing other brain functions like breathing) by inhibiting conformational switching in classes of proteins such as receptors, ion channels, enzymes and cytoskeletal subunits [25]. The anesthetic molecules are thought to bind in hydrophobic regions within these proteins: the same sites proposed by Fröhlich to house dipole oscillations. Anesthetics such as halothane have also been shown (at relatively high concentrations) to cause depolymerization of microtubules [1]. Anesthesia (the reversible cessation of consciousness) may be due to interruption of communicative interactions within and among cytoskeletal networks and their membrane connections.

We have demonstrated that a population of simple networks of paired MTA is able to learn two different patterns by using an evolutionary mechanism as well as associate nearby patterns. However, many improvements may be implemented in the model which can (a) more closely resemble biological activities, and (b) increase MTA network performance. Some of these are discussed in section 4.

We have described the cytoskeleton as a connectionist information network. As such, it may be compared with other connectionist systems like artificial neural networks, classifier systems, etc. Farmer (these Proceedings [23]) has described a group of parameters into which all such systems may be fit for comparison and clarity. These parameters include nodes, states, connections, parameters, interaction rules, learning algorithm and metadynamics. In table 2, we have catalogued

Table 2
Farmer's Rosetta Stone [23] for adaptive dynamic systems applied to microtubule automata (MTA).

	Single MT	MTA networks
nodes	cellular automata cells; MTA subunits	cellular automata networks; MTA-MAPA
states	α and β state patterns	α and β state patterns
connections	lattice geometry	MAPA and other connections
parameters	local thresholds	coding in MAPA connections
interaction rules	local dipole coupling forces	MAPA connections
learning algorithm	input/output learning; selection of the best in a population (selectionist learning)	input/output learning; selection of the best in a population (selectionist learning)
metadynamics	local threshold changes; metastable states	threshold change in MTA-MAPA loci and assembly/disassembly

both a single MT automaton and the adaptive MT automaton network according to Farmer's connectionist classifications.

Connectionist networks within single elements of larger connectionist networks suggest a self-similar "fractal-like" relationship. Information capacity of a high-resolution scale within a self-similar structure is far greater than the capacity at larger scales. Roboticist Hans Moravec [56] has attempted to compare the computing power of a computer and of the human brain. Considering the number of next states available per time in binary digits, a microcomputer has a capacity of about 10^6 bits per second. Moravec calculates brain "computing" power by assuming 40 billion neurons, each with perhaps one thousand synaptic connections which can change states hundreds of times per second, resulting in 4×10^{15} bits per second. We estimate approximately 10^{14} MT tubulin subunits in a human brain based on MTs spaced 100 nm apart and 40% of brain volume being neuronal cytoplasm. In our model of MT automata these 10^{14} brain MT subunits can change states 10^9 to 10^{11} times per second leading to a total brain capacity of 10^{23} to 10^{25} bits per second! Such a huge capacity could provide a high resolution to the grain of cognition, permit massive parallelism and redundancy, and account for cytoplasmic "housekeeping" chores not directly related to brain/mind function. Still, is such a huge capacity necessary to explain cognitive function? That question is presently unanswerable. However, we surmise that the highest level of brain/mind cognitive functions are collective emergent effects whose fine grain may exist within the cytoskeleton.

We conclude with possible applications of MTA molecular cognition. Deciphering real-time MTA codes may permit interfacing to emerging technologies such as spinoffs of scanning tunneling microscopy. These techniques should allow nanometer scale monitoring and programming of dynamic actions of individual protein subunits within assemblies such as MTs. Combining ge-

netic engineering of MT tubulin subunits with real-time programming could lead to replicating MTA with complex, purposeful activities. Perhaps akin to programmable viruses, mobile MTA might be capable of intracellular repair with profound medical applications.

Acknowledgements

We appreciate the discussions we had with Kuni Kaneko on how to design the input and the output for the adaptive microtubular automaton network.

Appendix. The learning algorithm

The process of teaching the MTA net to map two different sets of input to two different output patterns consists of six steps.

(1) Primarily depending on the shape of the desired output pattern, the thresholds for both MTA are set manually. This step demands certain knowledge about what kind of dynamics is possible for each value of the threshold parameter (recall fig. 8), and is not yet endogenous in the algorithm.

(2) A single random MAPA connection is placed at D successive MTA nets. Each of these MTA nets are then simulated for $l-(13+1)$ generations, at which time the Hamming distance, H_d, between the actual output O_{21}, and the desired output pattern, O_{21}^*, is calculated. The MAPA connection pattern which resulted in the smallest H_d with the two first input patterns (I_{11}, I_{21}) is kept for the next steps. This new connection topology is denoted by C_1.

(3) With C_1 as the basic (mother) system, D new random MAPA connections are tested in D different (daughter) systems. Again the system with the smallest $H_d = |O_{21}^* - O_{21}|$ is chosen. This new connection topology is denoted by C_2. (3) is then repeated until an acceptable H_d is reached. The connection topology for the new system is denoted by C_j.

(4) I_{11} and I_{21} are now replaced with I_{12} and I_{22}, still conserving C_j.

(5) Additional MAPA to C_j as in step (3) which is repeated until an acceptable $H_d = |O_{22}^* - O_{22}|$ is reached for a new C_k.

(6) The map $(I_{11}, I_{21}) \rightarrow O_{21}^*$ is then tested with C_k. If $|O_{21}^* - O_{21}|$ still is acceptable, the sequence is finished satisfactorily. If not, the sequence is either started all over again at (1) or repeated from (5).

BIOELECTROCHEMISTRY AND BIOENERGETICS

Conditions for coherent vibrations in the cytoskeleton

Jiří Pokorný *

Institute of Radio Engineering and Electronics, Academy of Sciences of Czech Republic, Chaberská 57, 18251 Prague 8, Czech Republic

Received 4 November 1998; received in revised form 8 December 1998; accepted 5 January 1999

Abstract

Mechanism of organization and order in biological systems is not satisfactorily explained yet. Biophysical theories predicted that coherent endogenous electric field of high frequency can play a significant role in organization. The polarity of vibration structures, spectral energy transfer caused by nonlinearities, and energy supply can lead to energy condensation and excitation of coherent states. These conditions are satisfied in the polymer structures of the cytoskeleton, in particular, in the microtubules as follows from experimental findings. Nonetheless, experimental verification of energy condensation and coherent vibrations in the cytoskeleton is still missing. © 1999 Elsevier Science S.A. All rights reserved.

Keywords: Biological order; Cytoskeleton; Microtubules; Actin filaments; Coherence; Fröhlich coherence

1. Introduction

Biological activity of living systems manifests a high degree of cooperation and organization. An inconceivable number of various macromolecules, polymers, and organelles interact, join together in chemical reactions, and form larger structures whose properties cannot be predicted from the characteristics of the components. All the processes of biochemical, biophysical, and biological nature are coordinated simultaneously and successively in time but the mechanisms of order and self-organization are largely unknown.

Living matter on the cellular, subcellular and molecular levels does not have spatial order typical for symmetrical structures of inorganic crystalline substances. The 'translation symmetry' of microtubules and actin filaments seems to be exceptional. Coordination of biochemical and biophysical processes, dynamic organization and coherence is fundamental to the self-organization of biological systems [1–3]. Self-organization principles are important for evolution and for existence of living matter.

The idea that self-assembly and order are based on biophysical mechanisms using energy is now generally accepted [4,5]. Nevertheless, the concrete mechanism seems still to be rather obscure. The biological matter has extraordinary polar and polarization properties which suggests that endogenous electric and electromagnetic fields can play a fundamental role in organization and order. Supply of metabolic energy is an important feature which together with nonlinear properties enable explanation of coherent states in biological systems as was done, e.g., by Fröhlich [6–9]. Experimental research on cytoplasmic structures disclosed a fundamental role of cytoskeleton in biological activity of cells. We will compare the properties of the cytoskeleton in living cells with the theoretical requirements for excitation of coherent states.

2. Fundamentals of the Fröhlich theory

In the original work, Fröhlich postulated that long-range quantum mechanical phase correlations exist in biological systems, that the majority of the degrees of freedom behave like being close to thermal equilibrium, that a few modes of motion are very strongly excited and remain far from thermal equilibrium, and that the strong polar character of biological objects suggest longitudinal oscillations as stabilising modes [6]. He deeply analyzed the physical properties of biological systems and developed theory of energy condensation [7–9]. In short, Fröhlich assumed that some modes of ubiquitous thermal vibrations in polar

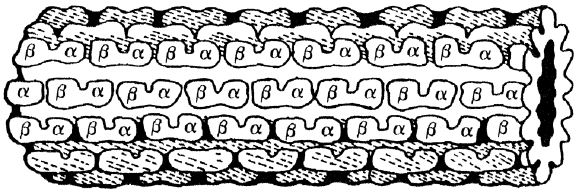

Fig. 1. A schematic figure of a microtubule with tubulin heterodimer molecules in parallel rows (protofilaments). After Refs. [10,12].

systems are excited far from thermodynamic equilibrium. The Fröhlich theory of coherent vibration states has three foundation stones: polar properties of the biological structures, energy transfer between vibration modes (spectral energy transfer), and energy supply to the system.

Long-range interactions within the vibration system as well as between the vibration system and its surroundings (i.e., the heat bath) depend on the electric nature of the vibrations that generate the oscillating electric field. The system may consist of N identical polar oscillators interacting with each other which results in a band of normal modes with frequencies $\nu_1 < \nu_2 \ldots < \nu_N$. Fröhlich postulated the rate equation in the form:

$$\dot{n}_i = s_i - \Phi_i\left[n_i \exp(\beta\nu_i) - (n_i + 1)\right] - \sum_j \chi_{ij}\left[n_i(n_j + 1)\exp(\beta\nu_i) - (n_i + 1)\, n_j \exp(\beta\nu_j)\right],$$

where $\dot{n}_i$ is the time derivative of the occupation number n_i of the normal mode with frequency ν_i, s_i is the number of energy quanta supplied from metabolic sources in the unit time, and Φ_i and χ_{ij} are the linear and the nonlinear transition probability of energy transfer, respectively. The nonlinear interaction makes possible energy transfer between two normal modes with different frequencies in the vibration system with participation of the heat bath. Energy transfer of this type is a fundamental property of the Fröhlich system and a necessary condition for energy condensation. If energy is not supplied (i.e., $s_i = 0$) the system is in thermodynamic equilibrium. In this case, the third term on the right hand side of the rate equation (the χ term) equals zero as well as the second term (the Φ term) and, therefore, $\dot{n}_i = 0$. The steady state solution of the rate equation (for $s_i \neq 0$), given by the relation:

$$n_i = A\frac{1}{\exp\left[\beta(\nu_i - \mu)\right] - 1},$$

where A is the amplitude and $\beta = h/kT$ has the usual meaning, shows that if the excitation potential μ depending on the excitation is high enough, the mode with the lowest frequency is highly excited.

The Fröhlich theory shows the possibility of energy condensation and coherence in the momentum space.

3. Electric properties of the cytoskeleton

The cytoskeleton is an important polymer structure for organization of the cell. The cytoskeleton is composed of intermediate filaments, actin filaments, microtubules, and associated proteins. The microtubules have a fundamental role in organization of the cytoskeleton. The microtubule is a cylindrical hollow tube with the outer diameter of about 25 μm composed of 13 (or 14) protofilaments which are one dimensional chains of heterodimer tubulin molecules (Fig. 1). Description of the cytoskeleton may be found, e.g., in Refs. [4,10–22]. The tubulin molecule is formed by two globular proteins—α- and β-tubulins. The heterodimer molecules can have two conformation states—nontilted and tilted by 29° from the microtubule axis (Fig. 2). The heterodimer molecule is an electric dipole. The microtubules are polar structures with the plus and the minus end embedded in the centrosome—a center of the cytoskeleton. Polarity of the microtubules are closely connected with their function. Fig. 3 shows positions of heterodimers on the wall of a microtubule (a), orientation of the dipole moments in the ferroelectric state—nontilted dimers (b), and the dipole moments of a structure with nontilted and tilted dimers (c). The function of the microtubules depends on phosphorylation and dephosphorylation of microtubule associated tau proteins [16].

4. Nonlinear properties

Vibrations in polar systems excite polarization waves that generate electromagnetic field (with the dominant near zone field electric component) around the vibration structure [5,23]. Energy is exchanged between the near zone field and the vibration structure. (If the vibrations are periodic the energy exchange is periodic too.) A part of the energy may be lost in the ambient medium. Conductivity losses cause ordinary damping represented by the linear transition probability (Φ) in the Fröhlich rate equation. Another type of interaction with the surroundings may exist. A photon of the field can excite a valence electron which loses a part of the energy in a collision (without emission) and then the electron reemit the remaining energy. The collision can increase the energy of the electron too. The emitted quantum of energy differs from the absorbed quantum. This mechanism enables energy trans-

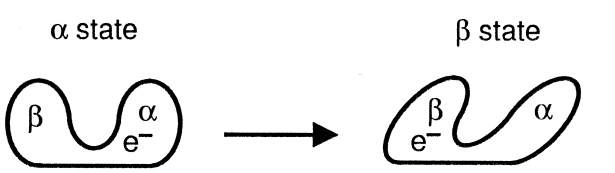

Fig. 2. Conformation change of a tubulin heterodimer from the α state to the β state. The symbol e^- indicates the position of mobile electron charge.

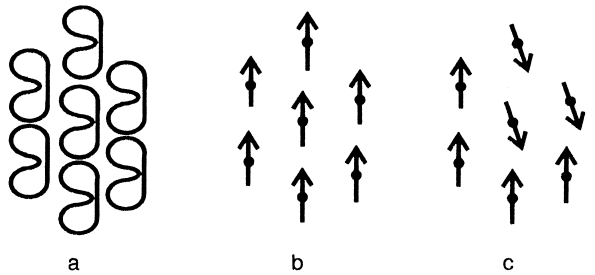

Fig. 3. Position of heterodimers on the wall of a microtubule (a), ferroelectric state of a part of the wall with nontilted heterodimers (b), and dipole moments of a structure with nontilted and tilted heterodimers (c).

fer between modes with different frequencies. Therefore, the polar vibrations in microtubules and actin filaments may be involved in the Fröhlich nonlinear energy transfer.

The microtubule structure is very likely nonlinear by itself. The binding energy of the tubulins in a heterodimer is very likely larger than that between two heterodimers. The elastic force constants along the microtubule chain are not equal and, therefore, the potential as a function of distance of the tubulin 'particle' is asymmetric with respect to the equilibrium position. The nonlinear systems can generate higher harmonic components and components with combination frequencies and enable spectral energy transfer too.

5. Vibrations in microtubules and energy supply

The heterodimers in a protofilament form a one dimensional chain. The globular tubulins in the chain may be considered as mass units with translation symmetry (Fig. 1). These mass units have internal vibrations (exerted by atoms and large parts of tubulins) as well as external vibrations in the chain (i.e., vibrations exerted by each tubulin as a whole). A similar rationale may be applied to the actin filaments. We have analyzed the external vibrations in the protofilaments and in the actin filaments using a method similar to that employed in solid state physics [5,24]. Frequency of vibrations have two branches: the optical and the acoustical branch. The highest frequencies of external vibrations are in the range 0.1–1 GHz [5,23,25]. The frequencies of internal vibrations may be much higher (in the submillimeter and far infrared regions).

The dynamics of the microtubules is very likely one of their most prominent features. The microtubules are capable of rapid polymerization and depolymerization which enables exchange of the subunits between soluble and polymer pool. A schematic picture of a microtubule structure with centrosome in the center is shown in Fig. 4. A microtubule grows towards the cell periphery and then shrinks back towards the centrosome. It may shrink partially and grow again or it may disappear completely to be replaced be new microtubules. This process is called the dynamic instability. The treadmilling (i.e., addition of the tubulin subunits at the plus end and removal of the tubulin subunits at the minus end) appears if both the ends of a microtubule are exposed. After polymerization the guanosine triphosphate (GTP) bound to the β-tubulin is hydrolyzed to the guanosine diphosphate (GDP). Depolymerization and repolymerization is a continual process in animal cells. A similar process of hydrolyzation of adenosine triphosphate (ATP) exists in actin filaments which are important parts of the cytoskeleton too.

Due to depolymerization and repolymerization, the majority of the heterodimer subunits (which are energetically exhausted) is replaced by the energy-rich subunits within about 20 min. The exchange of subunits is much faster in the M phase of the cell cycle. This exchange supplies the standard amount of energy. The dynamic instability provides additional energy supply above the standard value.

We will assess the amount of energy supplied by hydrolysis of the GTP's (attached to the β-tubulins) to the GDP's. The measurements of the hydrolysis of the GTP analogue guanylyl-(a,b)-methylene-diphosphonate (GMPCPP) in solution, in tubulin heterodimers, and in tubulin subunits in the microtubule led to a conclusion that the difference in the free energy was -5.18 kcal/mole, -3.79 kcal/mole, and $+0.7$ kcal/mole [19,26,27]. The reaction with the positive difference of the free energy is thermodynamically unfavorable. Nevertheless, this reaction will ultimately be favorable in the cell. As inorganic phosphate is buffered in the cytosol at approximately 1 mM, then for the equilibrium constant of the reaction smaller than 1, the energy released is -3.38 kcal/mole [27]. A part of the energy is expended on dissociation of the inorganic phosphate but a considerable part is stored in the microtubule lattice (1.7 kcal/mole).

6. Energy usage

Usage of the hydolysis energy is not well understood. The energy can change bond strengths [13,28] or excite

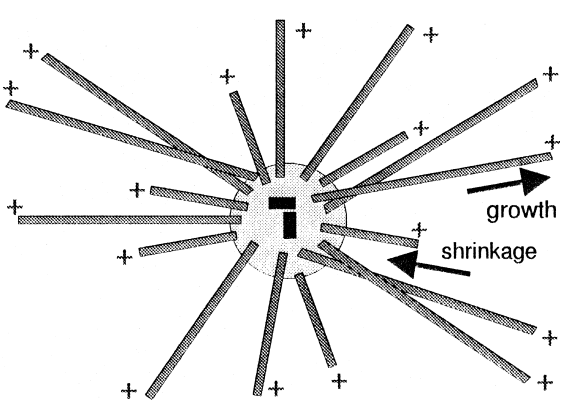

Fig. 4. A centrosome with attached microtubules. The arrows indicate growth and shinkage in the microtubule array.

Table 1
Theoretical requirements and cytoskeleton properties

Theoretical requirements	Properties of the cytoskeleton
Polar systems	Tubulin herodimers and actin molecules are dipoles
Long-range interaction	Interaction by the electric field
Spectral energy transfer by	Mediated by
(a) nonlinear interaction with a heat bath	(a) a near zone electric field
(b) nonlinear intrinsic properties	(b) nonlinear oscillations in asymmetric potential valleys
Energy supply	Hydrolysis of
	(a) GTP in microtubules
	(b) ATP in actin filaments
Consequences	
Energy condensation	Not experimentally proved
Coherence	

soliton or soliton-like waves [11,28]. It can be used for conformation changes of tubulin heterodimers (or for imparting energy via tubulin conformation changes) [12] and for kink wave reorientation of heterodimer dipoles [11,13]. It can excite coherent lattice vibrations by the Fröhlich mechanism [13,28] and/or by the intrinsic nonlinear mechanism. Real physical mechanisms of energy transformation are irreversible and a part of the energy is always transferred to vibrations. Even if the energy levels of two conformation states of a tubulin subunit are different (e.g., if the level of the β state is higher than that of the α state) after transition to the higher energy level, a part of the energy which is used to surmount the potential barrier between the conformation states can be transformed into vibration energy. (The opposite relaxation process should convert energy to vibrations too.) Creation of the tense state with altered forces between the subunits in the microtubule has to supply energy into the lattice. Therefore, we may assume that energy is stored in the microtubule lattice not only in the conformation changes and in the tense states of the lattice but also in the vibration states [5,25].

The energy stored in the microtubule can do work in the cell but a precise manner in which the energy is used is still not understood. We assume that the energy can excite the lattice vibrations and polarization waves, which may be coherent on account of the Fröhlich mechanism or of the intrinsic nonlinear mechanism. The majority of the energy stored in the microtubules may be converted into the vibrations. Therefore, the vibrations are excited and can be far from thermodynamic equilibrium. The electric field generated by the polar vibrations can do work in the surroundings of the microtubule. In the vicinity of the microtubule (e.g., at a distance of about 10 nm) the intensity of the electric field is about 10^5 V/cm (the vacuum value) [5,23].

We assessed the amount of energy which might be supplied to the cytoskeleton vibrations from the hydrolysis of GTP. If the energy supplied by the hydrolysis of GTP is 1.7 kcal/mole, then the energy per one entity is about three times greater than its energy in thermodynamic equilibrium in the frequency range from 10^7 to 10^{11} Hz. The standard amount of energy is supplied within about 20 min when the microtubule pool of heterodimers is exchanged. Due to dynamic instability, the total amount of energy supplied to the microtubule structure in this time interval is considerably greater.

7. Theoretical requirements and microtubule properties

Table 1 shows comparison of theoretical requirements for creation of coherent states and properties of the microtubules. The microtubules satisfy the conditions for energy condensation and coherence. The measured electromagnetic activity of living cells (observed, for instance, in yeast cells—*Saccharomyces cerevisiae* [29,30]) may be assigned to microtubules. Further measurements have to be carried out to prove or disprove coherence of the emitted electromagnetic field.

8. Conclusions

Microtubules are polar—their heterodimer tubulin subunits are electric dipoles whose near-zone field mediates interaction with the ambient medium. The microtubule structure is nonlinear. Energy supply is provided by the hydrolysis of GTP to GDP. The microtubules in the cytoskeleton satisfy the requirements for excitation of coherent vibrations but at present experimental proof of coherent states is missing. We assume that electromagnetic activity of living cells originates in the cytoskeleton and in particular in the microtubules.

Abstract

Technological computation is entering the quantum realm, focusing attention on biomolecular information processing systems such as proteins, as presaged by the work of Michael Conrad. Protein conformational dynamics and pharmacological evidence suggest that protein conformational states—fundamental information units ('bits') in biological systems—are governed by quantum events, and are thus perhaps akin to quantum bits ('qubits') as utilized in quantum computation. 'Real time' dynamic activities within cells are regulated by the cell cytoskeleton, particularly microtubules (MTs) which are cylindrical lattice polymers of the protein tubulin. Recent evidence shows signaling, communication and conductivity in MTs, and theoretical models have predicted both classical and quantum information processing in MTs. In this paper we show conduction pathways for electron mobility and possible quantum tunneling and superconductivity among aromatic amino acids in tubulins. The pathways within tubulin match helical patterns in the microtubule lattice structure, which lend themselves to topological quantum effects resistant to decoherence. The Penrose–Hameroff 'Orch OR' model of consciousness is reviewed as an example of the possible utility of quantum computation in MTs. © 2002 Elsevier Science Ireland Ltd. All rights reserved.

1. Introduction: proteins, anesthesia and quantum computation

1.1. Moore's law and quantum biology

Technology is approaching the limit of classical computing through the operation of Moore's Law, which states that the number of transistors or fundamental switches that can be fabricated on a silicon integrated circuit doubles every 18–24 months. This amazing trend has been miniaturizing microelectronics for close to four decades, and today the smallest available silicon chips contain up to 100 million transistors on a few square centimeters of wafer. This translates into dimensions on the order of 200 nm or less per fundamental switch. As further miniaturization occurs, switching processes enter the quantum world, with extremely useful potential advantages inherent in quantum computation.

Quantum computers are proposed to take advantage of the bizarre quantum property of superposition, in which particles may be in two or more states or locations simultaneously. Whereas conventional computers typically utilize binary 'bits' in which information is represented by particles in classical states of either 1 or 0, quantum computers utilize quantum superpositions of both 1 and 0 ('qubits'). While in superposition qubits interact with other qubits by another bizarre quantum feature, nonlocal entanglement, and ultimately each qubit 'collapses' or 'reduces' to classical states of either 1 or 0. The set of post-reduction classical bits is the solution, or output. Quantum computers will in principle solve at least certain types of difficult problems (e.g. searches, factoring large numbers into primes) with unprecedented speed, and other unique applications are likely to emerge. Quantum computation promises to be a dominant form of information technology.

Miniaturization also brings information technology into the biological realm. Moore's law predicts that in 10 years fundamental switches should reach a scale of about 2 nm roughly the size of proteins, which can act as conformational switches. Biology has had 4 billion years to evolve the most efficient form of information processing. It should not be surprising to find that protein conformational switching is regulated by quantum computation.

1.2. Protein conformational dynamics

Protein function—such as enzymatic catalysis, ion channel opening, cell movement and information processing—depends on regulated changes in protein shape, or conformation.

Individual proteins are synthesized as linear chains of amino acids which 'fold' into 3-D conformation. The precise folding depends on attractive and repulsive forces among various amino acid side groups, and a current view is that many possible intermediate conformations precede the final one (Baldwin, 1994). Predicting final 3-D folded shape using computer simulation has proven difficult if not impossible. This conundrum is known as the 'protein folding problem' and so far appears to be 'NP complete': the answer can be calculated in theory, but the space and time required of any classical computer is prohibitive. Perhaps protein folding is a quantum computation?

The main driving force in protein folding occurs as uncharged non-polar amino acid groups join together, repelled by solvent water. These 'hydrophobic' groups attract each other by van der Waals forces and bury themselves within the protein interior. Intra-protein hydrophobic pockets result, composed of side groups of non-polar (but polarizable) amino acids such as leucine, isoleucine, phenylalanine, tryptophan, tyrosine and valine. Hydrophobic pockets range in size from single non-polar amino acids, up to groups of them occupying $\sim$400 cubic Å, or 0.4 cubic nm (roughly 1/30–1/250 the total volume of a single protein). The physical solvent which most closely resembles hydrophobic pockets is olive oil, a medium in which anesthetic gases readily bind. Within hydrophobic pockets, quantum mechanical activities regulate protein conformational changes.

Proteins in a living state are dynamical, with transitions occurring at many scales. However, conformational transitions in which proteins move globally and upon which protein function generally depends occur in the ns (10^{-9} s) to 10 ps (10^{-11} s) time scale (Karplus and McCammon, 1983). Proteins are also only marginally stable. A protein of 100 amino acids is stable against denaturation by only $\sim$40 kJ mol^{-1} whereas thousands of kJ mol^{-1} are available in a protein from side group interactions including van der Waals forces. Consequently protein conformation is a 'delicate balance among powerful countervailing forces' (Voet and Voet, 1995).

1.3. Quantum effects in proteins

Can electron movements influence protein conformation? The Born–Oppenheimer approximation assumes that electrons cannot significantly influence the position of atomic nuclei (and hence the position of the atom) because the electron mass is so small compared with protons and neutrons (like a soccer ball to the earth). However, as Michael Conrad pointed out (Conrad,

1994) the Born–Oppenheimer approximation does not apply because electron charge is equivalent to proton charge. Quantum processes such as electron tunneling, delocalization, and superposition could, therefore, couple to nuclear locations and influence conformational changes, particularly if the quantum processes are collective and self-organized. Proteins may be designed to amplify these quantum processes. Within proteins ideal sites for electron delocalization are hydrophobic pockets (sites of anesthetic effect), in particular those containing aromatic rings like that of tryptophan.

Electron movements and dipoles are among several forces operating among amino acid side groups within a protein. These include charged interactions such as ionic forces and hydrogen bonds, as well as interactions between dipoles—separated charges in electrically neutral groups. Dipole–dipole interactions are known as van der Waals forces and include three types:

1. permanent dipole–permanent dipole.
2. Permanent dipole–induced dipole.
3. Induced dipole–induced dipole.

Type 3 induced dipole–induced dipole interactions are the weakest but most purely non-polar. They are known as London dispersion forces and they ensue from the fact that atoms and molecules which are electrically neutral and spherically symmetrical nevertheless have instantaneous electric dipoles due to asymmetry in their electron distribution ('electron cloud'). The electric field from each fluctuating dipole in an electron cloud couples to others in electron clouds of adjacent non-polar amino acid side groups. The couplings are quite delicate (40 times weaker than hydrogen bonds) but are numerous and influential. The London force attraction between any two atoms is usually less than a few kiloJoules, however, thousands occur in each protein. Electron clouds in aromatic ring structures (i.e. tryptophan, tyrosine, phenylalanine, histidine) are larger and more complex, and may give rise to cooperatively organized London forces particularly suited to governing protein conformational states. Due to inherent uncertainty in electron localization, London forces are quantum effects which may couple to 'zero point fluctuations' of the quantum vacuum (London, 1937; Milloni, 1994).

1.4. Quantum neuropharmacology: anesthesia and psychedelia

Quantum dipole oscillations within hydrophobic pockets were first proposed by Fröhlich (1968) to regulate protein conformation and engage in macroscopic coherence. In a series of proposals Conrad (e.g. 1994) showed how electron superpositions could influence nuclear movement (conformation), and suggested that quantum superposition of various possible protein conformations occurs before one is selected. Roitberg et al. (1995) showed functional protein vibrations which depend on quantum effects centered in two hydrophobic phenylalanine residues, and Tejada et al. (1996) have evidence to suggest quantum coherent states exist in the protein ferritin. And recently Matsuno (2001) has claimed to observe magnetic quantum coherence in actin, a main component of the contractile apparatus in muscle cells, and of the cytoskeleton in all cells.

Close examination of effects of general anesthetics (which erase consciousness) and hallucinogens (which are said to expand consciousness) reveal that both act in opposite ways on delicate quantum effects.

The mechanism of general anesthesia supports a role for quantum London forces in the phenomenon of consciousness. A century ago Meyer and Overton (working independently in Germany and England, respectively) showed a remarkable correlation between anesthetic potency and solubility in a particular lipid-like environment. Although these results were originally taken to imply that the anesthetics acted in lipids within the cell membrane, studies in the past decades (e.g. Wulf and Featherstone, 1957; Franks and Lieb, 1982, 1984, 1985, 1994; Halsey, 1989 and others) conclude that anesthetic gas molecules act in hydrophobic (lipid-like, water-excluding) regions within critical target proteins. The solubility/binding occurs by weak van der Waals London forces between the anesthetic and non-polar amino acid groups (the same type of endogenous interactions occurring between non-polar amino acid groups in the absence of anesthetics). Critical brain proteins affected by anesthetics include receptors for neurotransmit-

ters such as gamma amino butyric acid (GABA), acetylcholine, serotonin and glycine, as well as certain second messenger proteins, enzymes and tubulin which comprise microtubules (MTs) (Franks and Lieb, 1982, 1984, 1985). What do anesthetics do at their site of action?

Franks and Lieb (1994) suggested that anesthetics act simply by following the Meyer–Overton correlation: their mere presence in hydrophobic pockets prevents conformational switching. However, a variety of molecules, which follow the Meyer–Overton correlation and occupy the same pockets are nonanesthetic, or even convulsant (Fang et al., 1996). The mere presence of molecules in hydrophobic pockets may be insufficient to explain anesthesia.

Another view is that anesthetics somehow disrupt van der Waals London force interactions normally occurring in the critical hydrophobic pockets. Quantum superposition requires electron mobility—electron pairs must be relatively free to roam among allowed orbitals. Evidence shows that anesthetics retard electron mobility—the movement of free electrons in a corona discharge is inhibited by anesthetics (Hameroff and Watt, 1983). By forming their own London force attractions in hydrophobic pockets, anesthetics may inhibit electron mobility required for protein dynamics, quantum superposition and consciousness. Nonanesthetics may be understood as occupying hydrophobic pockets without altering electron mobility, and convulsants as forming cooperative van der Waals interactions, which promote excessive electron mobility and protein dynamics in excitatory proteins.

Another class of drugs, the hallucinogenic ('psychedelic') tryptamine, ergoline and phenylethylamine derivatives bind and act in hydrophobic pockets within serotonin receptors and elsewhere. For example the hallucinogens LSD (an ergoline) and DMT (a tryptamine) are based on indole rings, exactly like that in tryptophan. Nichols et al. (1977) showed that these psychedelic drugs bind in hydrophobic pockets of less than 0.6 nm (6 Å) length. Kang and Green (1970), Snyder and Merrill (1965) measured the capacity of a series of psychedelic drug molecules to donate electron orbital resonance energy. In both studies, the drug's electron resonance donation is correlated with psychedelic potency.

Taken together with dependence of protein conformational regulation on quantum van der Waals forces, the anesthetic and psychedelic studies suggest that (1) consciousness depends on quantum processes in hydrophobic pockets; (2) these quantum processes are inhibited by anesthetics which impair electron mobility in van der Waals London forces. The same processes are enhanced (hallucinations, but also enlightenment) in the presence of psychedelic drugs, e.g. those with indole rings donating electron resonance energy to indole rings in tryptophan within the hydrophobic pocket, forming a collective quantum state. Consciousness depends on quantum states of electrons within hydrophobic pockets in a class of brain proteins.

With conformational states controlled by a quantum process, proteins may thus be viewed as quantum bits, or 'qubits'. For quantum computation, qubits can be arranged in a geometrical lattice (Lloyd, 1993). In biological systems the protein tubulin is arranged in a particular geometrical lattice in MTs whose functions appear to include organization, communication and information processing. Are MTs quantum computers?

2. Information processing in microtubules

2.1. Microtubules and the cytoskeleton

Interiors of living cells are functionally organized by webs of protein polymers known as the cytoskeleton (Fig. 2). Major components of the cytoskeleton are MTs, self-assembling hollow crystalline cylinders whose walls are hexagonal lattices of subunit proteins known as tubulin (Fig. 3). Other major cytoskeletal components include actin, intermediate filaments, and centrioles, MT-based organelles, which orient the cell and guide cell movement and division.

MTs are essential for a variety of biological functions including cell movement, cell division (mitosis) and establishment and maintenance of cell form and function. In neurons (which lack centrioles), MTs self-assemble to extend axons

and dendrites and form synaptic connections. Microtubule-associated proteins (MAPs) interconnect MTs to form MT-MAP networks, which define cell architecture and function. Once established, MT-MAP networks maintain and regulate synaptic strengths responsible for learning and cognitive functions. MTs interact with membrane structures and activities (e.g. in actin-based dendritic spines) by linking proteins (e.g. fodrin, ankyrin) and 'second messenger' chemical signals. Woolf (1997) has shown that activation of neuronal acetylcholine receptors causes changes in MT-MAP connections. (For a more complete description of the role of MTs and other cytoskeletal structures in cognitive functions see Dayhoff et al., 1994; Hameroff and Penrose, 1996a; Hameroff, 1994). MTs have traditionally been considered as purely structural components, however, recent evidence has demonstrated MT mechanical signaling and communication functions (see Tables 1 and 2).

How might MTs signal and process information? Tubulin can undergo several types of conformational changes (e.g. Engelborghs, 1992; Cianci et al., 1986). In one example of tubulin conformational change observed in single protofilament chains, one monomer can shift 27° from the dimer's vertical axis (Melki et al., 1989). Whether that degree of mechanical deformation occurs in tubulin within intact MTs is unknown; neighbor tubulins in the MT lattice might be expected to constrain movement. However, cooperativity among MT subunit tubulins bound 'loosely' in the MT lattice by hydrophobic forces could coordinate conformational changes, and support propagation of wave-like vibrational sig-

nals. MTs are also ferroelectric with electron and proton conduction, which may couple by phonons to conformational vibrations. The crystal-like MT structure makes them attractive candidates for quantum coherent excitations, e.g. in the gigaHz range by a mechanism suggested by Fröhlich ('pumped phonons' Fröhlich, 1968, 1970, 1975, 1975 cf. Penrose and Onsager, 1956).

One particular model of MT information processing potential utilizes Fröhlich excitations of tubulin subunits within MTs to support computation and information processing (e.g. Rasmussen et al., 1990). The coherent excitations are proposed to 'clock' computational transitions occurring among neighboring tubulins acting as 'cells' as in molecular scale 'cellular automata'. Dipole coupling mediates logical interactions among neighboring tubulins, resulting in self-organizing patterns capable of information processing, memory and learning (Fig. 4).

In a series of simulations (e.g. Hameroff et al., 1984; Rasmussen et al., 1990) Fröhlich's excitations were used as a clocking mechanism and electrostatic dipole coupling forces as 'transition rules' for cellular automata behavior by dynamic conformational states of tubulins within MTs. In Fig. 3, each tubulin dimer conformation is ruled by a single London force electron pair coupling. For automata behavior, the dipole strength of each dimer is coupled to its six surrounding tubulin neighbors at each 'Fröhlich coherent' time step (e.g. 10^{-9}–10^{-11} s). The net electrostatic force F_{net} from the six surrounding neighbors acting on each tubulin can then be calculated as:

$$f_{net} = \frac{e^2}{4\pi\varepsilon} \sum_{i=1}^{6} \frac{Y_i}{r_i^3}$$

where y_i and r_i are inter-tubulin distances, e is the electron charge, and ε is the average protein permittivity. MT automata simulations (Fig. 5) show conformational pattern behaviors including standing waves, oscillators and gliders traveling one dimer length (8 nm) per time step (10^{-9}–10^{-11} s) for a velocity range of 8–800 m s^{-1}, consistent with the velocity of propagating nerve action potentials.

MT automata patterns can thus represent and process information through each cell; gliders may convey signals which regulate synaptic strengths, represent binding sites for MAPs (and thus neuronal and synaptic connectionist architecture) or material to be transported. Information could become 'hardened' in MTs by tubulin modifications or stored in neurofilaments via MAPs.

2.2. Tryptophan and histidine locations in tubulin

In conventional computers the 'currency' of information in semiconductors is electrons. Microtubule automata could utilize Fröhlich phonons for information currency, although other quasi-particles such as solitons, excitons, instantons, anyons, as well as photons, electrons and protons could serve. Electron propagation would be extremely useful, as conformational energy (e.g. in the form of phonons) could be coupled to electrons and both classical and quantum processes could be supported. However, proteins have never been considered especially conductive, nor in most cases semiconductive (of course neither has DNA which has recently been shown to be highly conductive, and perhaps superconductive (Barton, 1998; Kasumov et al., 2000)).

Electron (or proton) transfer within and among specific amino acid residues within proteins may mediate protein function. For example catalysis in the enzyme class 1 ribonuclease reductase utilizes electron or proton transfer over 3.5 nm from a tyrosine to a cysteine. Photoactivation in *E. coli* DNA photolyase enzyme involves electron 'hopping' or tunneling along a chain of three separate tryptophans (Aubert et al., 2000). Electron tunneling over significant distances within proteins has now been shown experimentally, and there is evidence of electron transfer from intra-protein tryptophan to DNA (Wagenknecht et al., 2000).

The amino acids tryptophan and tyrosine are convenient depots for electron hopping or tunneling because of the high polarizability of their ring structure. The 'aromatic' amino acids such as tyrosine, tryptophan, phenylalanine and histidine have residues with resonant ring structures in which electrons are mobile and delocalizable.

Tyrosine, phenylalanine and histidine have single rings; each tyrosine and phenylalanine have six-carbon benzene-like rings, and histidine has a

ring with three carbons and two nitrogens. Tryptophan has a particular double ring (an 'indole ring')—a six carbon ring conjoined with a five ring with one nitrogen and four carbons. The extra lines between the atoms in the rings in Fig. 1 signify shared, delocalized, or resonant electrons. Thus tryptophan has the greatest electron resonance (and thus is the most fluorescent), and histidine the lowest electron mobility, and least fluorescent. Becker et al. (1975) showed fluorescent resonance energy transfer (non-radiative photon exchange) between tryptophan and other aromatics in adjacent tubulins in MTs, and between MTs and membranes. Tryptophan is the most highly suited amino acid for transiting electrons and exchanging photons. In this study, we have begun to examine and map intra-tubulin

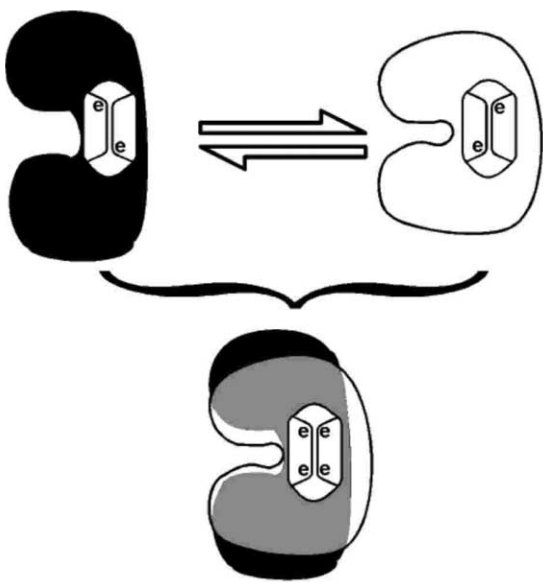

Fig. 1. Model of protein conformational switching. Tubulin is depicted as an example, and for simplicity one pair of electrons coupled by London forces is shown in a single hydrophobic pocket. Top: coupled electrons in one configuration in a single hydrophobic pocket correspond to 'open' (black) conformation. In the opposite London force electron coupling the protein is 'closed' (white). Bottom: since London forces are quantum mechanical, the electron pair may occupy both states, and the protein exist in a quantum superposition of both open and closed conformations. By going from bottom (quantum superposition) to top (one particular conformation) the protein functions as a qubit.

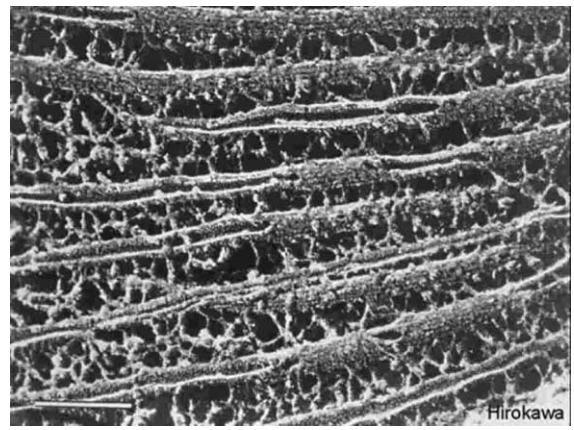

Fig. 2. The neuronal cytoskeleton. Immunoelectron micrograph of dendritic MTs interconnected by dendrite-specific MAPs. Some MTs have been sheared, revealing internal hollow core. The granular 'corn-cob' surface of MTs is barely evident to close inspection. Scale bar, lower left: 100 nms. With permission from Hirokawa, 1991.

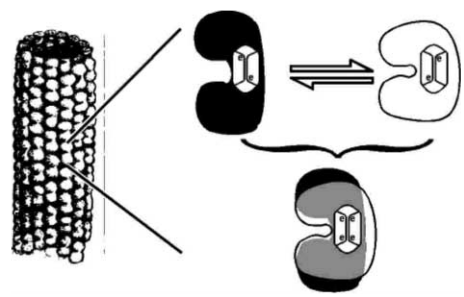

Fig. 3. Left: microtubule, a cylindrical lattice of tubulin proteins. Right (Fig. 1): coupled to position of a pair of quantum coupled electrons in an internal hydrophobic pocket, each tubulin may occupy two classical conformations (top) or exist in quantum superposition of both conformational states (bottom). A tubulin may thus act as a classical bit (top) or as a quantum bit, or 'qubit'.

locations of the aromatic amino acids tryptophan and histidine.

Tubulin dimers are 8 nm in length, and 4 nm wide (and 4 nm 'deep'). The peanut-shaped dimer is composed of two roughly equal monomers, alpha tubulin and beta tubulin each approximately $4 \times 4 \times 4$ nm. The distances between the tryptophans is thus no more than 2 nm. The 3-D crystallographic structure of tubulin was solved in 1998 by Nogales, Wolf and Downing (Nogales et

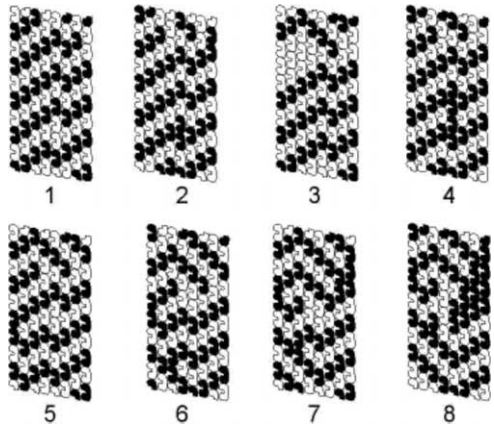

Fig. 4. Microtubule automaton simulation (from Rasmussen et al., 1990). Black and white tubulins correspond to states shown in Fig. 4. Eight ns time steps of a segment (eight of 13 protofilaments) of one microtubule are shown in 'classical computing' mode in which patterns ('gliders') move, evolve, interact and lead to emergence of new patterns.

al., 1998). Recently Alex Nip (now at University de Montreal) and Jack Tuszynski (University of Alberta, Starlab.org) simulated the locations of tryptophans and other aromatics in tubulin. Those results for tryptophan and histidine in 2-D projection are shown here. Tryptophan locations in the tubulin dimer are shown in Figs. 6–8, and histidine locations in Figs. 9–11.

Fig. 6 shows the 'front view'of tryptophan locations, looking at the tubulin dimer as looking at the microtubule from the outside, e.g. as in Fig. 3. However, the front view gives only a 2-D picture. We gain 3-D perspective by also looking at 'side' (within the MT wall) and 'top' (down the protofilament). There are eight tryptophans, four in the alpha (top) monomer, and four in the beta (bottom) monomer. Two tryptophans (one from each monomer) are in the neck, or hinge of the dimer.

The side view indicates that two of the tryptophans are alone in the extended portion of each monomer, separated from each other by exactly 4 nm. The other tryptophans are close to the inner surface and arrayed vertically. The top view shows that the tryptophans are arrayed vertically along three specific axes within the dimer.

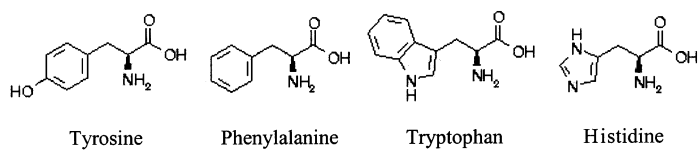

Fig. 5. The 'aromatic' amino acids contain ring structures with resonant (shared) electrons.

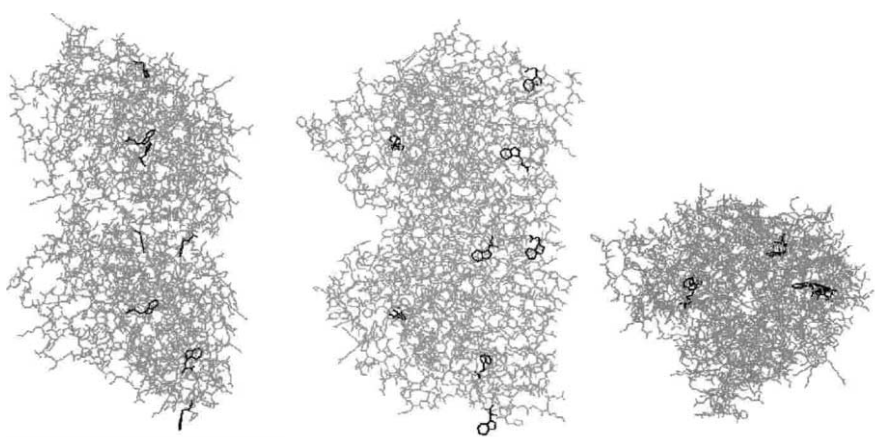

Fig. 6. Tryptophans (black) in the tubulin dimer. Left: front view (looking at the outer MT surface), Middle: side view (from within the MT wall), Right: top view (looking down on the MT protofilament).

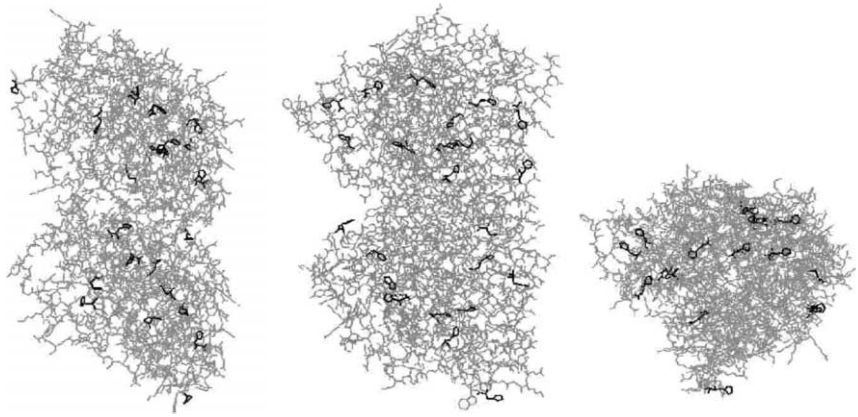

Fig. 7. Histidines (black) in the tubulin dimer. Left: front view, Middle: side view, Right: top view.

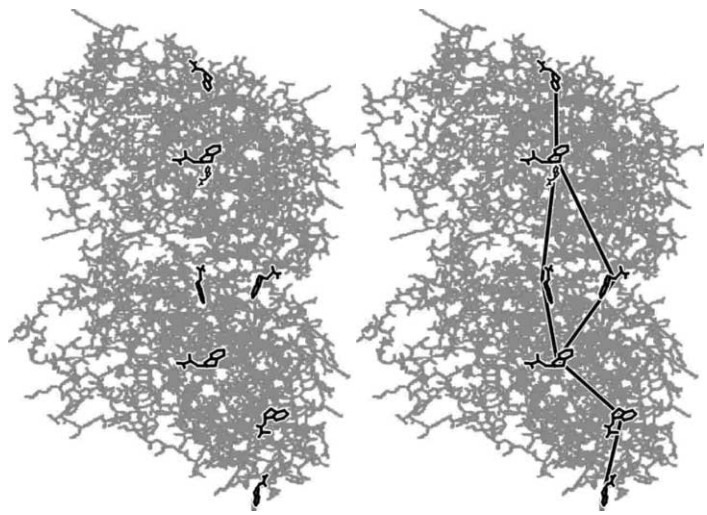

Fig. 8. Tryptophans in the tubulin dimer. Left: trypyophan locations in front view. Right: tryptophans interconnected by estimated shortest paths (2-D approximation). Typical separations are 2 nm, close enough for 'through-bond' hopping. The path separates near the cleft, or hinge of the dimer.

Histidines are more numerous than tryptophans, 22 per dimer, and their arrangement is more complex (Fig. 7).

We next consider possible electron pathways between tryptophans and histidines within tubulin.

2.3. Conduction pathways within tubulin

Conventional wisdom indicates that electron tunneling or hopping in proteins is only possible over distances under 1 nm. This is the 'Foerster distance' (maximum length of an excitation to travel). However the Foerster distance pertains to free hopping via an inert medium like an ionic solution. Within proteins electron movements may be facilitated by 'through bond hopping' over distances of 3 nm or more. Furthermore, if there are sufficient available electrons to fill half or more of the available sites, then conditions can exist within proteins at physiological temperature for (semi)conductivity comparable with silicon or

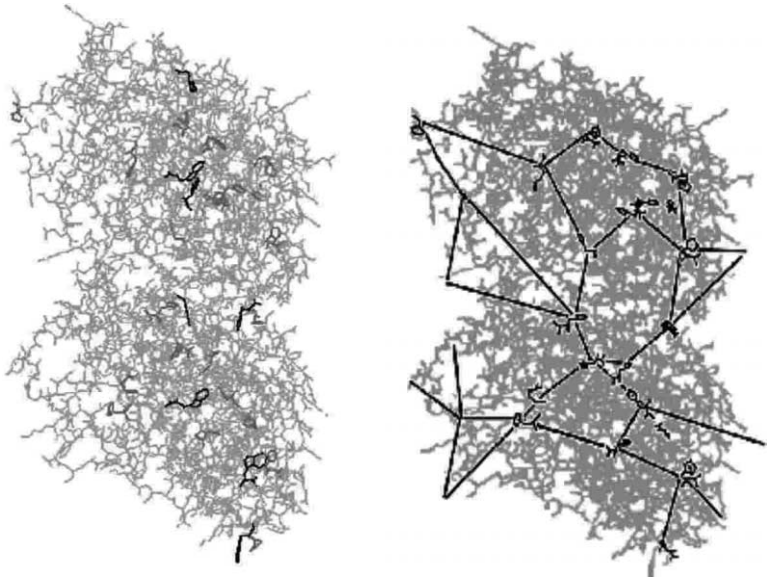

Fig. 9. Histidines in the tubulin dimer. Left: histidine locations in front view. Right: Histidines interconnected by estimated shortest paths. Typical separations are 1 nm.

even semi-metals (e.g. Brown, 1999). With dynamic water ordered at the protein surface, conductivity may be even further enhanced, and proton conduction can also occur.

As described earlier, in some enzymes electron hopping between amino acid residues may span 3.5 nm or more, and electron hopping along 3 tryptophans is known to occur in some enzymes. Based on a qualitative 2-D approximation, Fig. 8 estimates shortest direct paths between tryptophans in the tubulin dimer.

The tryptophan paths are mostly vertical, along the protofilament axis. The path separates near the cleft, or hinge of the tubulin. Occupation of one path versus the other path may control the dimer conformation, for example bending at the hinge.

In Fig. 9, we examine possible paths between histidines.

Estimation of shortest paths between histidines shows multiple loops and alternate possible routes. The average distance between histidines is about 1 nm.

Electron conduction between aromatic tryptophan and histidine amino acid residues is within range of known conduction mechanisms in proteins (tunneling, 'hopping', semiconduction).

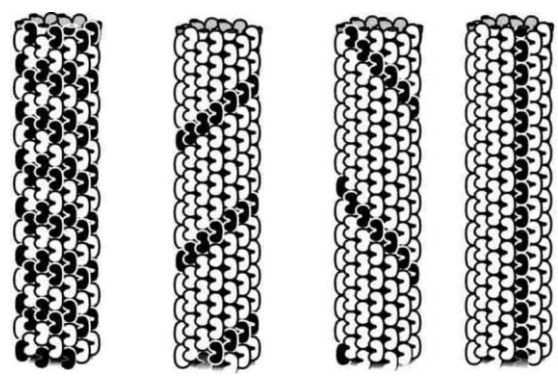

Fig. 10. Helical winding patterns of tubulin subunits within MTs. The windings repeat on any given protofilament according to the Fibonacci series: from left to right, 3, 5, 8 and 13 step repeats. The 3-step repeat is based on monomers, whereas the 5 and 8 step repeats are based on dimmrs. The 13-step repeat is simply the direct path along the vertical protofilaments. These patterns form the basis for attachment patterns of MAPs.

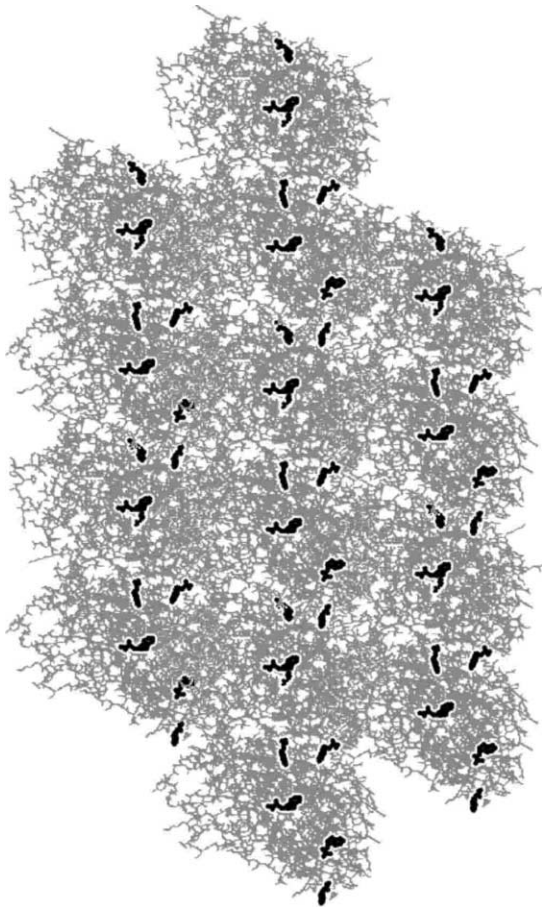

Fig. 11. A lattice neighborhood of seven tubulin dimers as found in a microtubule with tryptophans highlighted in black.

2.4. Inter-tubulin conduction pathways in microtubules

Tubulin dimers are arranged not only in vertical protofilament chains, but form a particular skewed hexagonal lattice whose crystal structure gives rise to helical winding patterns with regular repeat intervals. Increasingly steep winding patterns complete one cycle around the cylinder at a certain number of tubulins above where the cycle started (Fig. 10). These numbers, 3, 5, 8, 13, 21 etc. follow the well known 'Fibonacci series' found throughout nature. The repeating patterns also determine binding sites of MAPs'.

A neighborhood of seven tubulin dimers with tryptophans represented in black is shown in Fig. 11.

If we then show the intra-tubulin tryptophan paths in the lattice format by connecting nearest tryptophans (as in Fig. 12), we see that the tryptophan paths extend vertically along each protofilament.

Tryptophans seem oriented vertically whereas histidine locations suggest helical paths. When added to tryptophan, all possible structural winding pathways appear available (Figs. 13 and 14). In Section 4, we will discuss the possible implications for topological quantum error correction in microtubular computation.

3. Quantum computation in microtubules

3.1. Penrose–Hameroff 'Orch OR' model

Quantum theory and consciousness have been intertwined since the days of Schrödinger's cat when conscious observation was believed to cause collapse of the wave function. More recently, consciousness has itself been viewed as a collapse process, analogous to quantum computation. Penrose (1989, 1994) correlated the multiple possibilities of quantum superposition with multiple sub-conscious, or pre-conscious possibilities 'collapsing' to distinct choices or perceptions (cf. Stapp, 1993). In his early work in this area, Penrose suggested quantum superpositions of neurons both firing and not firing, collapsing or reducing (by his quantum gravity 'objective reduction' process, OR) to either firing or not firing. Thus the neuron was acting as qubit. However, for a variety of reasons MTs within each neuron were deemed better candidates for biological quantum computation, with individual tubulins within MTs acting as qubits.

The Penrose–Hameroff 'Orch OR' model portrays consciousness as quantum computation in MTs which collapse or reduce by an objective factor related to quantum gravity. For detailed explanations see Penrose and Hameroff, 1995; Hameroff and Penrose, 1996a,b; Hameroff, 1998, etc. The basic ideas are these:

- Conformational states of individual tubulins within neuronal MTs are determined by quantum mechanical London forces within the tubulin interiors which can induce conformational quantum superposition (Fig. 3).
- While in superposition, tubulins communicate/compute with entangled tubulins in the same microtubule, and in other MTs in the same neuron.
- Quantum states in MTs in any given neuron may extend to MTs in neighboring neurons, and through macroscopic regions of brain via tunneling through gap junctions (see Section 3.3, Fig. 16).
- Quantum states of tubulin/MTs are isolated/protected from environmental decoherence by biological mechanisms which include phases of actin gelation, ordered water, coherent pumping and topological quantum error correction (see Section 3.2).
- Microtubule quantum computations/superpositions are tuned or 'orchestrated' by MAPs during a classical, liquid phase which alternates (e.g. at 40 Hz) with a quantum, solid state phase.
- Following periods of pre-conscious quantum computation (e.g. on the order of tens to hundreds of milliseconds) tubulin superpositions reduce or collapse by Penrose quantum gravity 'objective reduction' (OR Fig. 15). The classical output states which result from the OR process are chosen non-algorithmically ('non-com-

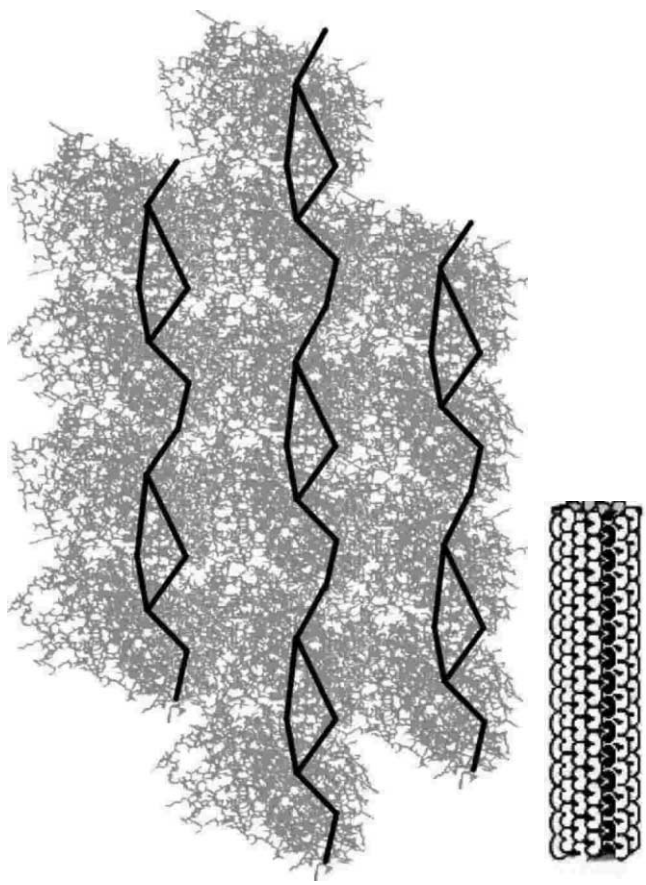

Fig. 12. Left: a lattice of seven tubulin dimers as found in the microtubule lattice. Black lines connect tryptophans. Right: vertical path along protofilament ('13 start' winding pattern) which corresponds with tryptophan conduction path.

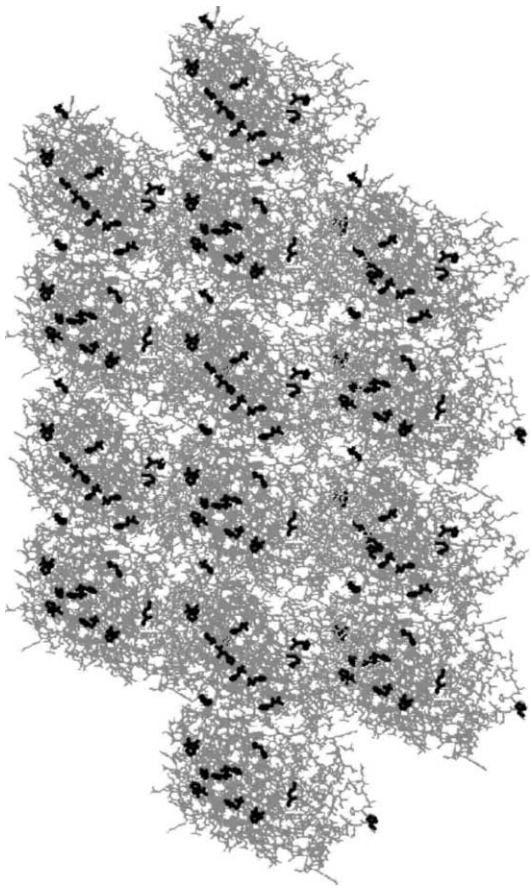

Fig. 13. A lattice neighborhood of seven tubulin dimers as found in a microtubule with histidines highlighted in black.

putably') and then govern neurophysiological events by binding of MAPs, regulating synapses and membrane functions etc.

- The reduction or 'self-collapse' in the orchestrated objective reduction 'Orch OR' model is suggested to be a 'conscious moment', linked to Penrose's quantum gravity mechanism which ties the process to fundamental spacetime geometry. This connection enables a panprotopsychist approach to the 'hard problem' of subjective experience (Chalmers, 1996a).

Other quantum models related to consciousness include those of Marshall (1989), Beck and Eccles (1992), Stapp (1993), Jibu and Yasue (1995).

Quantum models have potential explanatory value for the enigmatic features of consciousness (Table 3), but face at least two conceptual obstacles: (1) the apparent likelihood of rapid 'decoherence' (loss of quantum state) due to environmental thermal interactions in the seemingly-too-warm brain (Tegmark, 2000; Seife, 2000); and (2) the question of how a quantum state or field located within neurons might extend across membranes and anatomical regions to approach 'brain-wide' proportions. The next section deals with these issues.

3.2. Quantum states in the brain? Decoherence and biological feasibility

Quantum computing surpasses classical computing in certain critical functions (e.g. Grover's quantum search algorithm) and would be of extreme benefit to biological organisms for survival and adaptation. Billions of years of evolution may have solved the problems of decoherence and spatiotemporal spread. A number of mechanisms to prevent environmental decoherence have been suggested, specifically for quantum computation in MTs. These include (1) coherent pumping of the environment; (2) screening due to counterion Debye double layers surrounding MTs; (3) screening by actin gelation and ordered water; (4) quantum error correction; (5) topological effects of the microtubule cylindrical lattice. Recent calculations of protein decoherence times indicate quantum superpositions may indeed survive for neurophysiological time durations (Hagan et al., 2000), and brain imaging by 'quantum coherence MRI' utilizes quantum couplings of proton spins in proteins and water to give a neuroanatomical correlate of consciousness (Richter et al., 2000; Rizi et al., 2000). This quantum coherence is a MRI-induced artifact, but shows that quantum coherence of some sort can indeed occur in the brain.

Technological quantum computation became feasible with the advent of quantum error correction codes. This means that algorithms run on the quantum computer which detect and correct errors (random localized decoherence) before they destroy the global quantum state. In some cases topological structure of the quantum computer enhances the error correction. For example

toroidal surfaces (e.g. Kitaev, 1997) may have global, topological degrees of freedom which are protected from local errors and decoherence. Topological quantum computation and error correction have been suggested to occur in MTs by Porter (2001) and the helical windings discussed in Section 2 may correspond to quantum-computational 'basis states' distinguished by 'winding number' (Figs. 12 and 14).

3.3. Spatio-temporal spread of quantum states in the brain

Regarding spatial extension of a quantum (or 'quantum-like' (John, 2001)) field throughout the brain, a possible solution may be gap junctions-window-like 'electrical' connections between cells including neurons (e.g. Dermietzel and Spray, 1993). Gap junctions are more primitive and less

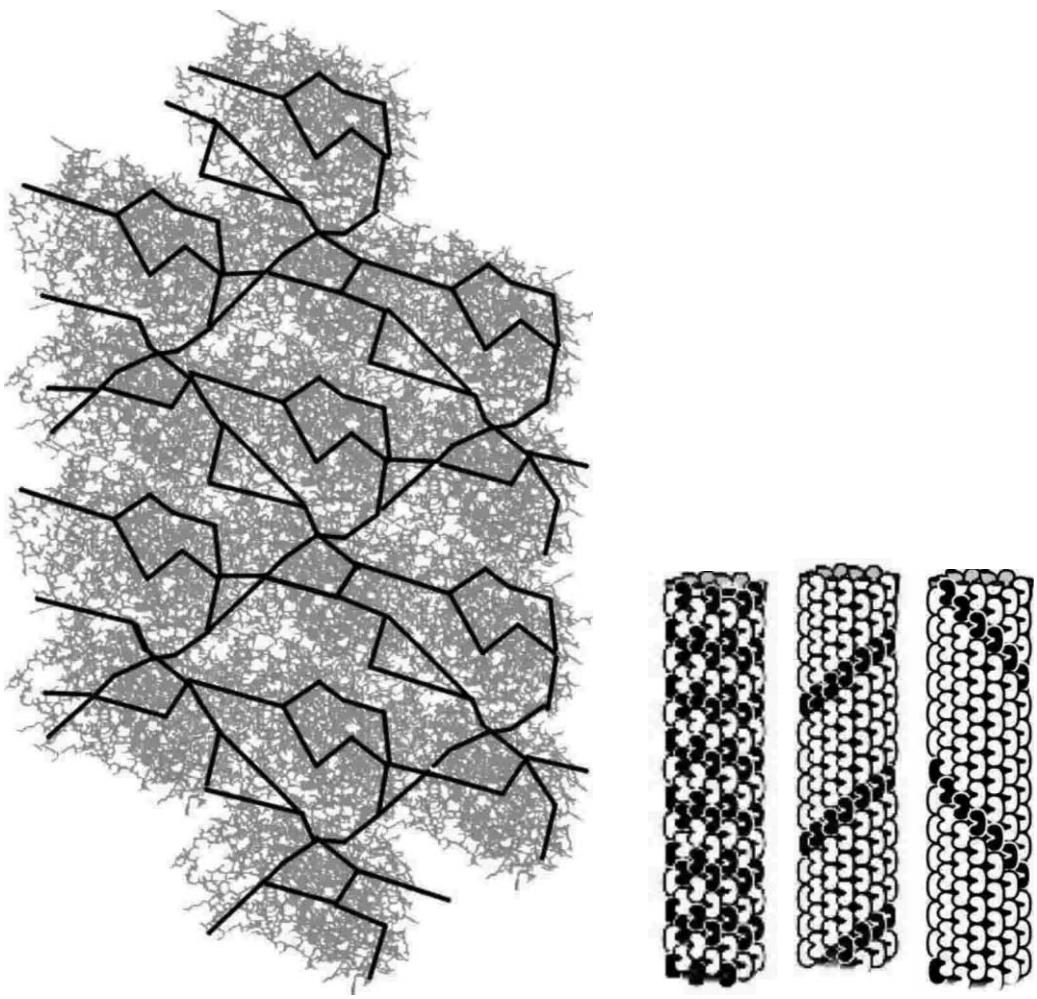

Fig. 14. Left: a lattice of seven tubulin dimers as found in the microtubule lattice. Black lines connect histidines. Right: 3, 5 and 8 start helical winding patterns in MTs. Histidine pathways in the lattice may be seen to follow these winding patterns.

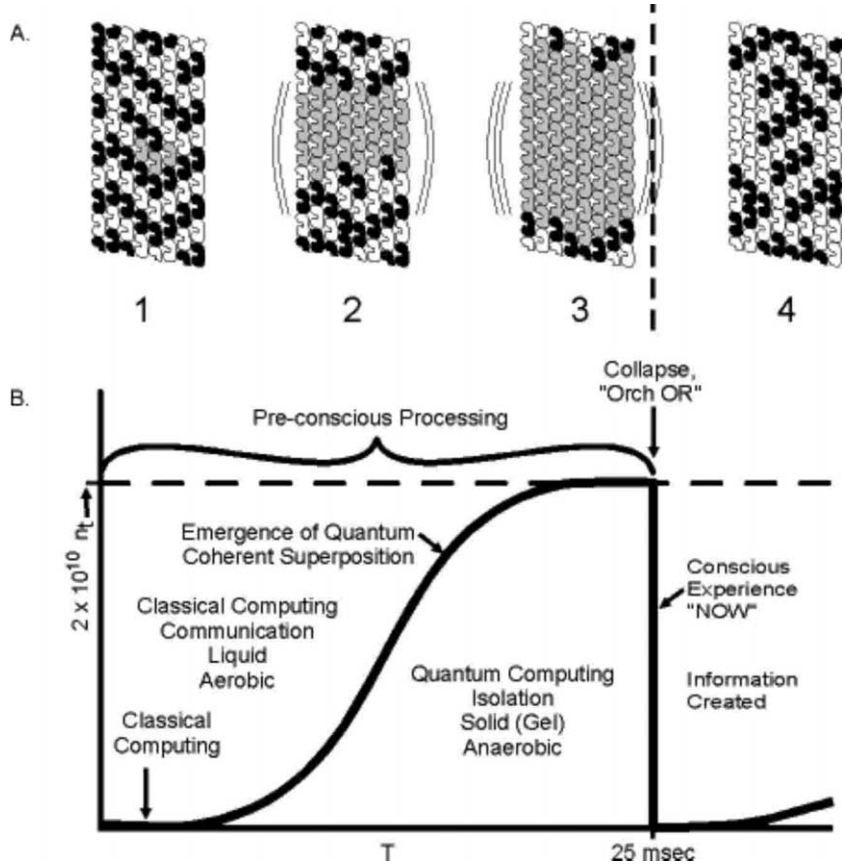

Fig. 15. An Orch OR event. (a) Microtubule simulation in which classical computing (step 1) leads to emergence of quantum coherent superposition and quantum computing (steps 2, 3) in certain (gray) tubulins. Step 3 (in coherence with other microtubule tublins) meets critical threshold related to quantum gravity for selfcollapse (Orch OR). A conscious event (Orch OR) occurs in the step 3 to 4 transition. Tubulin states in step 4 are noncomputably chosen in the collapse, and evolve by classical computing to regulate neural function. (b) Schematic graph of proposed quantum coherence (number of tubulins) emerging versus time in MTs. Area under curve connects superposed mass energy E with collapse time T in accordance with $E = h - \mathrm{bar}/T$. E may be expressed as N_t, the number of tubulins whose mass separation (and separation of underlying space time) for time T will selfcollapse. For $T = 25$ ms (e.g. 40 Hz oscillations), $N_t = 2 \times 10^{10}$ tubulins.

numerous connections than chemical synapses, and occur between dendrites, axons, cell bodies and/or glial cells. Dendritic–dendritic gap junctions in particular have been implicated in the mediation of conscious processes (Pribram, 1991; Eccles, 1992). Cell interiors (cytoplasm) are continuous through gap junctions so that cells connected by gap junctions have actually one complex interior. Quantum states isolated in one cell interior may thus extend to neighboring cells by quantum tunneling of electrons across the 4 nm gap junction. Specific intracellular organelles have been discovered in dendrites, immediately adjacent to dendritic–dendritic gap junctions. These are layers of membrane covering a mitochondrion, and are called 'dendritic lamellar bodies' (De Zeeuw et al., 1995). The dendritic lamellar bodies are tethered to small cytoskeletal proteins anchored to MTs, and it is suggested that the mitochondria within the bodies provide free electrons for tunneling, forming a tunneling diode pair or Josephson junction between cells (Fig. 16). As few as three gap junction connections per cortical neuron (with perhaps thousands of chem-

ical synapses) to neighboring neurons and glia which in turn have gap junction connections elsewhere may permit spread of cytoplasmic quantum states throughout significant regions of the brain, weaving a widespread syncytium whose unified interior hosts a unified quantum state or field (Hameroff and Penrose, 1996a,b; Woolf and Hameroff, 2000).

Kandel et al. (1991) remarked that neurons connected by gap junctions fire synchronously,

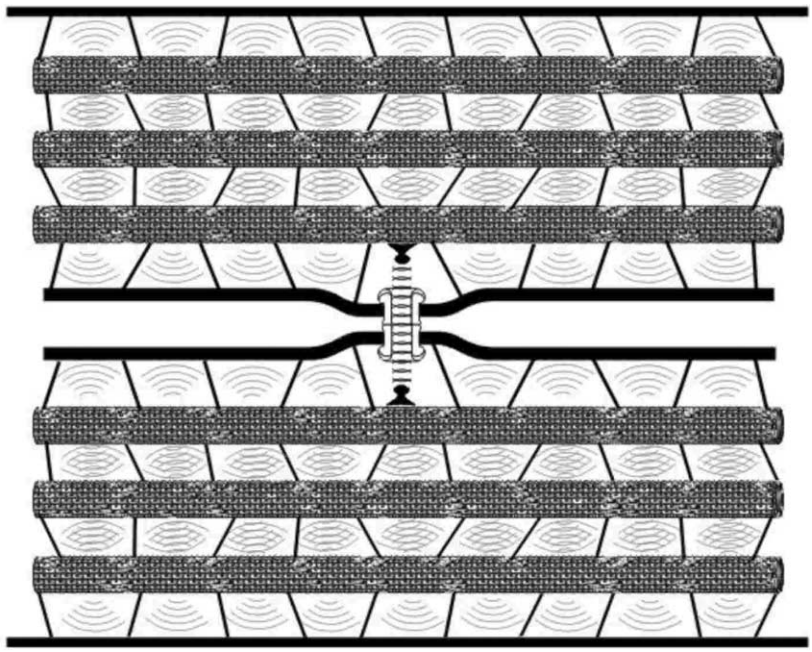

Fig. 16. Schematic representation of a gap junction connecting two dendrites in which MTs are in quantum superposition/quantum computation 'tuned' by interconnecting MAP proteins as suggested in the Penrose–Hameroff Orch OR model. On either side of the gap junction, dendritic lamellar bodies (DLBs) containing mitochondria may act as tunneling diodes to convey the quantum state between the dendrites.

Table 3
Enigmatic features of consciousness and possible solutions via the Orch OR model

Enigmatic feature of consciousness	Classical explanations	Possible Orch OR solutions
Essential nature of human experience ('qualia', the 'hard problem')	'Emergence': conscious experience emerges from computational complexity	Pan-protopsychist philosophy; qualia are fundamental features of spacetime geometry, accessed by quantum gravity OR
Unitary sense: 'binding problem'	Temporal synchrony e.g. coherent 40 Hz	(1) Non-local quantum coherence; indivisible macroscopic quantum state (e.g. Bose-Einstein condensate); (2) Instantaneous self-collapse of superpositioned states (Orch OR)
Transition from pre-conscious processes to consciousness	No apparent threshold	Collapse, or reduction of the quantum wave function, a la quantum computation
(Apparent) 'free will'	None	Non-computability in quantum gravity OR

Band theory (Brown and Tuszynski, 2001)

behaving like 'one giant neuron', and E.R. John (2001) has suggested that gap junction-connected neurons ('hyper-neurons') mediate zero phase lag coherence. Dendritic lamellar bodies are associated with synchronously firing neurons (De Zeeuw et al., 1997) and several studies (Galarreta and Hestrin, 1999; Gibson et al., 1999; Velasquez and Carlen, 2000) implicate gap junction-connected interneurons in the mediation of coherent ('40 Hz') oscillations. These gap junction-connected interneurons form 'dual' connections (gap junctions and GABAergic chemical synapses) with pyramidal cells and other cortical neurons. GABA inhibition could quiet membrane activities, avoiding decoherence to enable quantum states in neuronal cytoplasmic interiors to develop and spread among many gap junction-linked cells across wide areas of the brain. Thus gap junction-connected coherent 40 Hz neurons may support spatially extended quantum states.

4. Conclusion

Scientists speak of 'levels of theory', a hierarchy of models ranked by physical detail. The ultimate level would be a 'Theory of Everything'. One possible over-arching approach (suggested by Roger Penrose) attributes quantum state reduction to gravity. The Orch OR model asserts that this ultimate level is relevant to the physics of consciousness.

The discovery of the aromatic lattice within the microtubule has no immediately discernible implications at this ultimate level, but it suggests a host of new possibilities at simpler levels of theory (one-body quantum models, many-body quantum models, and quantum-field models). For example, in the Orch OR model it is assumed that neighboring dimers become entangled by the dipole–dipole interaction, which appears in the classical cellular automaton models of the microtubule. But it may be that mobile electrons following these newly recognized pathways contribute more to the entanglement process; tubulin dimers may become entangled indirectly, by way of interaction with strongly correlated mobile electrons.

Tables 4 and 5 list a few theoretical approaches to motion of electrons within the lattice of aromatic amino acids. These and others need to be explored and their predictions calculated (Brown and Tuszynski (2001) is a promising starting point). The structures of other biomolecules must also be examined, in order to show whether these pathways are unique to tubulin or found in many proteins. Logical candidates for examination include actin and other cytoskeletal proteins, the bacterial protein FtsZ, which is related to tubulin, and microtubule associated proteins such as MAP-2, MAP-4 and tau (Eva Nogales, personal communication).

ABSTRACT Several isotypes of the structural protein tubulin have been characterized. Their expression offers a plausible explanation for differences regarding microtubule function. Although sequence variation between tubulin isotypes occurs throughout the entire protein, it is the extreme carboxy-terminal tails (CTTs) that exhibit the greatest concentration of differences. In humans, the CTTs range in length from 9 to 25 residues and because of a considerable number of glutamic acid residues, contain over 1/3 of tubulin's total electrostatic charge. The CTTs are believed to be highly disordered and their precise function has yet to be determined. However, their absence has been shown to result in altered microtubule stability and a reduction in the interaction with several microtubule-associated proteins (MAPs). To characterize the role that CTTs play in microtubule function, we examined the global conformational differences within a set of nine human β-tubulin isotypes using replica exchange molecular dynamics simulations. Through the analysis of the resulting configuration ensembles, we quantified differences such as the CTTs sequence influence on overall flexibility and average secondary structure. Although only minor variations between each CTT were observed, we suggest that these differences may be significant enough to affect interactions with MAPs, thereby influencing important properties such as microtubule assembly and stability.

INTRODUCTION

Microtubules (MTs) are hollow cylinders constructed from linear chains of the protein tubulin. Tubulin is highly conserved throughout the entire eukaryotic kingdom, and the two main classes, α/β, are expressed from multiple genes, producing several isotypes with seemingly identical functions (1–3). At the cellular level, it has been hypothesized that MT stability is regulated by subtle variations observed between α and β isotypes (4–6). There is ~80%–95% sequence identity between isotypes; however, the extreme carboxy-terminal tails (CTTs) exhibit considerable differences, having only 50%–60% identity in this region (7,8). Early phylogenetic comparisons of the vertebrate β-tubulin families identified the CTTs, along with an internal variable domain, as the primary isotype defining features of the β-tubulin protein (9).

The importance of the CTTs has been demonstrated through their removal using limited proteolytic cleavage by substilisin. After cleavage, the critical tubulin concentration required for polymerization was found to be ~50 times lower than that for intact tubulin (10). This rate was shown to decrease further through the addition of MT-stabilizing compounds such as paclitaxel (11). Proteolyzed tubulin also exhibits altered protofilament-bending, resulting in the formation of sheets, bundles of twisted filaments, rings, unstructured aggregates, or MTs with reversed polarity (10,12). Finally, the presence of the highly charged CTTs is thought to obstruct tubulin/tubulin interactions, regulating the rate and conformation of MT assembly through unfavorable electrostatic interactions (13). This hypothesis is supported by the observation that divalent cations, or the substitution of acidic residues, results in an increased rate of MT assembly and a decreased rate of MT disassembly (14,15).

In addition to tubulin interactions within the MT itself, the functional stability of MTs in vivo has been shown to depend on interactions with MT-associated proteins (MAPs) through interactions with the CTTs. For example, the correct assembly of the kinetochore and the integrity of the mitotic spindle is dependent on the ability of the Dam1 complex to bind the CTTs of β-tubulin (16). Interactions between the CTTs and MAP2 or MAP τ have also been shown to result in the stabilization of MT structures in vivo (17,18). Interactions between kinesin and MTs may also be significantly modulated through direct contacts with the CTT (19) or through the indirect modulation of kinesin's ability to bind ATP (20). Recent evidence also suggests that the CTTs may play a role in apoptosis, as interactions between MTs and the proapoptotic and antiapoptotic members of the Bcl-2 family are also affected by the presence of the CTT regions of α- and β-tubulin (21), an observation that may offer a plausible explanation for the previously observed interactions between Bcl-2 and paclitaxel (22).

Although the presence of intact CTTs is seemingly essential for proper MT assembly and function, little is known about their structure and how this may affect interactions with other proteins. Several early studies have examined possible conformations of the CTTs using NMR and circular dichroism (CD) spectroscopy and demonstrated that there was

inherent disorder within the CTTs (23,24). Although a region of increased helicity toward the amino terminus was identified, a finding that was subsequently confirmed by electron crystallographic analysis, this has provided little additional information about CTT structure, as the last 10 residues of α-tubulin and the last 18 residues of β-tubulin were not visualized due to lack of density (25). A possible explanation for this lack of density is the nonhomogenous presence of tubulin isotypes in the MT preparations used in the crystallographic analysis. However, homogenous samples of $\alpha\beta$II and $\alpha\beta$III tubulin failed to improve the quality of density maps, and Nogales et al. (25) concluded that their lack of resolution was indeed due to disorder in this region.

Fortunately, molecular modeling provides us with the unique ability to examine conformations of the CTTs at a level of detail experimental analysis is unable to yet provide. However, even modeling has its limitations in this regard, where a persistent problem with low temperature protein-folding simulations is that of obtaining adequate sampling. This problem exists because simulations generally become trapped in one of a large number of local energy minima. Several generalized ensemble algorithms, based on non-Boltzmann probability weight factors, are capable of overcoming this problem by introducing a random walk in energy space (26). However, it is often not a trivial matter to determine the non-Boltzmann weight factors, and for this reason we chose replica exchange molecular dynamics (REMD) as a method to examine possible conformations of the tubulin CTTs (27,28). REMD utilizes a large number of parallel simulations at different temperatures, with exchanges between trajectories attempted periodically using Metropolis criteria. All replicas of the system then perform a random walk through temperature space and, as a consequence, also through energy space. A replica may therefore overcome an energy barrier through exchange with replicas at higher temperatures. This allows configurations to be sampled at a given temperature on timescales not otherwise possible while still maintaining a thermodynamically consistent ensemble of configurations. Here, we discuss the creation of nine models of human β-tubulin CTT peptides using REMD and their analysis for relative conformational flexibility within the ensemble.

METHODS AND MATERIALS

Peptide construction and system configuration

Based on our previous examination of β-tubulin isotypes, we chose a set of nine peptides corresponding to the consensus CTT sequences of βI (GI:34222261), βII (GI:68299771 and GI:42476191), βIII (GI:50592995), βIVa (GI:21361321), βIVb (GI:68051719), βV (GI:14210535), βVI (GI:41152077), βVII (TUBB4Q) (GI:55770867), and βVIII (TUBB8) (GI:42558278) (Table 1) (8). Accession numbers correspond to Entrez Nucleotide expressed mRNA sequence IDs contained only within the human genome. Using the crystallographic structure of tubulin (Protein Data Bank (PDB) ID: 1JFF) as a guide, we selected the conserved DA[TK]A motif that is positioned at the extreme end of helix H12 as the initiation point for the construction of all the peptides (29). This position marks the beginning of the structurally undefined region of the CTT in the structure and the domain examined using NMR and CD spectroscopy (23,24). All nine CTTs were prepared identically in an extended conformation, having the N-terminal charge neutralized by capping with an acetyl group using the PyMol v0.99 residue and fragment builder facility (30). The conventional protonation state at pH 7.0 was used for all residues, with a focus on His, which was protonated on the ε nitrogen throughout.

TABLE 1 ClustalW multiple sequence alignment of the CTT sequences

Isotype	Sequence	Length	Charge
I	DATAEEEED-FGEEAEEEA	18	−12
II	DATADEQGE-FEEEEGEDEA	19	−12
III	DATAEEEGEMYEDDEEESEAQGPK	24	−12
IVa	DATAEEGEF-EEEAEEEVA	18	−11
IVb	DATAEEEGE-FEEEAEEEVA	19	−12
V	DATANDGEEAFEDEEEEIDG	20	−12
VI	DAKAVLEED-EEVTEEAEMEPEDKGH	25	−11
VII	DATAEGGGV	9	−3
VIII	DATAEEEED-EEYAEEEVA	18	−12

The length and net charge at pH 7.0 was determined for each peptide, including the C-terminal cap.

Parameterization and model preparation

All calculations utilized the AMBER99 force field (31,32), which was applied using PDB2GMX in GROMACS 3.3 (33). Each peptide was placed in a rhombic-dodecahedron unit cell consisting of ~2800 TIP3P waters (34). Sodium and chlorine counterions were added to the most energetically favorable locations (as determined using GENION) such that the net charge of the system was neutralized and a final ion concentration of 100 mM was established. For all molecular dynamics (MD) and REMD calculations, rigid bonds were maintained using the LINCS algorithm for the peptide and SETTLE for waters. Particle Mesh Ewald (PME) was used for electrostatic interactions with a cutoff of 0.8 nm and a Lennard-Jones cutoff of 1.0 nm. Constant pressure was maintained by allowing the box size to fluctuate isotropically. Each system was minimized using a low-memory Broyden-Fletcher-Goldfarb-Shanno minimizer in GMXRUN until machine precision was achieved. This was followed by 20 ps of heating and 1.1 ns of equilibration.

REMD

To achieve a transition probability of 0.3, 43 target temperatures between 273 and 382 K were selected. Each replica was then heated/cooled to its target temperature over 50 ps and simulated without exchange for 500 ps, followed by 500 ps of REMD. Production REMD runs consisted of 10 ns of dynamics for each replica with exchanges attempted every 5 ps. Energy and conformational snapshots were saved every 1 and 10 ps, respectively. For each isotype, this produced an ensemble of 43,000 conformations and an aggregate simulation time of 430 ns over all temperatures.

Cluster analysis

A cluster analysis of the resulting REMD conformations was used to determine preferred conformations and relative populations of each peptide. The GROMOS clustering algorithm (39), implemented in G_CLUSTER, was used for this purpose. All Cα atoms were root mean-square deviation (RMSD) fit to the extended starting structure, and an RMSD cutoff was set for the Cα atoms; for each structure from the ensemble, all structures within

this cutoff were assigned as neighbors. The structure with the most neighbors was then identified as the center of a cluster and was removed from the pool with all its neighbors. This process was repeated until all structures had been assigned to a cluster. The RMSD cutoff was chosen such that the largest cluster contained 50% plus 1% of the structures.

Principal component analysis

As MD simulations tend to produce immense quantities of data, principal component analysis (PCA) is a powerful mathematical tool used to detect correlations in MD trajectories (40,41). To perform PCA, all of the conformations from the REMD ensemble were RMSD least squares fit to the reference structures, effectively removing all rotations and translations. Then, for non-mass-weighted PCA, the covariance matrix can be calculated as

$$\sigma_{ij} = \langle (r_i - \langle r_i \rangle)(r_j - \langle r_j \rangle) \rangle,$$

where $r_1 \ldots r_{3N}$ are the Cartesian coordinates of the N atoms used in the analysis and $\langle \ldots \rangle$ denotes the ensemble average. The resulting matrix can then be diagonalized, and the resulting $3N$-dimensional eigenvectors, $\mathbf{v}_i$, are organized in descending order of eigenvalues, λ_i. Eigenvalues represent the variance along their associated eigenvector, and the larger the eigenvalue the more significant the correlated motion.

A PCA of all nine isotypes of β-tubulin was performed at 311 K using the positions of all Cα atoms. To mimic the CTTs bound at their N-terminus, the backbone atoms of the first three amino acids of the ensemble were RMSD fit to the reference structure for the isotype at 311 K, producing an average structure (Fig. 1). This was essential for the physiological relevance of the PCA calculation and the considerable motion of the CTTs. Eigenvalues of different isotypes cannot be directly compared, as different numbers of atoms were used in the covariant analysis. This can be overcome by normalizing the eigenvalues by the number of atoms used in the analysis:

$$\sigma_i = \sqrt{\frac{\lambda_i}{N}},$$

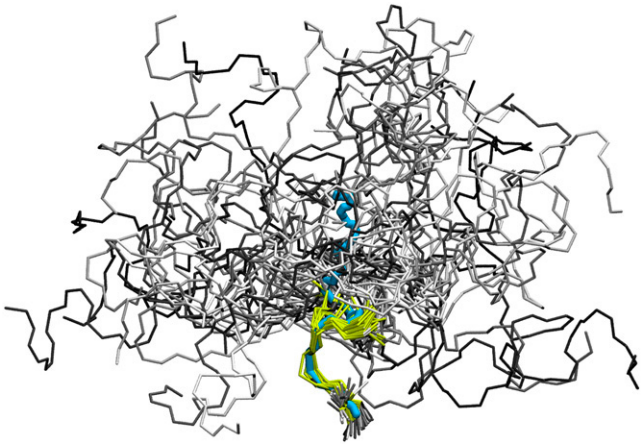

FIGURE 1 Human β-tubulin CTT sequence alignment and consensus. Illustration of reference and average structures used for PCA. The N, C, and Cα atoms from the three N-terminal residues of each conformation from the βI ensemble were RMSD fit to a representative structure backbone. The backbone atoms of 50 randomly selected conformers of the ensemble are shown in black, gray, and white to delineate conformers in no specific order. The first four residues of each peptide are shown in yellow. The average structure, used for subsequent PCA calculations, is shown in light blue. Image produced using VMD (63).

where σ_i is the root normalized eigenvalue representing the standard deviation along the ith eigenvector.

Sequence alignments

Sequence alignments of CTTs were performed with the default values using the European Bioinformatics Institute Clustal server (http://www.ebi.ac.uk/clustalw/), with the exception that the extended gap penalty was increased to a value of 0.5 (Table 1).

Motif identification

Structural motifs within the CTT ensemble were identified by performing pairwise alignment of each CTT sequence using the ClustalW alignment facility in MacVector (MacVector, Cary, NC). Motifs were identified as those sequences containing at least four consecutive identical residues. A structural similarity search was then performed using only sequence runs of four or more identical or similar residues. Structural similarity was determined by calculating the ρ_{sc} between all pairs of conformations from the ensembles of each isotype to create a 1001 $\times$ 1001 matrix. Here, ρ is defined as

$$\rho(A,B) = \frac{2 \times \mathrm{RMSD}(A,B)}{\left(R_{gyr}^2(A) + R_{gyr}^2(B) - \mathrm{RMSD}^2(A,B)\right)^{1/2}},$$

where A and B are structures with an equal number of points, R_{gyr} is the radius of gyration, and RMSD stands for the RMSD of the two structures. To obtain ρ_{sc}, we translate the centroid of each structure to the origin and rotate it such that the principal axes of inertia lie on the coordinate axes. Then, for both structures, we satisfy the condition that $R_{gyr}=1$ by scaling each axis independently such that each contributes equally to the radius of gyration. The ρ_{sc} provides a length-independent measure of conformational similarity of two structures (42). Structures with a ρ_{sc} of 0 are considered identical; those with a factor of 2 are considered maximally dissimilar. Mirror images have a value of $\sqrt{2}$, whereas structures with a factor of 0.3–0.5 indicate visual similarity. The fraction of conformational pairs with a ρ_{sc} of <0.3 is the fraction of time that regions within the two isotypes are structurally similar. See Table 3 for regions that showed higher than 50% ρ_{sc} similarity between isotypes.

RESULTS

Amino acid composition of CTT consensus sequences

The absolute length of each human β-tubulin CTT ranges from 9 to 25 residues; however, their typical length falls between 18 and 20 residues (Table 1). The exceptions are βVII, which contains only nine residues, and βIII/βVI, which have 24 and 25 residues, respectively. Although the overall amino acid composition of each CTT is quite similar, there are some notable factors to consider. When we examine all nine human CTT sequences in aggregate, the residue that occurs most frequently is Glu (42%). The occurrence of all other residues drops significantly from this value: Ala (18%), Asp (12%), Gly (8%), Thr (5%), Val (4%), and Phe (3%). The βVIII CTT contains no Gly, the βIVa/b CTTs have a proportionally low Asp content, and, finally, the βVII CTT has a reduced Glu content, which may simply be a result of its length. Interestingly, the remainder of the amino acids

occurs exclusively in the βIII (Lys, Met, Pro, Gln, Ser, and Tyr), βV (Ile, Asn), and βVI (His, Lys, Leu, and Pro) CTTs at frequencies of 1% or less. Finally, Cys, Trp, and Arg are absent from all the CTT sequences.

REMD and completeness of sampling

A notable exclusion from these simulations is the tubulin protein itself, a factor that will undoubtedly influence the results as they have been explained here. The decision to exclude the bulk tubulin was made due to its large system size and the computational resources that would be required to explore the conformational space of an entire tubulin dimer. Therefore, simulations of only the CTTs become a problem of protein folding, and adequate sampling is critical to the proper interpretation of the results. To increase sampling efficiency at different temperatures, we used replica exchange MD (REMD), which does not provide information on the dynamics of the system. However, as our ultimate interest is in the overall conformations of the CTTs, the loss of dynamics data was an acceptable compromise to gain increased sampling.

The completeness of sampling can be determined by calculating the normalized overlaps between two different parts of an MD trajectory. Such overlaps can indicate whether or not both parts are spanning over the conformational space equally and not diffusing to new parts (43–45). Subspace overlap between two sets of n orthonormal vectors $\mathbf{v}_1, \ldots, \mathbf{v}_n$ and $\mathbf{w}_1, \ldots, \mathbf{w}_n$ is defined as

$$\text{overlap}(\mathbf{v}, \mathbf{w}) \equiv \frac{1}{n} \sum_{i=1,j=1}^{n,n} (\mathbf{v} \times \mathbf{w})^2.$$

When the overlap has a value of 1, the sets $\mathbf{v}$ and $\mathbf{w}$ can be considered to span the same subspace. This measure, however, does not account for the magnitudes of the eigenvalues, meaning that differences between all eigenvectors contribute equally. Furthermore, when two or more eigenvalues are equal, the corresponding eigenvectors are random, causing a random variation in the subspace overlap number. An alternative method, suggested by Hess (45), is the normalized overlap, defined as

$$d = \sqrt{\text{tr}\left(\left(\sqrt{C_1} - \sqrt{C_2}\right)^2\right)}$$

$$\text{normalized overlap}(C_1, C_2) = 1 - \frac{d}{\sqrt{\text{tr}\left(C_1\right) + \text{tr}\left(C_2\right)}},$$

where d is the difference between the covariant matrices, C_1 and C_2, and tr is the trace. Here, if the overlap is 0, then the two sets are considered to be orthogonal, whereas an overlap of 1 indicates that the matrices are identical. Covariant analysis of the trajectories from each isotype at 311 K, chronologically divided into thirds, was performed using the same procedure used for the PCA. The subspace and normalized overlaps calculated between each of these thirds are reported in Table 2. The high overlap between the thirds indicates that each part of the simulation is sampling approximately the same conformational space, and it is unlikely that there are unexplored regions missed earlier in the run. Although not a guarantee of complete equilibrium sampling, we concluded that the overlap using both of the above mentioned methods is acceptable and that adequate sampling within all of these systems has been obtained.

TABLE 2 PCA overlap of CTT peptides

PCA overlap at 311 K for N-terminus fit						
	Subspace overlap			Normalized overlap		
Isotype	1st vs. 2nd	1st vs. 3rd	2nd vs. 3rd	1st vs. 2nd	1st vs. 3rd	2nd vs. 3rd
I	0.93	0.95	0.95	0.86	0.84	0.86
II	0.90	0.87	0.92	0.84	0.77	0.78
III	0.94	0.91	0.95	0.82	0.78	0.86
IVA	0.92	0.84	0.91	0.77	0.62	0.75
IVB	0.93	0.89	0.89	0.78	0.76	0.83
V	0.92	0.89	0.89	0.75	0.78	0.76
VI	0.88	0.88	0.94	0.72	0.71	0.84
VII	0.96	0.91	0.98	0.70	0.56	0.76
VIII	0.92	0.86	0.94	0.79	0.76	0.85

The subspace overlap consists of the first 10 eigenvectors only. For both overlap calculations, the ensemble was divided into thirds and all are compared to each other.

Clustering and secondary structure

Clustering each CTT peptide can provide a representation of probable folded conformations; however, a bell-shaped ρ_{sc} distribution about a representative structure demonstrates that there is actually no native folded conformation for most of the isotypes (Fig. 2). The only exception was the βVII CTT, which exhibited a significant population of folded structures with a $\rho_{sc} < 0.5$ and a second population of unfolded structures with a $\rho_{sc} > 0.5$. These results recapitulate previous observations that the CTTs are extremely flexible, and any structures within them are transient in nature and cannot be captured by the clustering methodology used in this study. Therefore, we felt that a more appropriate analysis was to consider the ensemble average of secondary structures as calculated from the entire 10 ns of ensemble conformations at 311 K by STRIDE (46) (Fig. 3). These results demonstrated that, whereas the ρ_{sc} distribution showed no native folded conformations, many of the CTTs contain regions that are either α- or 3–10-helical at least 40% of the time.

Motif identification

Having established the presence of transient secondary structures within the ensembles, we performed pairwise alignments of all the CTT sequences to identify potential sequence

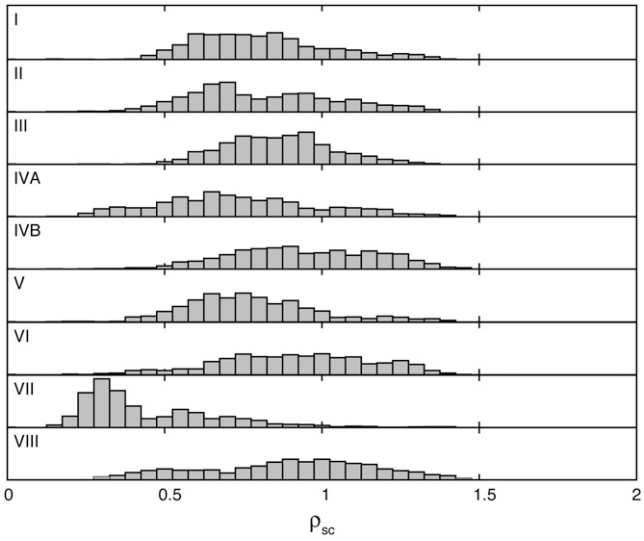

FIGURE 2 ρ_{sc} distributions of CTTs about representative structures. The large spread in the histograms of the $\boldsymbol{\rho_{sc}}$ distributions for each CTT indicates the lack of a single folded conformation. A distinct population of 67% conformers have a $\boldsymbol{\rho_{sc}} < 0.5$ for the βVII isotype, suggesting a distinct folded conformation for this CTT.

motifs with which to correlate our modeling results. A ρ_{sc} matrix was then calculated for all the conformations across each isotype at 311 K. Only those motifs having a high fraction of low ρ_{sc} were determined to be significantly similar (ρ_{sc} of 0.3 or less) (Table 3). Through this analysis, we identified two motifs that showed both sequence and conformational similarities. To visually compare the motifs, the conformations of the aligned subsequences were clustered as described in Materials and Methods. Illustrated in Fig. 4 are RMSD alignments of representative structures (those with the most neighbors) from each isotype containing the respective motif. The first of these motifs was identified as a probable casein kinase-2 (CK-2) binding motif at the N-terminal end of the peptide (Fig. 4 *A*). This motif was also independently identified using a Prosite search for motifs within each of the CTT sequences (47) (not shown). The second motif was determined to correspond to a previously identified MAP2 binding motif found within α-tubulin (Fig. 4 *B*) (48). We should note that although a common conformation for each of the motifs across isotypes has been identified, these are not stable folds; and depending on the isotype and residues included in the search, anywhere between 1% and 69% of the ensemble structures have a $\rho_{sc} < 0.3$ when compared to the motif conformation.

PCA

Not only is the secondary structure of each CTT significant, but their flexibility is also of critical importance when attempting to understand how they are able to conform when interacting with MAPs. Because of the complex interplay of many factors, sophisticated statistical analysis of conformational ensembles, such as PCA, appears to be the most appropriate computational tool to characterize the flexibility. PCA was performed on the ensemble at 311 K, with the backbone atoms of the first three residues RMSD fit to a reference structure (Fig. 1). Resulting eigenvectors were ordered by descending eigenvalues, which represent the variance of the motion along the principal components. In Fig. 5, the six largest root normalized eigenvalues are shown for each isotype. Except for βVII and βIVa, to a lesser extent, three components can be identified with prominent eigenvalues of comparable magnitude, which is significantly higher than the magnitude of other eigenvalues. The three components with the largest eigenvalues represent correlated motions of the peptide fragments with the most significant standard deviations of the motion along the corresponding orthogonal directions. Since the standard deviations shown in Fig. 5 were normalized for the number of residues, they can be employed as a universal measure for comparison of conformational motions in different CTT peptides.

Two-dimensional projections of the REMD conformation ensemble

A more detailed representation of the conformational motions in peptides is provided by projections of the ensemble of conformations onto the planes spanned by the most important principal components (Fig. 6). Here, the spatial distributions of occupancies of the various conformational states are shown over the planes spanned by the first and second and by the first and third principal components. A representative isotype, βV, illustrates that both distributions are smooth and without evidence of considerable clustering. Similar behavior exists in all isoforms considered except for βIVa and βVII, which show significant clustering of conformational occupancy, with maxima at (0.1,0) and (−0.2,0), respectively. The widths of the distributions shown in Fig. 6 are not directly dependent on the length of the peptide, as the eigenvalues have been normalized by the number of residues. The reduced width of βVII, therefore, indicates its reduced mobility. The bin size of the histogram has been chosen in proportion to the width of the distribution; so the maxima seen for βIVa and βVII are not artifacts of the sampling but represent regions of increased occupancy. Since the occupancy of a conformational state is inversely proportional to the free energy of that state (49,50), the lack of clustering in the other isotypes suggests that the global minima are broad or that there are generally no significant local minima. In contrast, βVII has a significant basin of attraction, indicative of a folded conformation. This observation is consistent with the preceding cluster analysis, which identified a well-defined folded state in the βVII isoform only. Although less defined, the occupancy distribution for βIVa also exhibits a preferred folded conformation, demonstrating that the PCA methodology is more sensitive to transient structural motifs than the

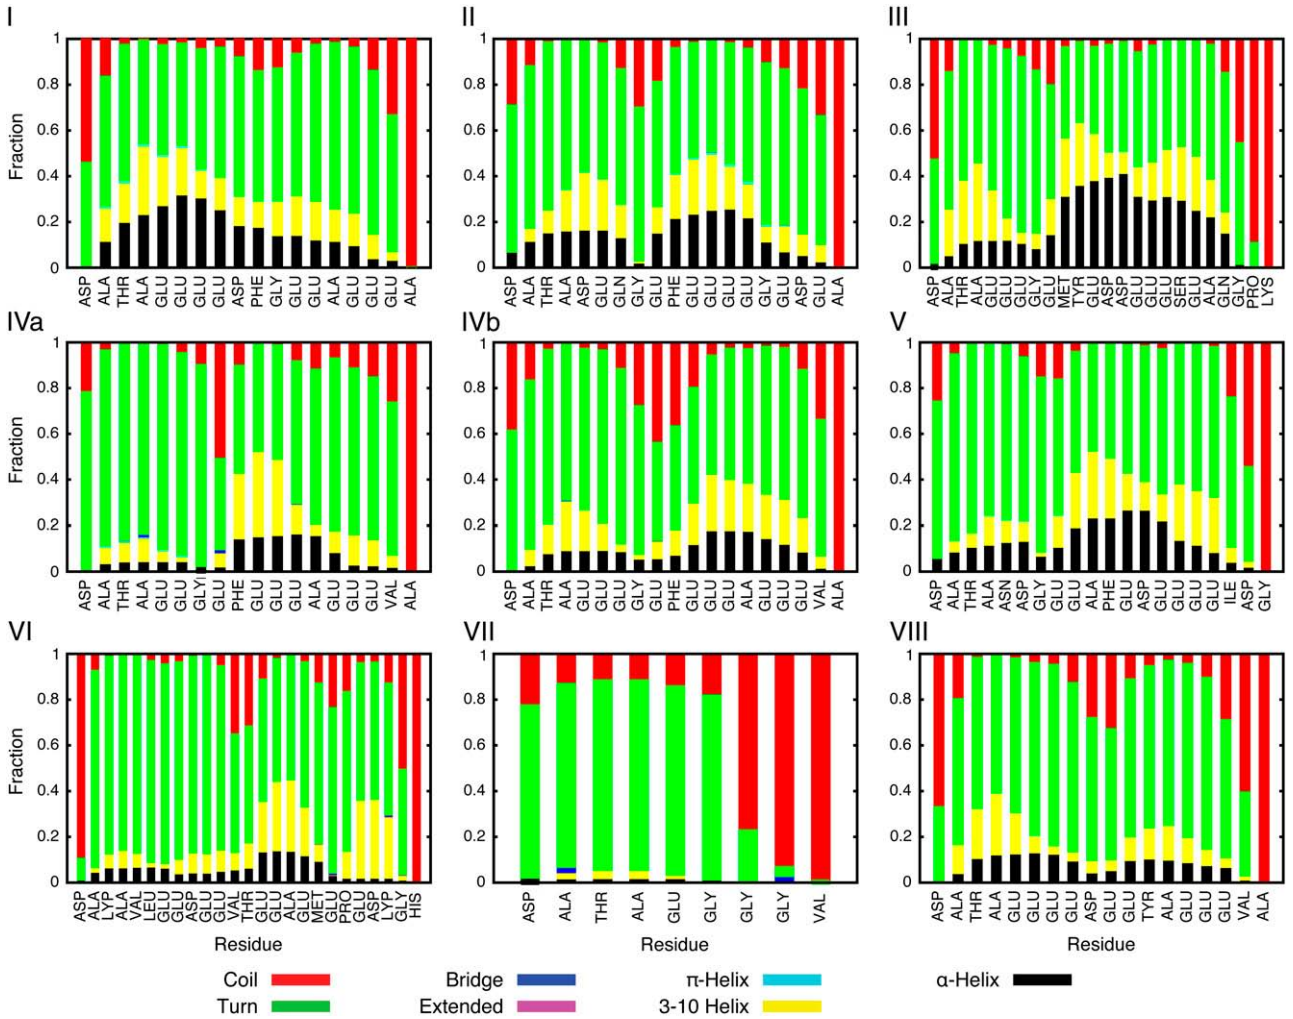

FIGURE 3 Time average of each type of secondary structure for each CTT. The total fractional secondary structure content was determined as an average over the entire 10 ns MD simulation at 311 K. The fractional time averages of each type of secondary structure are stacked to sum up to one. Although experimental studies of tubulin suggest that the CTTs are unstructured, these results suggest that many of the CTTs contain a significant amount of transient helix.

clustering analysis. One more noteworthy feature is that the two-dimensional distributions over the first and second components are largely similar to those over the first and third components, suggesting a significant level of symmetry among principal components.

Relative CTT flexibility

In addition to information regarding the motion of each CTT peptide, PCA provides the ability to compare relative flexibilities. As we studied only the nine human β-tubulin isotypes, it is not possible to comment on the flexibility of the CTT peptides in an absolute sense. However, there have been a few studies discussing the flexibility of small peptides. Although they use a different approach to calculating the flexibility, Ma et al. made a survey of 28 short peptides and determined that the native helical structures of the peptides were more flexible than random or disordered conformations, in agreement with our observations (Fig. 7 *B*) (51). Unfortunately, their methodology, calculating the vibrational free energy, does not allow comparison of flexibility between peptides. Here, as a measure of the relative flexibility of each peptide, the eigenvalues of principal components were compared. To characterize the flexibility, we employed the value $\sigma_{12} = \sqrt{\sigma_1^2+\sigma_2^2}$, where σ_1 and σ_2 are the normalized eigenvalues for the first and the second principal components, respectively. The magnitude of the PCA eigenvalue parameter σ_{12} can be viewed as the mean square width of the two-dimensional REMD configuration ensembles shown in Fig. 6, and thus σ_{12} can be directly interpreted as the flexibility of the peptide associated with its major correlated motions. Although the CTTs are characterized by three principal components (Fig. 5), the considerable symmetry between the second and third component demonstrated in Fig. 6 allows the use of only two components out of three to quantify the flexibility of CTTs. The correlations between the normalized distance (the distance between the N- and C-termini Cαs, divided by the number of residues),

Pairwise alignments of each CTT sequence identified several similar regions between peptides. Structural similarity between sequences was determined by calculating the ρ_{sc} between all pairs of conformations. Those pairs with high conformational and sequence similarity were used to characterize the motif conformations for the CK-2 and MAP2 domains (Fig. 4).

the time-averaged helical content, and the average clustering parameter $\langle \rho_{sc} \rangle$ with the value σ_{12}, which we use as the major measure of flexibility, can be seen in Fig. 7.

DISCUSSION

The CTT's involvement in MT regulation is critical; it is essential to understand the conformational differences adopted by different tubulin isotypes. We suggest that the sequence variability within the CTTs may have arisen as a mechanism to conserve the overall tubulin structure to maintain proper MT assembly, while still providing a flexible, solvent-exposed region of increased variability for interactions with proteins that affect MT function (see alignment in Table 1). This is both an attractive and reasonable hypothesis, as the role of intrinsically disordered proteins in protein interactions has been implicated as a mechanism to enhance specificity (52). The following discussion addresses three main points about the CTTs and their interactions with MAPs: first, the relative flexibilities of each of the CTT peptides; second, the presence of transient structure within these peptides; and finally, how this may influence protein interactions. We will discuss this possibility further when examining CTT flexibility in the context of MAP interactions, in particular interactions with the CK-2 and MAP2 binding motifs that we identified in this work.

CTT flexibility and secondary structure

Accurate flexibility and secondary structure measurements are critical when the goal is to propose mechanisms for MAP interactions with the large number of possible CTT conformations on the MT surface. The overall distribution of amino acids within the CTT will obviously have an effect on their

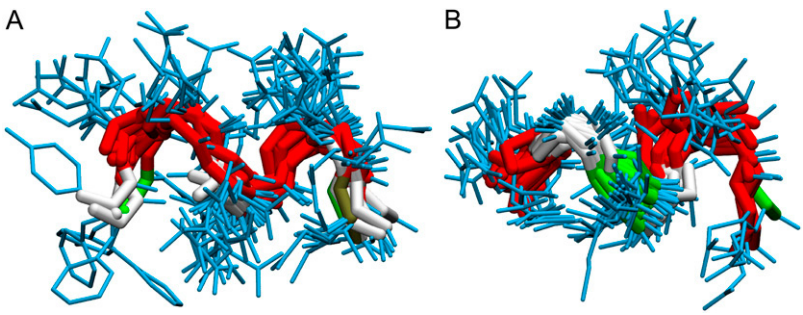

FIGURE 4 Sequence motif identification. High scoring sequence pairs from Table 3 were RMSD fit to illustrate the overall fold and position of side chains in the structural motifs. In both images, red residues are acidic, white residues are nonpolar, green residues are polar, and all side chains are blue. Image created using VMD (63).

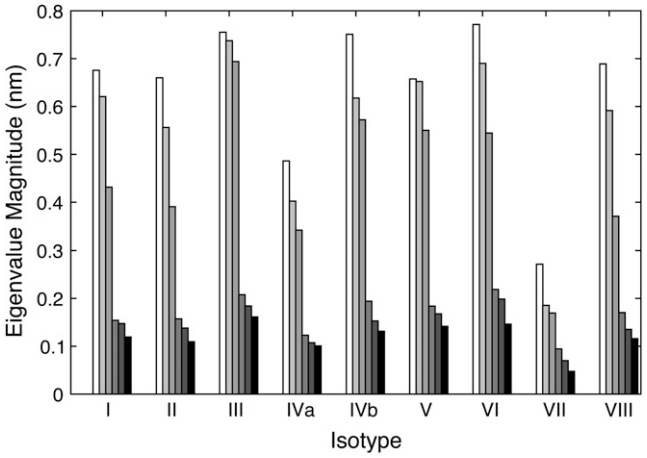

FIGURE 5 Root mean-square normalized eigenvalues for each isotype. The magnitudes of the first six root normalized eigenvalues (*white* to *black*) are shown for each isotype and represent the standard deviation of the motion along the eigenvector normalized for the overall length of the peptide. The relative size of the root-normalized eigenvalues indicates the relative flexibilities of the individual peptides.

flexibility and result in secondary structure. For example, the overall helical propensity of βII, βIII, βIVa, βIVb, and βV is interrupted by the presence of Gly (Fig. 3). Additionally, regions with uninterrupted stretches of Glu also tend to produce regions with greater helical propensity, providing an argument for the prevalence of this residue within the CTT sequences. This observation can be compared with the results of Roe et al. for simulations performed on decaalanine (53). Although shorter than all but the βVII peptide, the overall α- and 3–10-helical content within decaalanine was similar to the helical content observed here. However, through the analysis of the distribution of secondary structure along the CTT sequences, we note that our results differ from that of Roe et al. in that the helical content of the CTTs drops near the middle of the sequence for most isotypes whereas for decaalanine the central residues have a maximal amount of helix.

Three characteristics emerge which are representative of the behaviors of CTTs: the end-to-end distance, normalized by the number of residues, the PCA-based eigenvalues, and the averaged helical content (Fig. 7, *A* and *B*). To test the applicability of PCA as a measure of relative flexibility, we compared PCA-based flexibilities with the average parameter of structural similarity $\langle\rho_{sc}\rangle$, which we computed from the distributions in Fig. 2 (Fig. 7 *C*). Although less detailed than PCA, the distributions of conformations over the parameter ρ_{sc} provide an alternative statistical characterization of the CTTs configurations, and thus they can be expected to correlate with the PCA-based results. The correlation between the PCA-based flexibilities and $\langle\rho_{sc}\rangle$ is more pronounced than any other correlation that we investigated. Most of the CTTs show a clear proportionality between σ_{12} and $\langle\rho_{sc}\rangle$, and the variability of $\langle\rho_{sc}\rangle$ that corresponds to similar σ_{12} is $<15\%$. This similarity of results from two fundamentally different statistical tools demonstrates that these statistical methodologies are the best suited to characterize CTTs' flexibility. Interestingly, rather than the expected exponential decay, the magnitudes of the first three eigenvalues are of similar magnitude and significantly larger than the remaining eigenvalues, indicating an isotropy of occupancies in the three-dimensional space (Fig. 5).

More simply, the CTTs are flexible enough for the ensemble of their configurations to be spherically symmetric with respect to an immobilized base of amino acids (Fig. 1). Since these three eigenvalues are significantly larger than all the others, three-dimensional symmetry is likely reached through a few highly flexible bonds within the peptides that allow rotations of large angles, thereby generating nearly spherically symmetric distributions of occupancies. In Fig. 6 this is illustrated by a comparison of the histogram for βV, which is representative of a significant level of symmetry typical for most isotypes, with the less symmetric ones for

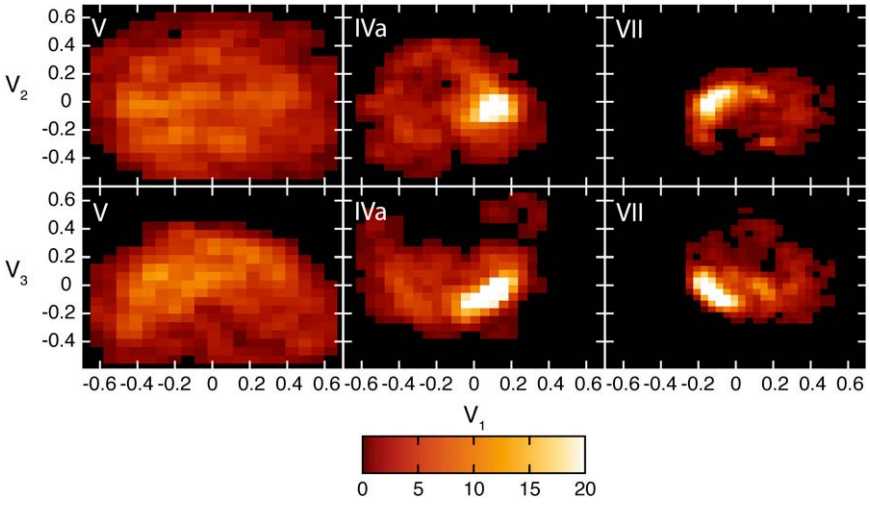

FIGURE 6 Projections of the ensemble of conformations onto the planes of the three most important principal components. The first and second principal components (*upper row*) and the first and third principal components (*lower row*) are plotted on the *x* and *y* axes, respectively, for βV, βIVa, and βVII. The histograms represent the occupancies of the corresponding conformation states, with lighter colors indicating more frequently visited areas. The same coloring scheme is used for all isotypes and is capped at 20 counts. βV is typical of the remaining isotypes in the width of the distribution and lack of a significant maxima.

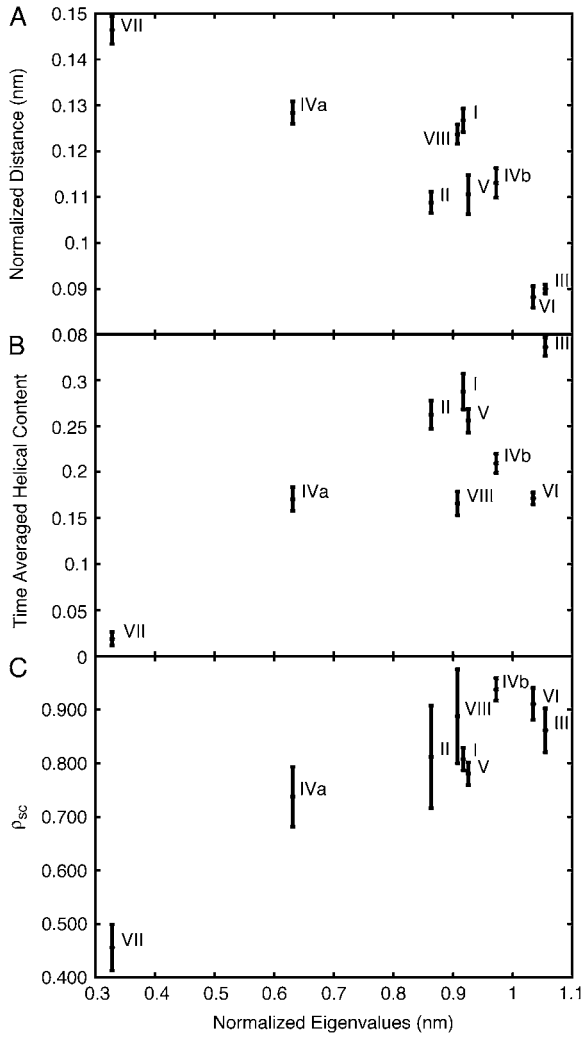

FIGURE 7 Peptide's flexibility indicators. The end-to-end distance normalized by the number of residues (*A*), time average helicity (*B*), and $\langle \rho_{sc} \rangle$ (*C*) of each CTT peptide at 311 K plotted as functions of σ_{12}. The plots demonstrate the correlation between each of the above values and the major flexibility indicator, σ_{12}. In *b*, βVI can be excluded from the trend due to the presence of a Pro, which disrupts the secondary structure but contributes to the flexibility of the peptide. The error in all three plots is the standard error calculated using box averaging (64).

βIVa and βVII. As the magnitudes of the eigenvalues shift to an exponential decay, spherical symmetry is lost and correlated motions begin to appear. At the same time, an individual CTT may preserve relatively stable motifs contained within some secondary structure. In terms of the PCA results presented in Fig. 5, these motifs are represented by the fourth, fifth, and higher eigenvalues. The fact that these components, although significantly less pronounced than the first three, still have considerable nonzero eigenvalues indicates that the conformational motifs within the CTTs are of transient nature and subject to variability over the trajectory. This is consistent with our observation of a significant amount of transient helicity (Fig. 3), indicated by a substantial amount of 3–10-helix.

Considering the PCA eigenvalue parameter σ_{12} as the measure of flexibility, it is evident that the βIII and βVI CTTs are the most flexible of all CTTs. These are the longest two sequences, which may account for some of their flexibility, but interestingly they also have the shortest end-to-end distance per residue. The cause of these shared structural properties differs in the two cases: whereas the βIII CTT has among the highest degree of secondary structure, the βVI CTT has among the lowest. The βVI CTT differs from all the other fragments, as it contains a Pro near the C-terminus of the peptide. This Pro breaks the helical structure of the fragment and, at the same time, does not facilitate an extended conformation. This accounts for the lack of secondary structure but is in contrast to βIII, which lies predominantly in the α-helical region of the Φ/Ψ distribution. When accounting for the lone Pro and omitting the data for βVI, the correlation between helicity and flexibility becomes greater. The βII, βIVb, and βV CTTs show the same spring-like flexibility of βIII, exhibiting a similar helical content and moderate end-to-end distance per residue. These CTTs also contain Gly at the same position that breaks the helical content of the fragment. In contrast, the βIVa and βVII CTTs displayed the least amount of flexibility. In the case of βIVa, one reason for this reduction in flexibility may be the early occurrence of Gly in its sequence, which stiffens this region of the peptide by decreasing the helicity. This decrease in helicity in the first seven residues, compared to βIVb, can be seen in Fig. 3. βIVa also contained the most stable DA[TK]AEE motif (data not shown), which resulted in the largest normalized distance of all the common isotypes.

The observation that peptides containing a significant amount of transient helical conformations are more flexible than an extended one may seem counterintuitive. The correlation between the normalized distance and flexibility in Fig. 7 *A* is most easily understood in terms of entropy. Take the following example: the freely jointed, or ideal chain, polymer model states that compact forms of the polymer contain more states that are accessible (i.e., have greater entropy) than do extended states (54). Thus, an entropic force drives the polymer or polypeptide into compact conformations. A greater number of accessible states suggests that the chain is more flexible and that extended states are more rigid. Although the ideal chain has no internal energy and is free to collapse, a peptide fragment does contain internal energy that can stiffen the peptide. The source of the force that causes the peptides to be in a rigid, extended state is the peptide backbone. Individual residues that induce a compact conformation through helical propensity or residues that induce a turn (such as proline) provide flexibility to the structure of the peptide while reducing the normalized distance. However, there is not a complete one-to-one correspondence between the flexibility and the normalized distance. For example, βI and βVIII have a normalized distance comparable to βIVa but a σ_{12} closer to the more compact βV. Although the normalized distance of the peptide is a strong indicator of flexibility,

the details of the compact structure, such as the degree of helicity, also contribute. We are not the first to observe this phenomenon in peptides; Ma et al. calculated the vibrational free energy of 28 short peptides in native helical and random extend states and determined that the native helical structures of the peptides were more flexible in all cases (51).

It is becoming clear that each β-tubulin isotype has a unique pattern of expression ranging from specific for βII, βIII, βIVa, and βVI to constitutive for βI and βIV (56,57). The βI isotype is the most commonly expressed in humans and, as such, is also the most common isotype found in cancer cells (58). Our observations also suggest that the CTT of this isotype shows ''typical'' behavior in our analysis. It is difficult to correlate our results to biological function; however, a clear pattern illustrating βIII as a statistical outlier has emerged. The βIII CTT was one of the most flexible peptides and contained a large amount of transient secondary structure. This is interesting, as βIII-tubulin has been observed at increased levels in human tumors and implicated in the development of drug resistance to standard chemotherapy treatments (59–61). In addition to the altered expression of βIII, the alteration of tubulin regulatory proteins such as MAP4 has also been implicated in changes to MT dynamics and the development of drug resistance (62). Because several MAPs have now been shown to interact directly with the CTTs (16–19,21), the differences that we observed here may have a significant impact on their affinity to the surface of an MT.

Motifs and MAP interactions

Using the conformational similarities for each CTT peptide, in combination with sequence comparisons, we identified two distinct transient structural motifs (Table 3). Several similar regions were observed as significant conformations throughout the trajectory files, indicating that they may be common motifs that could potentially be recognized by MAPs. The first motif was identified as a putative CK-2 phosphorylation site for which the consensus motif has been identified as [ST]XX[DE] (47). All of the CTTs, with the exception of βVI and βVII, were shown to contain this motif within the conserved DA[TK]A sequence. The second motif identified was the MAP2 binding site, for which the consensus sequence has previously been characterized as EEAEEE (48). Only the CTT of βI, βIVa, and βIVb strictly contain this motif; however, most of the other CTTs also contain a similar motif (Table 3). The conformations identified for βI, βIVa, βIVb, and βVI most commonly form a transient helix that is between four and five residues in length. In βVIII, there seems to be an increasing amount of unstructured loop associated with this region, which is most likely a result of the displacement of the amino end due to the presence of a bulky Tyr residue. Both the CK-2 and MAP2 motifs display a significantly higher degree of helical propensity when compared to the entire ensemble of CTT conformations (Fig. 3). Interestingly, with the exception of βVI and βVII, the increased helical propensity of the proposed CK-2 domain suggests that the H12 helix may extend several additional residues farther than those that have already been observed in the crystal structures of tubulin.

Finally, the motifs identified here are not stable structures but rather commonly occurring, transient conformations. For example, in the ''stiffest'' isotype, βIVa, the CK-2 DATA motif is occupied 69% of the time whereas the MAP2 motif EEEV is occupied 17% of the time (Table 3). The two motifs are simultaneously folded in the ensemble of CTT trajectories only 12% of the time. As the sequences contained within the two motifs are extended to include DATAEE and AEEEVA, respectively, this drops to 2% (Table 3). Rather, the shared similarity of the folded states indicates that these conformations are individually inducible, particularly when binding to their respective substrates. As we are dealing with a subset of all CTTs, we were unable to determine accurately if any additional structural or sequence motifs exist in the tails. A more accurate determination of CTT motifs would require a larger survey of CTTs across all identified α- and β-tubulin isotypes (see Table 1).

CONCLUSIONS

The role of the unstructured tubulin CTTs, particularly concerning MT stability and interactions with MAPs, is a question that has yet to be conclusively answered. Here we have shown, using a combination of REMD and PCA, that although the experimental structures of tubulin suggest the CTTs are unstructured, many contain a significant amount of transient conformations that are linked by a few highly rotatable bonds. We believe that the role of the transient secondary structure, coupled with increased CTT flexibility, may be twofold. First, global flexibility coupled with weak helical tendencies could provide a mechanism that allows the CTTs to search conformational space and hence easily bind to other proteins. This could provide a convenient mechanism for MAPs to dock to the MT surface. Second, increased flexibility could also enhance binding affinities to MAPs as a result of their ability to conform to a specific binding site. The presence of well-defined structural motifs within the CTTs may, consequently, play an important role in binding specificity, where the presence of smaller domains provides a common structural signal for binding, while the global flexibility of the CTT is maintained.

The role of β-tubulin CTTs in MT function is appealing, since subtle differences in a small stretch of amino acids could have profound consequences on MAP interactions. Unfortunately, it is extremely challenging at this time to elicit tight correlations between the results presented here and their biological consequences, as there is very little experimental data regarding CTTs explicitly in the context of tubulin isotypes. As interest in the properties of tubulin isotypes and their potential role in targeted chemotherapy

treatments increases, we anticipate a significant body of data to become available soon. As a result, a clear understanding of CTT structure and function may provide the means by which we can begin to rationally design and develop novel drugs or peptide mimetics that target CTT binding sites, providing better selectivity for chemotherapies.

All calculations were performed on the Westgrid Glacier cluster and the Center of Excellence in Integrated Nanotools cluster. We thank Dr. Richard Luduñena for his inspiration and insightful commentary during the assembly of this manuscript.

This research was directly funded through grants from the National Science and Engineering Research Council (NSERC), Mathematics of Information Technology and Complex Systems, and the Canadian Space Agency (under the contract PWGSC/CSA 9F007-052743/001/ST) awarded to J.A.T. Additional financial support from the Allard Foundation, Technology Innovations of Rochester, NY, and Oncovista of San Antonio, TX, is also gratefully acknowledged. This research was also supported in part by grant No. W81XWH-05-1-0238 from the U.S. Army/Department of Defense to Richard F. Luduñena (University of Texas Health Science Center at San Antonio, San Antonio, TX). T.L. acknowledges financial support from the Province of Alberta, NSERC, National Research Council, and the University of Alberta.

Abstract: What *is* consciousness? Some philosophers have contended that 'qualia', or an experiential medium from which consciousness is derived, exists as a fundamental component of reality. Whitehead, for example, described the universe as being comprised of 'occasions of experience'. To examine this possibility scientifically, the very nature of physical reality must be re-examined. We must come to terms with the physics of space–time — as is described by Einstein's general theory of relativity — and its relation to the fundamental theory of matter — as described by quantum theory. This leads us to employ a new physics of *objective reduction*: '**OR**' which appeals to a form of 'quantum gravity' to provide a useful description of fundamental processes at the quantum/classical borderline (Penrose, 1994; 1996). Within the **OR** scheme, we consider that consciousness occurs if an appropriately organized system is able to develop and maintain quantum coherent superposition until a specific 'objective' criterion (a threshold related to quantum gravity) is reached; the coherent system then self-reduces (objective reduction: **OR**). We contend that this type of objective self-collapse introduces non-computability, an essential feature of consciousness. **OR** is taken as an instantaneous event — the climax of a self-organizing process in fundamental space–time — and a candidate for a conscious Whitehead-like 'occasion' of experience. How could an **OR** process occur in the brain, be coupled to neural activities, and account for other features of consciousness? We nominate an **OR** process with the requisite characteristics to be occurring in cytoskeletal microtubules within the brain's neurons (Penrose and Hameroff, 1995; Hameroff and Penrose, 1995; 1996).

In this model, quantum-superposed states develop in microtubule subunit proteins ('tubulins'), remain coherent, and recruit more superposed tubulins until a mass–time–energy threshold (related to quantum gravity) is reached. At that stage, self-collapse, or objective reduction (**OR**) abruptly occurs. We equate the pre-reduction, coherent superposition ('quantum computing') phase with pre-conscious processes, and each instantaneous (and non-computable) **OR**, or self-collapse, with a discrete conscious event. Sequences of **OR** events give rise to a 'stream' of consciousness. Microtubule-associated proteins can 'tune' the quantum oscillations of the coherent superposed states; the **OR** is thus self-organized, or 'orchestrated' ('**Orch OR**'). Each **Orch OR** event selects (non-computably) microtubule subunit states which regulate synaptic/neural functions using classical signalling.

The quantum gravity threshold for self-collapse is relevant to consciousness, according to our arguments, because macroscopic superposed quantum states each have their own space–time geometries (Penrose, 1994; 1996). These geometries are also superposed, and in some way 'separated', but when sufficiently separated, the superposition of space–time geometries becomes signifcantly unstable, and reduce to a single universe state. Quantum gravity determines the scale of the instability; we contend that the actual choice of state made by Nature is non-computable. Thus each **Orch OR** event is a self-selection of space–time geometry, coupled to the brain through microtubules and other biomolecules.

If conscious experience is intimately connected with the very physics underlying space–time structure, then **Orch OR** in microtubules indeed provides us with a completely new and uniquely promising perspective on the hard problem of consciousness.

Introduction: Self-Selection in an Experiential Medium?

The 'hard problem' of incorporating the phenomenon of consciousness into a scientific world-view involves finding scientific explanations of qualia, or the subjective experience of mental states (Chalmers, 1995; 1996). On this, reductionist science is still at sea. Why do we have an inner life, and what exactly is it?

One set of philosophical positions, addressing the hard problem, views consciousness as a fundamental component of physical reality. For example an extreme view — 'panpsychism' — is that consciousness is a quality of all matter: atoms and their subatomic components having elements of consciousness (e.g. Spinoza, 1677; Rensch, 1960). 'Mentalists' such as Leibniz and Whitehead (e.g. 1929) contended that systems ordinarily considered to be physical are constructed in some sense from mental entities. Bertrand Russell (1954) described 'neutral monism' in which a common underlying entity, neither physical nor mental, gave rise to both. Recently Stubenberg (1996) has claimed that qualia are that common entity. In monistic idealism, matter and mind arise from consciousness — the fundamental constituent of reality (e.g. Goswami, 1993). Wheeler (1990) has suggested that information is fundamental to the physics of the universe. From this, Chalmers (1995; 1996) proposes a double-aspect theory in which information has both physical and experiential aspects.

Among these positions, the philosophy of Alfred North Whitehead (1929; 1933) may be most directly applicable. Whitehead describes the ultimate concrete entities in the cosmos as being actual 'occasions of experience', each bearing a quality akin to 'feeling'. Whitehead construes 'experience' broadly — in a manner consistent with panpsychism — so that even 'temporal events in the career of an electron have a kind of 'protomentality'. Whitehead's view may be considered to differ from panpsychism, however, in that his discrete 'occasions of experience' can be taken to be related to 'quantum events' (Shimony, 1993). In the standard descriptions of quantum mechanics, randomness occurs in the events described as quantum state reductions — these being events which appear to take place when a quantum-level process gets magnified to a macroscopic scale.

Quantum state reduction (here denoted by the letter **R**; cf. Penrose 1989, 1994) is the random procedure that is adopted by physicists in their descriptions of the quantum measurement process. It is still a highly controversial matter whether **R** is to be taken as a 'real' physical process, or whether it is some kind of illusion and not to be regarded as a fundamental ingredient of the behaviour of Nature. Our position is to take **R** to be indeed real — or, rather to regard it as a close approximation to an objectively real process **OR** (objective reduction), which is to be a non-computable process instead of merely a random one (see Penrose 1989; 1994). In almost all physical situations, **OR** would come about in situations in which the random effects of the environment dominate, so **OR** would be virtually indistinguishable from the random **R** procedure that is normally adopted by quantum theorists. However, when the quantum system under consideration remains coherent and well isolated from its environment, then it becomes possible for its state to collapse spontaneously, in accordance with the **OR** scheme we adopt, and to behave in non-computable rather than random ways. Moreover, this **OR** scheme intimately involves the geometry of the physical universe at its deepest levels.

Our viewpoint is to regard experiential phenomena as also inseparable from the physical universe, and in fact to be deeply connected with the very laws which govern the physical universe. The connection is so deep, however, that we perceive only glimmerings of it in our present day physics. One of these glimmerings, we contend, is a necessary non-computability in conscious thought processes; and we argue that this

non-computable = describes a problem that is not solvable

non-computability must also be inherent in the phenomenon of quantum state *self*-reduction — the 'objective reduction' (**OR**) referred to above. This is the main thread of argument in *Shadows of the Mind* (Penrose, 1994). The argument that conscious thought, whatever other attributes it may also have, is non-computable (as follows most powerfully from certain deductions from Gödel's incompleteness theorem) grabs hold of one tiny but extremely valuable point. This means that at least some conscious states cannot be derived from previous states by an algorithmic process — a property which distinguishes human (and other animal) minds from computers. Noncomputability *per se* does not directly address the 'hard problem' of the nature of experience, but it is a clue to the kind of physical activity that lies behind it. This points to **OR**, an underlying physical action of a completely different character from that which would appear to underlie nonconscious activity. Following this clue with sensitivity and patience should ultimately lead to real progress towards understanding mental phenomena in their inward manifestations as well as outward.

In the **OR** description, consciousness takes place if an organized quantum system is able to isolate and sustain coherent superpositions until its quantum gravity threshold for space–time separation is met; it then *self*-reduces (non-computably). For consciousness to occur, *self*-reduction is essential, as opposed to the reduction being triggered by the system's random environment. (In the latter case, the reduction would itself be effectively random and would lack useful non-computability, being unsuitable for direct involvement in consciousness.) We take the *self*-reduction to be an instantaneous event — the climax of a *self*-organizing process fundamental to the structuring of space–time — and apparently consistent with a Whitehead 'occasion of experience'.

As **OR** could, in principle, occur ubiquitously within many types of inanimate media, it may seem to imply a form of 'panpsychism' (in which individual electrons, for example, possess an experiential quality). However according to the principles of **OR** (as expounded in Penrose, 1994; 1996), a single superposed electron would spontaneously reduce its state (assuming it could maintain isolation) only once in a period longer than the present age of the universe. Only large collections of particles acting coherently in a single macroscopic quantum state could possibly sustain isolation and support coherent superposition in a timeframe brief enough to be relevant to our consciousness. Thus, only very special circumstances could support consciousness:

1) High degree of coherence of a quantum state — a collective mass of particles in superposition for a time period long enough to reach threshold, and brief enough to be useful in thought processes.

2) Ability for the **OR** process to be at least transiently isolated from a 'noisy' environment until the spontaneous state reduction takes place. This isolation is required so that reduction is not simply random. Mass movement in the environment which entangles with the quantum state would effect a random (not non-computable) reduction.

3) Cascades of **OR**s to give a 'stream' of consciousness, huge numbers of **OR** events taking place during the course of a lifetime.

By reaching the quantum gravity threshold, each **OR** event has a fundamental bearing on space–time geometry. One could say that a cascade of **OR** events charts an actual course of physical space–time geometry selections.

It may seem surprising that quantum gravity effects could plausibly have relevance at the physical scales relevant to brain processes. For quantum gravity is normally viewed

Copyright (c) Imprint Academic 2019
For personal use only -- not for reproduction

as having only absurdly tiny influences at ordinary dimensions. However, we shall show later that this is not the case, and the scales determined by basic quantum gravity principles are indeed those that are relevant for conscious brain processes.

We must ask how such an **OR** process could actually occur in the brain? How could it be coupled to neural activities at a high rate of information exchange; how could it account for preconscious to conscious transitions, have spatial and temporal binding, and both simultaneity and time flow?

We here nominate an **OR** process with the requisite characteristics to be occurring in cytoskeletal microtubules within the brain's neurons. In our model, microtubule-associated proteins 'tune' the quantum oscillations leading to **OR**; we thus term the process 'orchestrated objective reduction' (**Orch OR**).

it is natural and intuitive to think of every object being in its own eigenstate. This is another way of saying that every object appears to have a definite position, a definite momentum, a definite measured value, and a definite time of occurrence.

Space–time: Quantum Theory and Einstein's Gravity

Quantum theory describes the extraordinary behaviour of the matter and energy which comprise our universe at a fundamental level. At the root of quantum theory is the wave/particle duality of atoms, molecules, and their constituent particles. A quantum system such as an atom or subatomic particle which remains isolated from its environment behaves as a 'wave of possibilities' and exists in a coherent complex-number valued 'superposition' of many possible states. The behaviour of such wave-like, quantum-level objects can be satisfactorily described in terms of a state vector which evolves deterministically according to the Schrödinger equation (unitary evolution), denoted by **U**.

Somehow, quantum microlevel superpositions lead to unsuperposed stable structures in our macro-world. In a transition known as wave function collapse, or state reduction (**R**), the quantum wave of alternative possibilities reduces to a single macroscopic reality — an 'eigenstate' of some appropriate operator. (This would be just one out of many possible alternative eigenstates relevant to the quantum operator.) This process is invoked in the description of a macroscopic measurement, when effects are magnified from the small, quantum scale to the large, classical scale.

According to conventional quantum theory (as part of the standard 'Copenhagen interpretation'), each choice of eigenstate is entirely random, weighted according to a probability value that can be calculated from the previous state according to the precise procedures of the quantum formalism. This probabilistic ingredient was a feature with which Einstein, among others, expressed displeasure: 'You believe in a God who plays dice, and I in complete law and order.'[1] Penrose (1989; 1994) has contended that, at a deeper level of description, the choices may more accurately arise as the result of some presently unknown 'non-computational' mathematical/physical (i.e. 'Platonic realm') theory, that is they cannot be deduced algorithmically. Penrose argues that such non-computability is essential to consciousness, because (at least some) conscious mental activity is unattainable by computers.

It can be argued that present-day physics has no clear explanation for the cause and occurrence of wave function collapse **R**. Experimental and theoretical evidence through the 1930's led quantum physicists (such as Schrödinger, Heisenberg, Dirac, von Neumann, and others) to postulate that quantum-coherent superpositions persist indefinitely in time, and would, in principle be maintained from the micro to macro levels. Or perhaps they would persist until conscious observation collapses, or reduces, the wave function (subjective reduction, or '**SR**'). Accordingly, even macroscopic objects, if unobserved, could remain superposed. To illustrate the apparent absurdity of this notion, Erwin

Schrödinger (e.g. 1935) described his now-famous 'cat in a box' being simultaneously *both* dead and alive until the box was opened and the cat observed.

As a counter to this unsettling prospect, various new physical schemes for collapse according to objective criteria (objective reduction — '**OR**') have recently been proposed. According to such a scheme, the growth and persistence of superposed states could reach a critical threshold, at which collapse, or **OR** rapidly occurs (e.g. Pearle, 1989; Ghirardi *et al.*, 1986). Some of these schemes are based specifically on gravitational effects mediating **OR** (e.g. Károlyházy, 1966; Károlyházy *et al.*, 1986; Diósi, 1989; Ghirardi *et al.*, 1990; Penrose, 1989; 1994; Pearle and Squires, 1995; Percival, 1995). Table 1 categorizes types of reduction.

Context	**Cause of Collapse (Reduction)**	**Description**	**Acronym**
Quantum coherent superposition	No collapse	Evolution of wave function (Schrödinger equation)	**U**
Conventional quantum theory (Copenhagen interpretation)	Environmental entanglement, Measurement, Conscious observation	Reduction; Subjective reduction	**R** **SR**
New physics (Penrose,1994)	Self-collapse — quantum gravity induced (Penrose, Diosi, etc.)	Objective reduction	**OR**
Consciousness (present paper)	Self-collapse, quantum gravity threshold in microtubules orchestrated by MAPs etc.	Orchestrated objective reduction	**Orch OR**

Table 1: Description of wave function collapse

The physical phenomenon of gravity, described to a high degree of accuracy by Isaac Newton's mathematics in 1687, has played a key role in scientific understanding. However, in 1915, Einstein created a major revolution in our scientific world-view. According to Einstein's theory, gravity plays a unique role in physics for several reasons (cf. Penrose, 1994). Most particularly, these are:

1) Gravity is the only physical quality which influences causal relationships between space–time events.
2) Gravitational force has no local reality, as it can be eliminated by a change in space–time coordinates; instead, gravitational tidal effects provide a *curvature* for the very *space–time* in which all other particles and forces are contained.

It follows from this that gravity cannot be regarded as some kind of 'emergent phenomenon', secondary to other physical effects, but must be a 'fundamental component' of physical reality.

There are strong arguments (e.g. Penrose, 1987; 1996) to suggest that the appropriate union of general relativity (Einstein's theory of gravity) with quantum mechanics — a union often referred to as 'quantum gravity' — will lead to a significant change in *both* quantum theory and general relativity, and, when the correct theory is found, will yield a

Copyright (c) Imprint Academic 2019
For personal use only -- not for reproduction

profoundly *new* understanding of physical reality. And although gravitational *forces* between objects are exceedingly weak (feebler than, for example, electrical forces by some 40 orders of magnitude), there are significant reasons for believing that gravity has a fundamental influence on the behaviour of quantum systems as they evolve from the micro to the macrolevels. The appropriate union of quantum gravity with biology, or at least with advanced biological nervous systems, may yield a profoundly new understanding of consciousness.

Curved Space–time Superpositions and Objective Reduction ('OR')

According to modern accepted physical pictures, reality is rooted in 3-dimensional space and a 1-dimensional time, combined together into a 4-dimensional space–time. This space–time is slightly curved, in accordance with Einstein's general theory of relativity, in a way which encodes the gravitational fields of all distributions of mass density. Each mass density effects a space–time curvature, albeit tiny.

This is the standard picture according to *classical* physics. On the other hand, when *quantum* systems have been considered by physicists, this mass-induced tiny curvature in the structure of space–time has been almost invariably ignored, gravitational effects having been assumed to be totally insignificant for normal problems in which quantum theory is important. Surprising as it may seem, however, such tiny differences in space–time structure *can* have large effects: for they entail subtle but fundamental influences on the very rules of quantum mechanics.

Superposed quantum states for which the respective mass distributions differ significantly from one another will have space–time geometries which correspondingly differ. Thus, according to standard quantum theory, the superposed state would have to involve a quantum superposition of these differing space–times. In the absence of a coherent theory of quantum gravity there is no accepted way of handling such a superposition. Indeed, the basic principles of Einstein's general relativity begin to come into profound conflict with those of quantum mechanics (cf. Penrose, 1996). Nevertheless, various tentative procedures have been put forward in attempts to describe such a superposition. Of particular relevance to our present proposals are the suggestions of certain authors (e.g. Károlyházy, 1966; 1974; Károlyházy *et al.*, 1986; Kibble, 1981; Diósi, 1989; Ghirardi *et al.*, 1990; Pearle and Squires, 1995; Percival, 1995; Penrose, 1993; 1994; 1996) that it is at this point that an objective quantum state reduction (**OR**) ought to occur, and the rate or timescale of this process can be calculated from basic quantum gravity considerations. These particular proposals differ in certain detailed respects, and for definiteness we shall follow the specific suggestions made in Penrose (1994; 1996). Accordingly, the quantum superposition of significantly differing space–times is unstable, with a life-time given by that timescale. Such a superposed state will decay — or 'reduce' — into a single universe state, which is one or the other of the space–time geometries involved in that superposition.

Whereas such an **OR** action is not a generally recognized part of the normal quantum-mechanical procedures, there is no plausible or clearcut alternative that standard quantum theory has to offer. This **OR** procedure avoids the need for 'multiple universes' (cf. Everett, 1957; Wheeler, 1957, for example). There is no agreement, among quantum gravity experts, about how else to address this problem. For the purposes of the present article, it will be assumed that a gravitationally induced **OR** action is indeed the correct resolution of this fundamental conundrum.

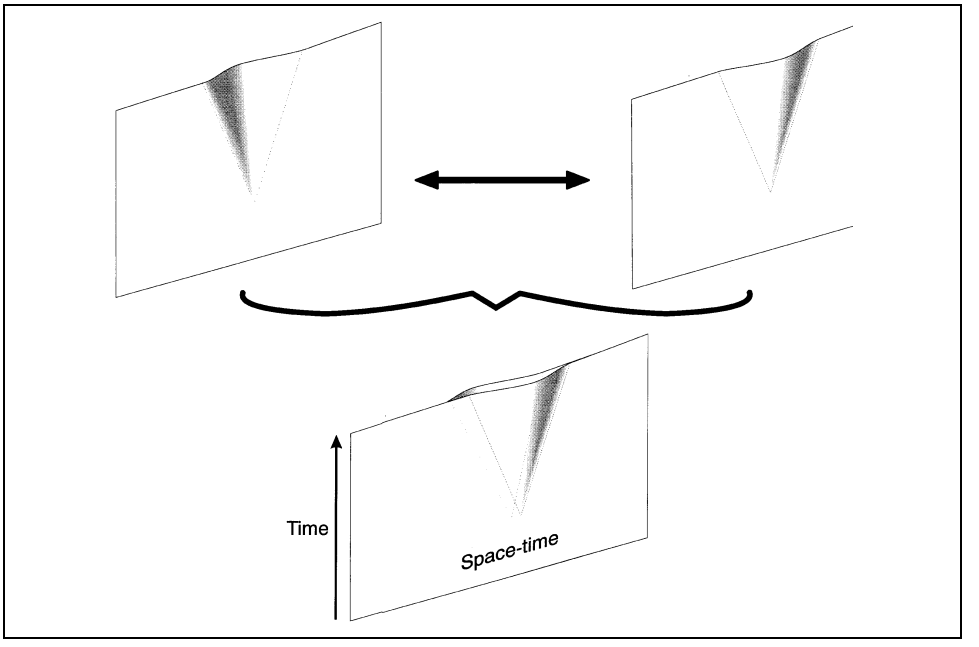

Figure 1. Quantum coherent superposition represented as a separation of space–time. In the lowest of the three diagrams, a bifurcating space–time is depicted as the union ('glued together version'), of the two alternative space–time histories that are depicted at the top of the Figure. The bifurcating space–time diagram illustrates two alternative mass distributions actually in quantum superposition, whereas the top two diagrams illustrate the two individual alternatives which take part in the superposition (adapted from Penrose, 1994, p. 338).

Figure 1 (adapted from Penrose, 1994, p. 338) schematically illustrates the way in which space time structure can be affected when two macroscopically different mass distributions take part in a quantum superposition. Each mass distribution gives rise to a separate space–time, the two differing slightly in their curvatures. So long as the two distributions remain in quantum superposition, we must consider that the two space–times remain in superposition. Since, according to the principles of general relativity, there is no natural way to identify the points of one space–time with corresponding points of the other, we have to consider the two as separated from one another in some sense, resulting in a kind of 'blister' where the space–time bifurcates.

A bifurcating space–time is depicted in the lowest of the three diagrams, this being the union ('glued together version') of the two alternative space–time histories that are depicted at the top of Figure 1. The initial part of each space–time is at the lower end of each individual space–time diagram. The bottom space–time diagram (the bifurcating one) illustrates two alternative mass distributions actually in quantum superposition, whereas the top two illustrate the two individual alternatives which take part in the superposition. The combined space–time describes a superposition in which the alternative locations of a mass move gradually away from each other as we proceed in the upward direction in the diagram. Quantum mechanically (i.e. so long as **OR** has not taken place), we must think of the 'physical reality' of this situation as being illustrated as an actual superposition of these two slightly differing space–time manifolds, as indicated in the bottom diagram. As soon as **OR** has occurred, one of the two individual space–times takes over, as depicted as one of the two sheets of the bifurcation. For clarity only, the bifurcating parts of these two sheets are illustrated as being one convex and the other

Copyright (c) Imprint Academic 2019
For personal use only -- not for reproduction

concave. Of course there is additional artistic licence involved in drawing the space–time sheets as 2-dimensional, whereas the actual space–time constituents are 4-dimensional. Moreover, there is no significance to be attached to the imagined '3-dimensional space' within which the space–time sheets seem to be residing. There is no 'actual' higher dimensional space there, the 'intrinsic geometry' of the bifurcating space–time being all that has physical significance. When the 'separation' of the two space–time sheets reaches a critical amount, one of the two sheets 'dies' — in accordance with the **OR** criterion — the other being the one that persists in physical reality. The quantum state thus reduces (**OR**), by choosing between either the 'concave' or 'convex' space–time of Figure 1.

It should be made clear that this measure of separation is only very schematically illustrated as the 'distance' between the two sheets in the lower diagram in Figure 1. As remarked above, there is no physically existing 'ambient higher-dimensional space' inside which the two sheets reside. The degree of separation between the space–time sheets is a more abstract mathematical thing; it would be more appropriately described in terms of a *symplectic measure* on the space of 4-dimensional metrics (cf. Penrose, 1993) — but the details (and difficulties) of this will not be important for us here. It may be noted, however, that this separation is a space–time separation, not just a spatial one. Thus the *time* of separation contributes as well as the spatial displacement. Roughly speaking, it is the product of the temporal separation $\boldsymbol{T}$ with the spatial separation $\boldsymbol{S}$ that measures the overall degree of separation, and **OR** takes place when this overall separation reaches the critical amount. [This critical amount would be of the order of unity, in absolute units, for which the Planck-Dirac constant □□ (= h/2π), the gravitational constant G, and the velocity of light c, all take the value unity; cf. Penrose, 1994, pp. 337–9.] Thus for small $\boldsymbol{S}$, the lifetime $\boldsymbol{T}$ of the superposed state will be large; on the other hand, if $\boldsymbol{S}$ is large,then $\boldsymbol{T}$ will be small. To calculate $\boldsymbol{S}$, we compute (in the Newtonian limit of weak gravitational fields) the gravitational self-energy $\boldsymbol{E}$ of the difference between the mass distributions of the two superposed states. (That is, one mass distribution counts positively and the other, negatively; see Penrose, 1994; 1996.) The quantity $\boldsymbol{S}$ is then given, in absolute units, by:

ħ = h/(2π)

$$\boldsymbol{S} = \boldsymbol{E}$$

Thus, restoring standard units,

$$\boldsymbol{T} = \square\square\boldsymbol{E}^{-1}$$

Schematically, since $\boldsymbol{S}$ represents three dimensions of displacement rather than the one dimension involved in $\boldsymbol{T}$, we can imagine that this displacement is shared equally between each of these three dimensions of space — and this is what has been depicted in Figure 3 (below). However, it should be emphasized that this is for pictorial purposes only, the appropriate rule being the one given above. These two equations relate the mass distribution, time of coherence, and space–time separation for a given **OR** event. If, as some philosophers contend, experience is contained in space–time, **OR** events are *self*-organizing processes in that experiential medium, and a candidate for consciousness.

But where in the brain, and how, could coherent superposition and **OR** occur? A number of sites and various types of quantum interactions have been proposed. We strongly favour microtubules as an important ingredient; however various organelles and biomolecular structures including clathrins, myelin (glial cells), presynaptic vesicular grids (Beck and Eccles, 1992) and neural membrane proteins (Marshall, 1989) might also participate.

Microtubules

Properties of brain structures suitable for quantum coherent superposition, **OR** and relevant to consciousness might include: 1) high prevalence, 2) functional importance (for example regulating neural connectivity and synaptic function), 3) periodic, crystal-like lattice dipole structure with longrange order, 4) ability to be transiently isolated from external interaction/observation, 5) functionally coupled to quantum-level events, 6) hollow, cylindrical (possible wave-guide), and 7) suitable for information processing. Membranes, membrane proteins, synapses, DNA and other types of structures have some, but not all, of these characteristics. Cytoskeletal microtubules appear to qualify in all respects.

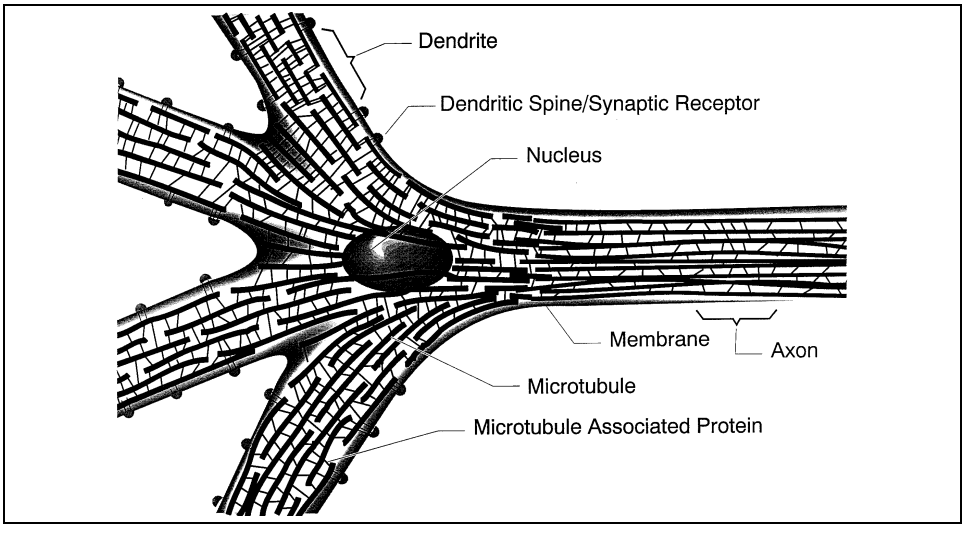

Figure 2. Schematic of central region of neuron (distal axon and dendrites not shown), showing parallel arrayed microtubules interconnected by MAPs. Microtubules in axons are lengthy and continuous, whereas in dendrites they are interrupted and of mixed polarity. Linking proteins connect microtubules to membrane proteins including receptors on dendritic spines.

Interiors of living cells, including the brain's neurons, are spatially and dynamically organized by *self*-assembling protein networks: the cytoskeleton. Within neurons, the cytoskeleton establishes neuronal form, and maintains and regulates synaptic connections. Its major components are microtubules, hollow cylindrical polymers of individual proteins known as tubulin. Microtubules ('MTs') are interconnected by linking proteins (microtubule-associated proteins: 'MAPs') to other microtubules and cell structures to form cytoskeletal lattice networks (Figure 2).

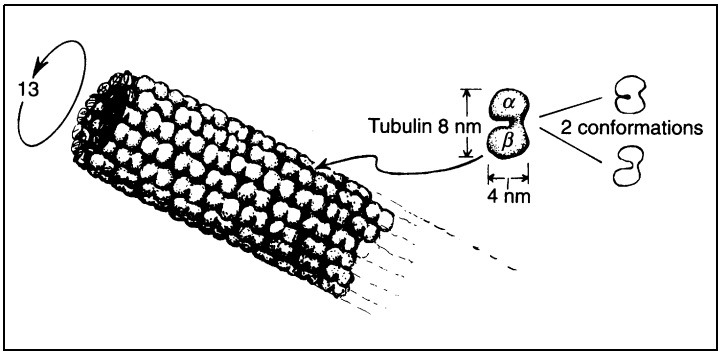

Figure 3.

Microtubule structure: a hollow tube of 25 nanometers diameter, consisting of 13 columns of tubulin dimers. Each tubulin molecule is capable of (at least), two conformations. (Reprinted with permission from Penrose, 1994, p. 359.)

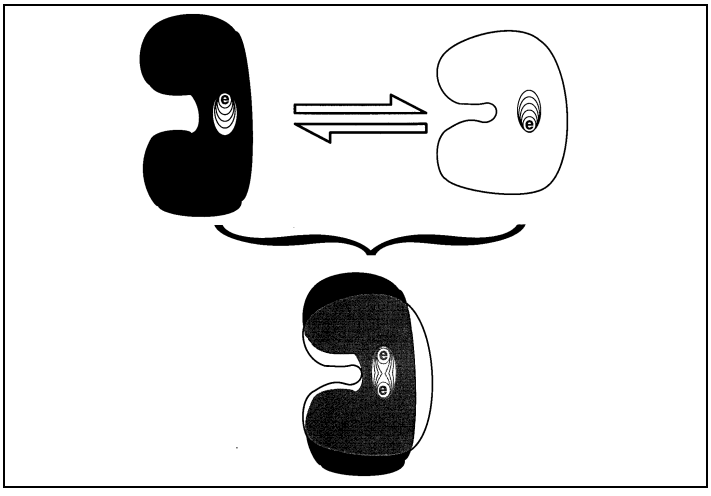

Figure 4.

Top:
Two states of tubulin in which a *single* quantum event (electron localization), within a central hydrophobic pocket is coupled to a *global* protein conformation. Switching between the two states can occur on the order of nanoseconds to picoseconds.

Bottom:
Tubulin in quantum coherent superposition.

MTs are hollow cylinders 25 nanometers (nm) in diameter whose lengths vary and may be quite long within some nerve axons. MT cylinder walls are comprised of 13 longitudinal protofilaments which are each a series of subunit proteins known as tubulin (Figure 3). Each tubulin subunit is a polar, 8 nm dimer which consists of two slightly different 4 nm monomers (α and β tubulin — Figure 4). Tubulin dimers are dipoles, with surplus negative charges localized toward monomers (DeBrabander, 1982), and within MTs are arranged in a hexagonal lattice which is slightly twisted, resulting in helical pathways which repeat every 3, 5, 8 and other numbers of rows. Traditionally viewed as the cell's 'bonelike' scaffolding, microtubules and other cytoskeletal structures also appear to fill communicative and information processing roles. Numerous types of studies link the cytoskeleton to cognitive processes (for review, cf. Hameroff and Penrose, 1996). Theoretical models and simulations suggest how conformational states of tubulins within microtubule lattices can interact with neighbouring tubulins to represent, propagate and process information as in molecular-level 'cellular automata', or 'spinglass' type computing systems (Figure 5; e.g. Hameroff and Watt, 1982; Rasmussen

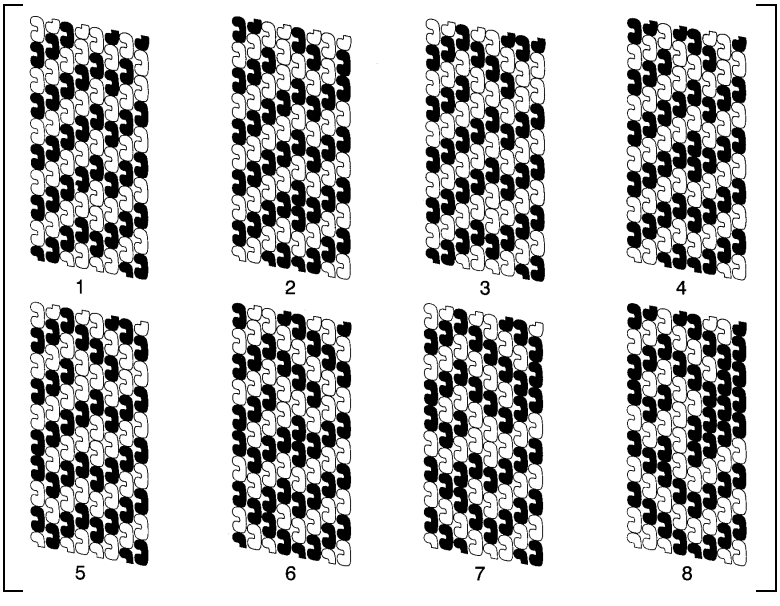

Figure 5. Microtubule automaton simulation (from Rasmussen *et al*., 1990). Black and white tubulins correspond to states shown in Figure 2. Eight nanosecond time steps of a segment of one microtubule are shown in 'classical computing' mode in which patterns move, evolve, interact and lead to emergence of new patterns.

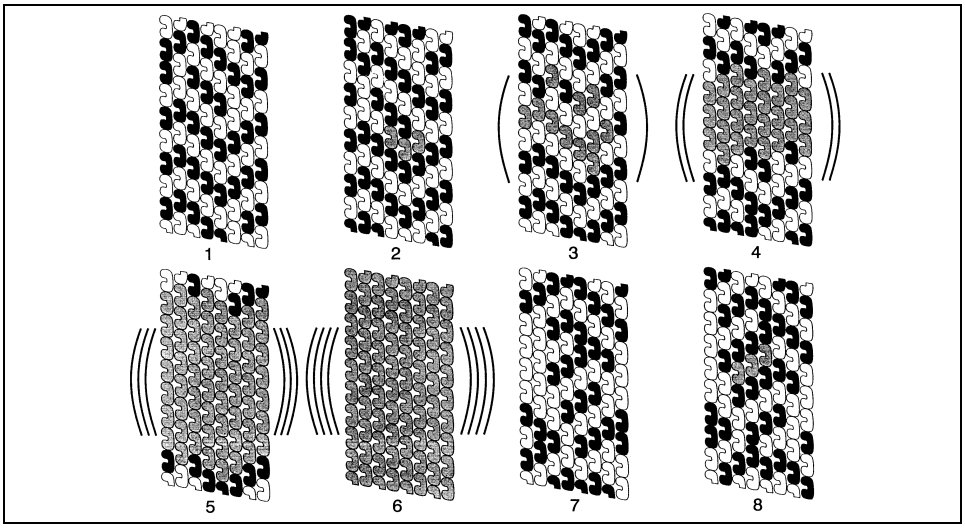

Figure 6. Microtubule automaton sequence simulation in which classical computing (step 1), leads to emergence of quantum coherent superposition (steps 2–6), in certain (grey) tubulins due to pattern resonance. Step 6 (in coherence with other microtubule tubulins) meets critical threshold related to quantum gravity for self–collapse (**Orch OR**). Consciousness (**Orch OR**) occurs in the step 6 to 7 transition. Step 7 represents the eigenstate of mass distribution of the collapse which evolves by classical computing automata to regulate neural function. Quantum coherence begins to re–emerge in step 8.

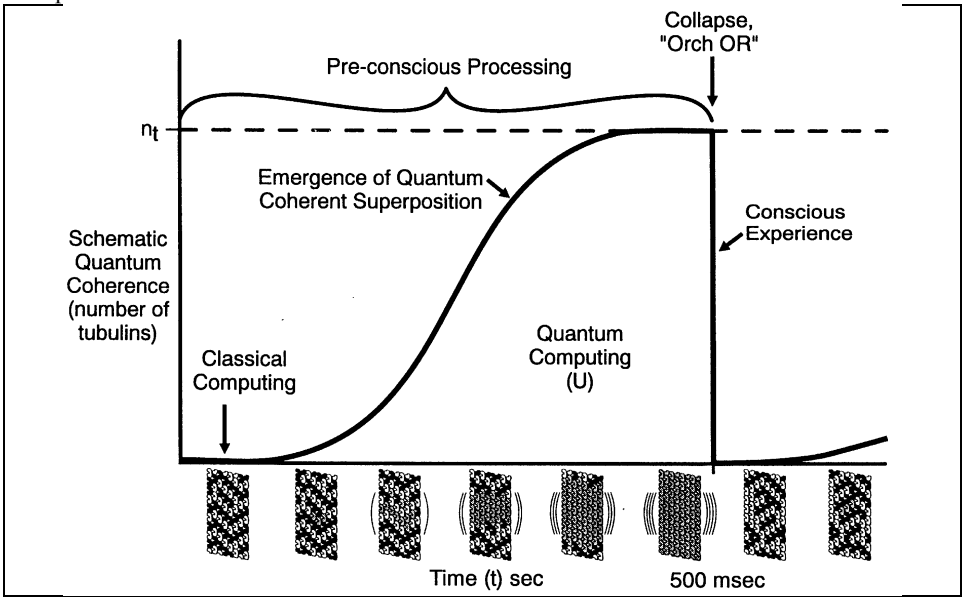

Figure 7. Schematic graph of proposed quantum coherence (number of tubulins), emerging vs time in microtubules. 500 milliseconds is time for pre–conscious processing (e.g. Libet *et al.*, 1979). Area under curve connects mass–energy differences with collapse time in accordance with gravitational **OR**. This degree of coherent superposition of differing space–time geometries leads to abrupt quantum → classical reduction ('self–collapse' or 'orchestrated objective reduction: **Orch OR**').

et al., 1990; Tuszy□ski *et al.*, 1995). In Hameroff and Penrose (1996, and in summary form Penrose and Hameroff, 1995), we present a model linking microtubules to consciousness, using quantum theory as viewed in the particular 'realistic' way referred to

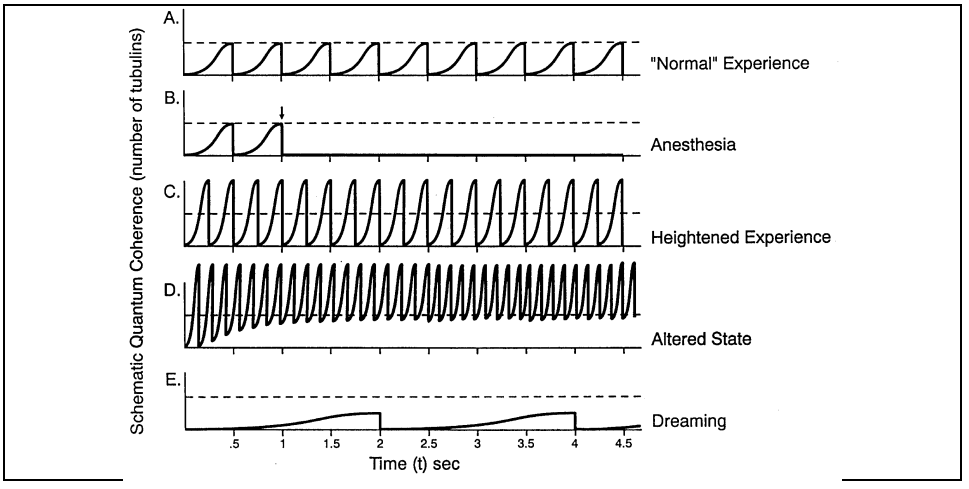

Figure 8. Quantum coherence in microtubules schematically graphed on longer time scale for five different states related to consciousness. Area under each curve equivalent in all cases. A. Normal experience: as in Figure 8. B. Anaesthesia: anaesthetics bind in hydrophobic pockets and prevent quantum delocalizability and coherent superposition (e.g. Louria and Hameroff, 1996). C. Heightened Experience: increased sensory experience input (for example), increases rate of emergence of quantum coherent superposition. **Orch Or** threshold is reached faster (e.g. 250 msec), and **Orch Or** frequency is doubled. D. Altered State: even greater rate of emergence of quantum coherence due to sensory input and other factors promoting quantum state (e.g. meditation, psychedelic drug, etc.). Predisposition to quantum state results in baseline shift and only partial collapse so that conscious experience merges with normally sub–conscious quantum computing mode. E. Dreaming: prolonged quantum coherence time. (Highly schematic.)

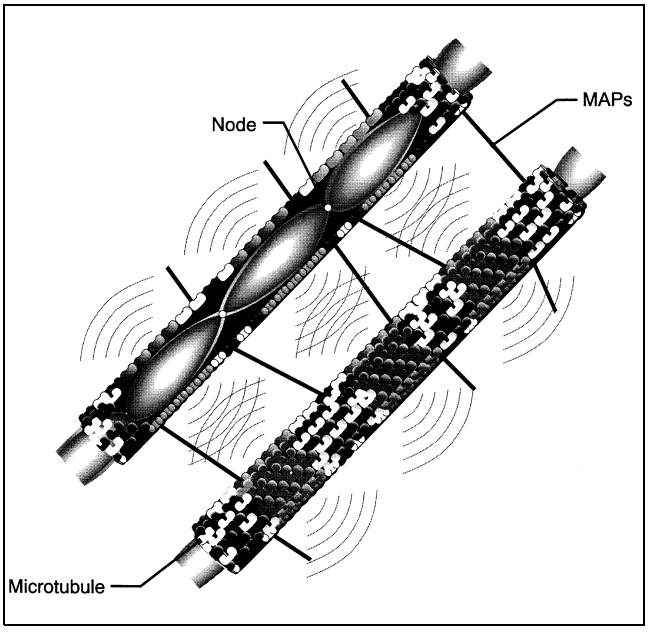

Figure 9. Quantum coherence in microtubules. Having emerged from resonance in classical automaton patterns, quantum coherence non–locally links superpositioned tubulins (grey), within and among microtubules. Upper microtubule: cutaway view shows coherent photons generated by quantum ordering of water on tubulin surfaces, propagating in microtubule waveguide. MAP (microtubule-associated protein), attachments breach isolation and prevent quantum coherence; MAP attachment sites thus act as 'nodes' which tune and orchestrate quantum oscillations and set possibilities and probabilities for collapse outcomes ('orchestrated objective reduction': **Orch OR**).

above, and as described in *Shadows of the Mind* (Penrose, 1994). In our model, quantum coherence emerges, and is isolated, in brain microtubules until the differences in mass–energy distribution among superposed tubulin states reach the above threshold of instability, related to quantum gravity (Figure 6). The resultant *self*-collapse (**OR**), considered

Copyright (c) Imprint Academic 2019
For personal use only -- not for reproduction

to be a time-irreversible process, creates an instantaneous 'now' event in our model. Sequences of such events create a flow of time and consciousness (Figures 7 and 8).

We envisage that attachments of MAPs on microtubules 'tune' quantum oscillations, and 'orchestrate' possible collapse outcomes (Figure 9). Thus we term the particular *self*-organizing **OR** occurring in MAP-connected microtubules, and relevant to consciousness, orchestrated objective reduction ('**Orch OR**'). **Orch OR** events are thus *self*-selecting processes in fundamental space–time geometry. If experience is truly a component of fundamental space–time, **Orch OR** may indeed begin to to address the 'hard problem' of consciousness.

Summary of the 'Orch OR' Model for Consciousness

The full details of this model are given in Hameroff and Penrose (1996). The picture we are putting forth involves the following ingredients:

(1) Aspects of quantum theory (e.g. quantum coherence) and of the suggested physical phenomenon of quantum wave function '*self*-collapse' (objective reduction: **OR** — Penrose, 1994; 1996) are essential for consciousness, and occur in cytoskeletal microtubules (MTs) and other structures within each of the brain's neurons.

(2) Conformational states of MT subunits (tubulins) are coupled to internal quantum events, and cooperatively interact with other tubulins in both classical and quantum computation (Hameroff *et al.*, 1992; Rasmussen *et al.*, 1990 — Figures 4, 5 and 6).

(3) Quantum coherence occurs among tubulins in MTs, pumped by thermal and biochemical energies (perhaps in the manner proposed by Fröhlich, 1968; 1970; 1975). Evidence for some kind of coherent excitation in proteins has recently been reported by Vos *et al.* (1993).

It is also considered that water at MT surfaces is 'ordered' — dynamically coupled to the protein surface. Water ordering within the hollow MT core (acting something like a quantum waveguide) may result in quantum coherent photons (as suggested by the phenomena of 'super-radiance'and '*self*-induced transparency' — Jibu *et al.*, 1994; 1995). We require that coherence be sustained (protected from environmental interaction) for up to hundreds of milliseconds by isolation (a) within hollow MT cores, (b) within tubulin hydrophobic pockets, (c) by coherently ordered water, (d) sol-gel layering (Hameroff and Penrose, 1996). Feasibility of quantum coherence in the seemingly noisy, chaotic cell environment is supported by the observation that quantum spins from biochemical radical pairs which become separated retain their correlation in cytoplasm (Walleczek, 1995).

(4) During preconscious processing, quantum coherent superposition/computation occurs in MT tubulins and continues until the mass-distribution difference among the separated states of tubulins reaches a threshold related to quantum gravity. Self-collapse (**OR**) then occurs (Figures 6 & 7).

(5) The **OR** *self*-collapse process results in classical 'outcome states' of MT tubulins which then implement neurophysiological functions. According to certain ideas for **OR** (Penrose, 1994), the outcome states are 'non-computable'; that is they cannot be determined algorithmically from the tubulin states at the beginning of the quantum computation.

(6) Possibilities and probabilities for post**OR** tubulin states are influenced by factors including initial tubulin states, and attachments of microtubule-associated proteins (MAPs) acting as 'nodes' which tune and 'orchestrate' the quantum oscillations (Figure 9). We thus term the *self*-tuning **OR** process in microtubules 'orchestrated objective reduction' — **Orch OR**.

(7) According to the arguments for **OR** put forth in Penrose (1994), superposed states each have their own space–time geometries. When the degree of coherent mass–energy

Copyright (c) Imprint Academic 2019

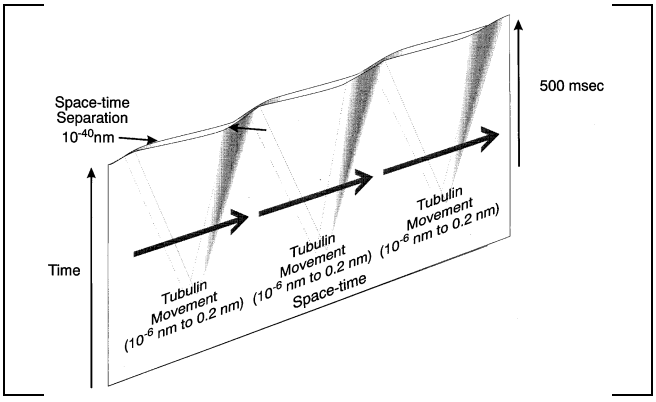

Figure 10.

Schematic space–time separation illustration of three superposed tubulins. The space–time differences are very tiny in ordinary terms (10^{-40} nm), but relatively large mass movements (e.g. hundreds of tubulin conformations, each moving from 10^{-6} nm to 0.2 nm), indeed have precisely such very tiny effects on the space–time curvature.

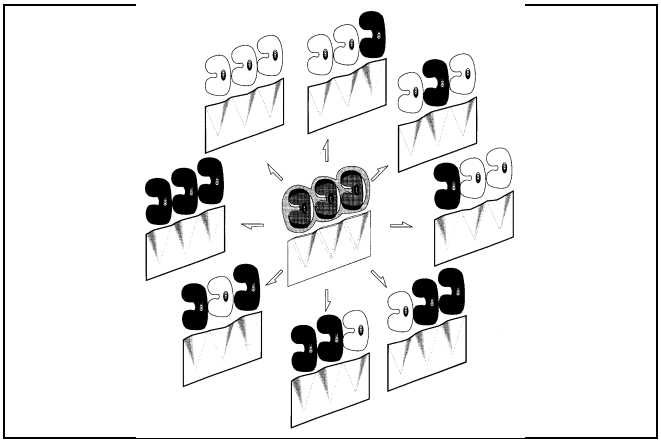

Figure 11.

Centre:
Three superposed tubulins (e.g. Figure 4), with corresponding schematic space–time separation illustrations (Figures 1 and 10). Surrounding the superposed tubulins are the eight possible post–reduction 'eigenstates' for tubulin conformation, and corresponding space–time geometry.

Copyright (c) Imprint Academic 2019
For personal use only -- not for reproduction

difference leads to sufficient separation of space–time geometry, the system must choose and decay (reduce, collapse) to a single universe state. Thus **Orch OR** involves *self*-selections in fundamental space–time geometry (Figures 10 & 11).

(8) To quantify the **Orch OR** process, in the case of a pair of roughly equally superposed states, each of which has a reasonably well-defined mass distribution, we calculate the gravitational *self*-energy $\boldsymbol{E}$ of the difference between these two mass distributions, and then obtain the approximate lifetime $\boldsymbol{T}$ for the superposition to decay into one state or the other by the formula $\boldsymbol{T} = \hbar/\boldsymbol{E}$. Here, $\hbar$ is Planck's constant over 2π. We call $\boldsymbol{T}$ the coherence time for the superposition (how long the coherence is sustained). If we assume a coherence time $\boldsymbol{T}$ = 500 msec (shown by Libet *et al*., 1979, and others to be a relevant time for preconscious processing), we calculate $\boldsymbol{E}$, and determine the number of MT tubulins whose coherent superposition for 500 msec will elicit **Orch OR**. This turns out to be about 10^9 tubulins.

(9) A typical brain neuron has roughly 10^7 tubulins (Yu and Baas, 1994). If, say, 10 % of tubulins within each neuron are involved in the quantum coherent state, then roughly 10^3 (one thousand) neurons would be required to sustain coherence for 500 msec, at which time the quantum gravity threshold is reached and **Orch OR** then occurs.

(10) We consider each *self*-organized **Orch OR** as a single conscious event; cascades of such events would constitute a 'stream' of consciousness. If we assume some form of excitatory input (e.g. you are threatened, or enchanted) in which quantum coherence emerges faster, then, for example, 10^{10} coherent tubulins could **Orch OR** after 50 msec,

or 10^{11} after 5 msec (e.g. Figure 8c). Turning to see a bengal tiger in your face might perhaps elicit 10^{12} in 0.5 msec, or more tubulins, faster. A slow emergence of coherence (your forgotten phone bill) may require longer times. A single electron would require more than the age of the universe.

(11) Quantum states are non-local (because of quantum entanglement — or 'Einstein-Podolsky-Rosen' (EPR) effects), so that the entire non-localized state reduces all at once. This can happen if the mass movement that induces collapse takes place in a small region encompassed by the state, or if it takes place uniformly over a large region. Thus, each instantaneous **Orch OR** could 'bind' various superpositions which may have evolved in separated spatial distributions and even over different time scales, but whose net displacement *self*-energy reaches threshold at a particular moment. Information is bound into an instantaneous event (a 'conscious now'). Cascades of **Orch OR**s could then represent our familiar 'stream of consciousness', and create a 'forward' flow of time (Aharonov and Vaidman, 1990; Elitzur, 1996; Tollaksen, 1996).

It may be interesting to compare our considerations with subjective viewpoints that have been expressed with regard to the nature of the progression of conscious experience. For example, support for consciousness consisting of sequences of individual, discrete events is found in Buddhism; trained meditators describe distinct 'flickerings' in their experience of reality (Tart, 1995). Buddhist texts portray consciousness as 'momentary collections of mental phenomena', and as 'distinct, unconnected and impermanent moments which perish as soon as they arise'. Each conscious moment successively becomes, exists, and disappears — its existence is instantaneous, with no duration in time, as a point has no length. Our normal perceptions, of course, are seemingly continuous, presumably as we perceive 'movies' as continuous despite their actual makeup being a series of frames. Some Buddhist writings even quantify the frequency of conscious moments. For example the Sarvaastivaadins (von Rospatt, 1995) described 6,480,000 'moments' in 24 hours (an average of one 'moment' per 13.3 msec), while other Buddhist writings decribe one moment per 0.13 msec (Conze, 1988), and some Chinese Buddhism as one 'thought' per 20 msec. These accounts, including variations in frequency, seem to be consistent with our proposed **Orch OR** events. For example a 13.3 msec preconscious interval would correspond with an **Orch OR** involving 4×10^{10} coherent tubulins, a 0.13 msec interval would correspond with 4×10^{12} coherent tubulins, and a 20 msec interval with 2.5×10^{10} coherent tubulins. Thus Buddhist 'moments of experience', Whitehead 'occasions of experience', and our proposed **Orch OR** events seem to correspond tolerably well with one another.

The **Orch OR** model thus appears to accommodate some important features of consciousness:

1) control/regulation of neural action
2) pre-conscious to conscious transition
3) non-computability
4) causality
5) binding of various (time scale and spatial) superpositions into instantaneous 'now'
6) a 'flow' of time, and
7) a connection to fundamental space–time geometry in which experience may be based.

Conclusion: What Is It Like To Be a Worm?

The **Orch OR** model has the implication that an organism able to sustain quantum coherence among, for example, 10^9 tubulins for 500 msec might be capable of having conscious experience. More tubulins coherent for a briefer period, or fewer for a longer period ($\boldsymbol{E} = \square / \boldsymbol{T}$) will also have conscious events. Human brains appear capable of, for example, 10^{12} tubulin, 0.5 msec 'bengal tiger experiences', but what about simpler organisms?

From an evolutionary standpoint, introduction of a dynamically functional cytoskeleton (perhaps symbiotically from spirochetes, e.g. Margulis, 1975) greatly enhanced eukaryotic cells by providing cell movement, internal organization, separation of chromosomes and numerous other functions. As cells became more specialized with extensions like axopods and eventually neural processes, increasingly larger cytoskeletal arrays providing transport and motility may have developed quantum coherence via the Fröhlich mechanism as a by-product of their functional coordination.

Another possible scenario for emergence of quantum coherence leading to **Orch OR** and conscious events is 'cellular vision'. Albrecht-Buehler (1992) has observed that single cells utilize their cytoskeletons in 'cellular vision' — detection, orientation and directional response to beams of red/infrared light. Jibu *et al.* (1995) argue that this process requires quantum coherence in microtubules and ordered water, and Hagan (1995) suggests the quantum effects/cellular vision provided an evolutionary advantage for cytoskeletal arrays capable of quantum coherence. For whatever reason quantum coherence emerged, one could then suppose that, one day, an organism achieved sufficient microtubule quantum coherence to elicit **Orch OR**, and had a 'conscious' experience.

At what level of evolutionary development might this primitive consciousness have emerged? A single cell organism like *Paramecium* is extremely clever, and utilizes its cytoskeleton extensively. Could a paramecium be conscious? Assuming a single paramecium contains, like each neuronal cell, 10^7 tubulins, then for a paramecium to elicit **Orch OR**, 100% of its tubulins would need to remain in quantum coherent superposition for nearly a minute. This seems unlikely.

Consider the nematode worm *C elegans*. It's 302 neuron nervous system is completely mapped. Could *C elegans* support **Orch OR**? With 3×10^9 tubulins, *C elegans* would require roughly one third of its tubulins to sustain quantum coherent superposition for 500 msec. This seems unlikely, but not altogether impossible. If not *C elegans*, then perhaps *Aplysia* with a thousand neurons, or some higher organism. **Orch OR** provides a theoretical framework to entertain such possibilities.

Would a primitive **Orch OR** experience be anything like ours? If *C elegans* were able to *self*-collapse, what would it be like to be a worm? (cf. Nagel, 1974). A single, 10^9 tubulin, 500 msec **Orch OR** in *C elegans* should be equal in gravitational *self*-energy terms (and thus perhaps, experiential intensity) to one of our 'everyday experiences'. A major difference is that we would have many **Orch OR** events sequentially (up to, say, 50 per second) whereas *C elegans* could generate, at most, 2 per second. *C elegans* would also presumably lack extensive memory and associations, and have poor sensory data, but nonetheless, by our criteria a 10^9 tubulin, 500 msec **Orch OR** in *C elegans* could be a conscious experience: a mere smudge of known reality, the next space–time move.

Consciousness has an important place in the universe. **Orch OR** in microtubules is a model depicting consciousness as sequences of non-computable *self*-selections in fundamental space time geometry. If experience is a quality of space–time, then **Orch OR** indeed begins to address the 'hard problem' of consciousness in a serious way.

Contractils: Quantum Mechanical Fibrils

S. ROWLANDS, C. P. EISENBERG and L. S. SEWCHAND,
Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4

ABSTRACT: When an erythrocyte rouleau is pulled apart by micromanipulation the cells remain attached to each other by long fibrils which may reach lengths of over 100 μm. The tension and length of the fibrils are drastically reduced when the cellular membrane potential is abolished or when the cells are depleted of ATP. It is inferred that the fibrils consist of macromolecules and that the tension is largely derived from a quantum mechanical long-range interaction which accords with the theory of Fröhlich.

INTRODUCTION

HERBERT FRÖHLICH'S THEORY (1968, 1980) of a phonon-maser-like phenomenon in cell membranes predicts intercellular forces of range several orders of magnitude longer than London-van der Waals' force. Interactions between human erythrocytes at a range of several micrometers have recently been demonstrated by deviation from Brownian movement (Rowlands et al. 1981, 1982a, 1982b). Essential to Frohlich's hypothesis are (a) an organized array of molecules in a membrane, (b) a membrane potential to polarize membrane molecules and (c) a supply of metabolic energy which, if it exceeds a minimum value, will trigger membrane vibrations into a coherent polar oscillatory mode ($\nu \approx 10^{11}$Hz), a process analogous with the transition to coherence in a maser or in a laser. When the membrane of the erythrocyte is disorganized with glutaraldehyde the deviations from Brownian movement disappear and they disappear *reversibly* when the membrane potential is reduced to zero or if the cells are deprived of ATP (Rowlands et al. 1981, 1982a, 1982b). The presence of macromolecules in the medium suspending the erythrocytes is essential to the interaction (Rowlands et al. 1982b: Sewchand et al. 1982b) and although the necessary and sufficent properties of the macromolecules have yet to be delineated they need to have an extended chain structure.

In the experiments described by Rowlands et al. the Fröhlich interaction is superimposed on Brownian movement and the two motions are comparable in magnitude. When erythrocytes in Brownian motion collide they adhere and quite quickly (in the time frame of the experiment) slide face to face. Further cells and groups of cells adhere and so columns of erythrocytes develop, which is the well-known process of erythrocyte rouleau formation. In the present work rouleaux are pulled apart by micromanipulation, In the process long contractile fibrils (contractils) form between the cells. The properties of these contractils vary when membrane function is interfered with by the methods (a), (b) and (c) above and these variations provide additional evidence for a Fröhlich mechanism in human erythrocytes.

METHODS

Fresh heparinized blood with the haematocrit adjusted to about 1% was placed on a large cover slip on an inverted microscope (Leitz Diavert, Rockleigh, NJ). In some experiments a tiny chamber was constructed on the cover slip with pieces of microscope slides and of cover slips. Micropipettes could be inserted into a specimen of blood in the chamber and then the whole preparation sealed with medicinal paraffin. These latter experiments showed that the observed phenomena were not a consequence of the specimen drying out. In both types of experiment the end cells of a rouleau were held by gentle suction on each of two diametrically opposed micropipettes of internal diameter <3 μm. Canham and Burton (1968) showed that human erythrocytes have a "minimum cylindrical diameter" of 3 μm. That is, a cell will deform into a cylinder, with hemispherical ends, of this diameter without change of volume or of surface area. With a pipette of internal diameter <3 μm gentle suction pulls part of the cell into the pipette and thus the cell is firmly held. If the pipettes are now separated, so as to exert traction on the rouleau, the cells do not fall apart but remain linked by fibrils of length 15 μm or more (Fig. 1). If the negative pressure in one pipette is cut off, or if a fibril breaks, the remaining fibrils contract, pulling the cells through the plasma at velocities of the order of tens of micrometers per second. Observations were recorded with a still camera, a television camera, and tape recorder, or with a 16mm. cine-camera.

Experimental modification of the cells. The methods used were those fully described in Rowlands et al. (1982b). In brief, the membrane potential was brought close to zero by reducing the pH of plasma to 6.3 and restored by returning it to pH = 7.4. (Funder and Wieth, 1966; Lassen et al. 1980). The membrane potential was calculated from measurements of the chloride ratio $[Cl_i^-/Cl_o^-]$ using the Nernst equation. The other (nonreversible) method of reducing the membrane potential involved the use of the ionophore A23187 and the procedure of Flatman and Lew (1980). Metabolic depletion was achieved by incubation for 24 hr at 37°C and cells were repleted by further incubation after adding 30 mM adenosine (Meiselman and Baker 1977). The membrane was disorganized by a 24 hr incubation in 0.04g% glutaraldehyde (Rowlands et al. 1982b). In whatever manner the cells were modified, they were resuspended in their own plasma, except in the following experiments.

Mixed species experiments. Rouleaux composed of a mixture of cells from man and rabbit were examined. The cells cannot be suspended in human plasma because of immunological reactions. The suspending liquid was 0.4g% polyvinylpyrrolidone (molecular weight 360,000) in standard phosphate-buffered saline. Human serum albumin (0.2g%) was added to prevent crenation of the cells. Polyvinylpyrrolidone is a rouleau-inducing agent and it also transmits the long-range Fröhlich interaction between human erythrocytes (Sewchand et al. 1982b).

Scanning Electron Microscopy. The contractils are very thin and we have not succeeded, with the light microscope, in making a picture which demonstrates contractils unequivocally. The two younger authors of this paper see contractils by direct vision, but the old one never does. We therefore

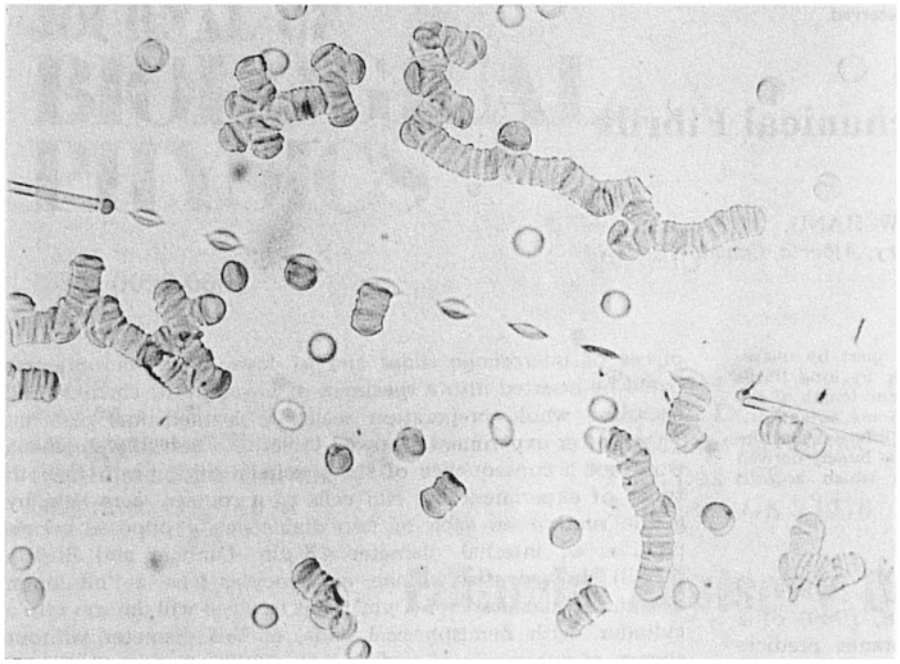

Fig. 1 A branched rouleau has been extended between the micropipettes seen at extreme left and right. The internal diameter of the pipettes is less than the cellular minimum cylindrical diameter (see text) and so the end cells are firmly held by negative pressure. Branches of the original rouleau are seen still attached to cells three, four, and eight of the chain. Human erythrocytes in their own plasma. Red cell diameter ≈ 8 μm.

embarked on scanning electron microscopy. In the end success was achieved but the technique demands the utmost delicacy. Contractils were pulled in an open chamber which could be perfused. With a satisfactory chain of cells in view through the light microscope, glutaraldehyde (0.5g% in phosphate-buffered saline) slowly replaced the rouleau-inducing fluid. This was followed by flow of distilled water (40 ml) to remove all the glutaraldehyde solution. The water was sucked out of the chamber and the specimen was allowed to dry overnight, still on the light microscope with micromanipulators and pipettes in place. If the specimen looked satisfactory the next day, the micropipettes were rigidly glued to the floor of the chamber with a drop or two of epoxy cement. When the cement was hard the outer parts of the pipettes were sheared off with heavy metal cutters. The flow chamber could now be taken from the light microscope. The glass floor of the chamber was removed and cut around the tips of the attached pipettes to a size to fit a metal sample holder. The rest was the standard technique of scanning electron microscopy. The thickness of the gold coating, according to the machine calibration, was 80 nanometres.

RESULTS

The chain of cells in Fig. 1 was drawn from a large branched rouleau such as seen elsewhere in the field of view. That is why small rouleaux are attached to some of the cells in the chain. The gaps in the chain are on the average 10 μm long. These are by no means the longest contractils we have seen. The maximum length of a contractil before breaking varies from rouleau to rouleau and from day to day in the blood of the same donor.

Glutaraldehyde-fixed cells. Our method leaves the shape, area, and volume of the cells unaffected. Such cells are rigid and cannot be drawn into a pipette. Rouleaux do not form. Occasionally cells will stick together and they can be separated by shear from the tips of the pipettes. There is no sign of a contractil. Once separated the cells fall apart.

Ionophore-treated (A23187) cells. Two experiments were done with identical results. Rouleaux formed without delay and their appearance was normal; Yet no contractils were seen. As soon as the cell at one end of a rouleau was sucked into the first pipette, the cell came away. The cells could be picked off one by one from a rouleau with a single pipette.

Variation of membrane potential by varying pH (four experiments). At pH = 6.3 when the membrane potential is within 1.5 mV of zero (Rowlands et al. 1982b) some rouleaux fell apart on manipulation but others formed short (<4 μm) contractils which gave the appearance of being weak, perhaps because further extension led to rupture. No long contractils were formed. Restoring the pH to 7.4 gave contractils with most rouleaux and they were consistently longer (>6 μm) than at pH = 6.3.

Metabolic depletion and repletion (four experiments). The majority of metabolically depleted cells are crenated. Crenated cells do not form rouleaux but they often stick together. They can be sucked easily into a micropipette and on manipulation adhering cells immediately fall apart with no sign of a contractil. A minority of cells are normal in appearance and some of these form rouleaux. Some of the rouleaux fall apart on micromanipulation: others demonstrated contractils but always they were short (<4 μm) as in the pH = 6.3 low membrane potential experiments. When the cells were repleted with adenosine crenation disappeared and rouleaux formed normally. Contractils reappeared and they were >8 μm in length but, as when the membrane potential was restored, fully normal contractils were rarely seen.

Interspecies Experiments. Rouleaux which form from mixtures of erythrocytes from different species of mammals are not random in their grouping of cells. (Sewchand and Canham 1976). This non-randomness is further evidence for a Fröhlich interaction between erythrocytes (Rowlands et al. 1982a,b). A human-rabbit mixed rouleau comprises short runs of cells of the two species and the cells can be identified by size. On micromanipulation such a mixed rouleau always separates at a junction between a rabbit cell and a human cell. There is sometimes a short contractil at the break. But when a mixed rouleau is stripped until the remaining rouleau is all rabbit or all human and then pulled apart, normal contractils occur.

Scanning Electron Microscopy. In dozens of attempts a break always occurred in all but the shortest contractils subsequent to removal from the light microscope. The contractil shown in Fig. 2 is no exception. Such breaks can occur in any

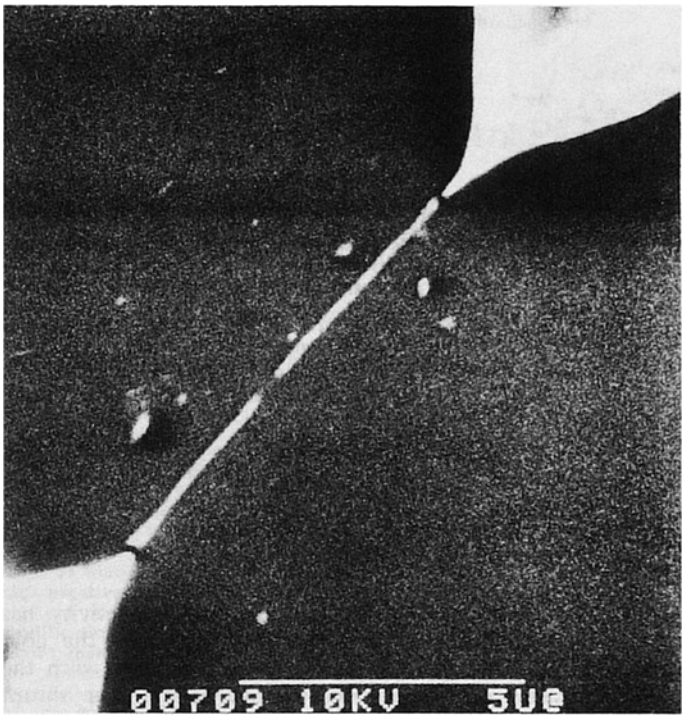

Fig. 2 Scanning electron microscope picture. See text for technique. The break in the middle of the contractil is an artefact. The breaks where the contractils begin to widen and merge with the contours of the cells are always present. The line above the identification marks is 5 μm long.

position along the fibre. Quite consistently, however, two additional and very short discontinuities are seen at the ends of each contractil just as it begins to widen and merge with the contours of the two cells to which it is attached. Since contractils and cells, after fixation, were washed in distilled water and then dried, the contractils as prepared for scanning electron microscopy, are stretched in air. Two breaks would cause them to fall and be displaced from alignment with the pointed aspects of the cells. Such displacement is never seen. This finding is considered in the Discussion.

Velocity of recoil. If a contractil breaks or if the negative pressure in one micropipette is released the stretched chain of cells recoils back into a rouleau. The maximum velocity of recoil measured by frame analysis of a cine-film was 180 $\mu m.s^{-1}$. The length of the contractil at this velocity was 18 μm. By observing Brownian movement of erythrocytes resting on horizontal surfaces we have made extensive measurements on drag coefficients (Rowlands et al. 1982a,b; Sewchand et al. 1982a). If we assume for the purposes of an order of magnitude calculation that the cell was traveling at its terminal velocity under the force (F) from the contractil then

$$F = \nu\mu$$

where ν is the velocity and μ is the drag coefficient. Such a calculation gives a value of the force of 10^{-6} N. If, from the width of the image of a contractil by scanning electron microscopy is subtracted the thickness of the gold shadow, the contractil itself comes out to be of width 0.2 μm (which explains the difficulty of resolution by light miscroscopy). From this a very rough estimate of the cross-sectional area and so of the stress in a contractil can be calculated giving 10^7 N/m^2. This must be regarded as an upper limit.

DISCUSSION

Coherent quantum mechanical excitations in cell membranes as postulated by Fröhlich provide a mechanism for many cell processes which await explanation (Fröhlich 1977; Cooper 1979). There is evidence, from Raman spectroscopy, of vibrations of the predicted frequency. Irradiation with microwaves of microorganisms and of cells in tissue culture demonstrates resonances as frequency is varied. Fröhlich (1980) has reviewed this evidence. But the important prediction of the theory is for the existence of ultra-long-range specific interactions for which evidence is only recently beginning to accumulate (Pohl 1980,1981a,b,c; Rowlands et al. 1981, 1982a,b; Sewchand et al. 1982b). In brief Pohl has shown that particles of high dielectric constant will adhere to cells more readily than particles of low dielectric constant. Rowlands et al. have demonstrated an interaction between erythrocytes in their own plasma at a range of several micrometers. The interaction requires a membrane potential and a supply of energy.

The Rowlands et al. interaction takes place *before* cellular contact. Contractils arise *after* contact when the cells are pulled apart by micromanipulation. Certain macromolecules are essential to both processes and the inference is that the Fröhlich interaction of erythrocytes is transmitted by these macromolecules (Rowlands et al. 1982b; Sewchand et al. 1982b). Solutions of macromolecules can be pulled out into thin threads (e.g. polyethylene oxide) and it is no surprise that erythrocytes, adhering by virtue of suspension in a macromolecular solution, maintain adherence by thin threads when pulled apart. It is therefore necessary to review the evidence that the threads are powered and that the power is compatible with the predictions of Fröhlich's theory.

Glutaraldehyde-fixed cells. Although suspended in the same medium, fixed cells do not form contractils. They are, however, much more rigid than normal cells and so their area of contact is small. Therefore the area from which macromolecules could be recruited into a thread is much smaller than for normal cells. Thus the absence of contractils with fixed cells might merely be an area effect.

Ionophore-treated cells. These form normal-looking rouleaux which fall apart on micromanipulation. They are not so flexible as normal cells but they have a much larger area of contact than gluraraldehyde-fixed cells, as large as for normal cells. But reduced flexibility could prevent the macromolecules holding the cells together from being drawn towards the final point of membrane contact as the cells come apart.

Change of membrane potential by change in pH. At pH = 6.3 when the membrane potential was close to zero, rouleaux occur and sometimes these formed short, weak threads. The cells were of normal flexibility, the area of contact was maximal, and so these threads were probably a passive drawing out of the macromolecules which had held the membranes together. They never exceeded 4 μm in length and they broke within a few seconds. With normal cells the threads are very much longer, at least 10 μm and sometimes over 100 μm in length. Moreover threads from normal cells continue to exist for half an hour or more prior to fixation in the scanning electron microscope experiments. Restoring pH to 7.4 and so the membrane potential nearly to normal (Rowlands et al. 1982b) partially restored the contractils. They were longer and longer lasting than at pH = 6.3 but we never observed the very long contractils seen with normal cells.

Metabolic depletion and repletion. No contractils formed when the depleted cells were crenated and they reappeared when the metabolism was restored with adenosine. A minority of depleted cells have normal appearance, but formed rouleaux and weak contractils. These cells may not have been depleted as much as those which crenated.

Interspecies experiments. The nonrandomness of the arrangement of the cells in mixed rouleaux has been adduced as

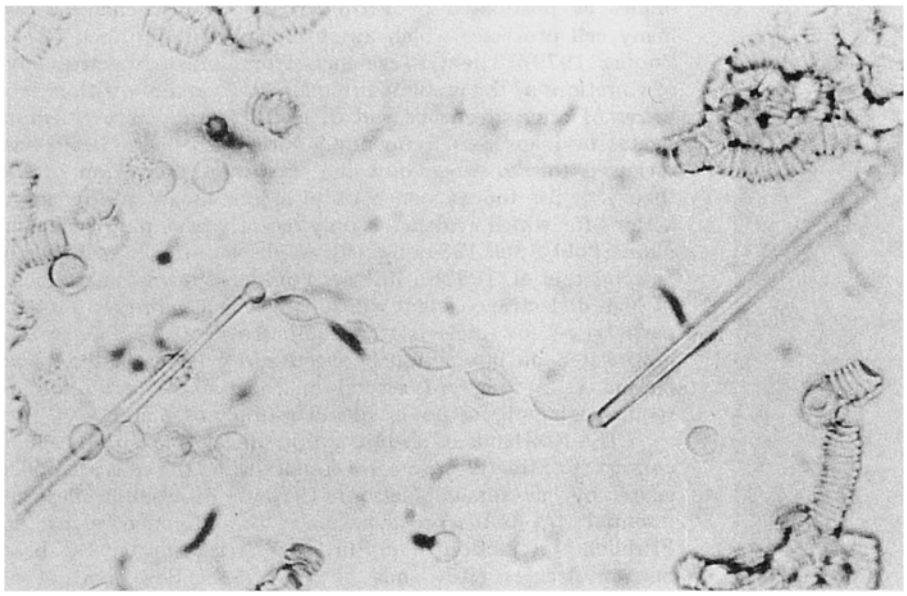

Fig. 3 The pipettes are offset and the axis of the contractils is seen to be radial with respect to the spherical external part of each of the two cells held in the micropipettes. As the extent of the offset is varied the contractils always point towards the centres of the spheres. Human erythrocytes in their own plasma. Red cell diameter ≈ 8 μm.

evidence for specificity in the interaction of erythrocytes (Rowlands et al. 1982a,b). The present experiments clearly demonstrate an adhesiveness between cells of different species which is lower than that between cells of the same species.

General Discussion. The experiments described in this paper are technically difficult and the results are qualitative. Partly this is a consequence of the technique but mainly because there is considerable variation in the properties of the cells in a single sample from an individual. There is for instance a very wide variation in the permeability of single cells to various non-electrolytes (Jay and Rowlands 1975). One "defective" cell in a rouleau would vitiate contractil formation. Such defective cells might be ripe for destruction in the spleen. Nevertheless the properties of these threads vary regularly in the manner expected if their tension is derived, in the main, from the living state of the erythrocytes. There are two further important pieces of evidence. When one contractil breaks the remaining cells are pulled together at great speed by the remaining contractils back into a rouleau. If the thread was just visco-elastic, it would shorten, but not down to a zero length, so rapidly bringing the membranes again into contact. Moreover a passive thread would always attach at the point on the membrane from which it originated. Reference to Fig. 3 shows that the line of attachment of the contractil to the spherical portion of the end cells held in the micropipettes is radial, directed towards the center of the sphere. As the pipettes are moved out of and into alignment, with the tips kept at a fixed distance apart, the attachment moves over the spherical surfaces, always directed towards the center of the sphere without hysteresis. If the pressure in the pipette is released slightly so that the sphere sags, then a point appears at the attachment which also moves freely with the contractil as its orientation is changed.

We conclude that the observed fibrils have an active contraction powered by the cells and that the contraction is consistent with the interaction postulated by Fröhlich.

An unequivocal picture of a contractil by light microscopy was not obtained. What two out of three of the authors saw might have been an optical illusion because the line of a contractil is clearly oriented by the direction of the points on the parent cells. Scanning electron microscopy proved the existence of a physical thread, which is composed of macromolecules. The constant gaps in the contractils which occur just as they merge into the cell outline are difficult to explain. By the time the gold, which is what is seen, falls on the contractils they and the cells have been fixed in glutataldehyde, washed in distilled water and air dried overnight, so all quantum activity has ceased. There must still be continuity otherwise the gold threads would have been displaced from alignment with the points of the cells. Clearly there must be a rather abrupt thinning of the contractil close to the pointed distortion of the cell membrane. Rowlands et al. (1982b) have suggested that the interaction is transmitted by quantum quasi-particles which may be tunnelling at this point between the membrane and the contractil.

COOPERATIVE BEHAVIOR IN BIOLOGICAL SYSTEMS

T.M. WU and Steven AUSTIN
Department of Physics, State University of New York at Binghamton, Binghamton, NY 13901, USA

Received 23 November 1977

Fröhlich's model of Bose condensation in biological systems is discussed. A criticism of the theory levied by Lifshits is examined utilizing microscopic techniques. It is subsequently concluded that the criticism is invalid.

Cooperative behavior in biological systems. The possible participation of the vibrations of the dipolar segments of biological macromolecules in fundamental biological processes has been discussed repeatedly [1–10]. Fröhlich [1–5] proposed that such coherent behavior is feasible if energy is supplied to the dipolar constituents above a certain critical rate which causes the oscillating subunits to condense into the lowest energy mode in a manner characteristic of Bose condensation. Fröhlich's analysis was based upon rate equations whereby each dipolar segment was considered to be suspended in a heat bath.

Subsequently, other investigators [6–10] approached the theoretical problem from differing standpoints. Lifshits [6] concluded that the Fröhlich model was erroneous because omitted in the rate equations is a "two quantum" term which, when included, obliterates the Bose condensation effect.

The purpose of the present paper is to illustrate that Lifshits' argument is incorrect, and that Bose condensation does occur even when the Lifshits term is included in the calculation.

According to Fröhlich, the biological system is presumed to consist of (i) oscillating units of giant dipoles (e.g., sections of the membrane of cells or parts of H-bonds within biological macromolecules), (ii) the remainder of the biological system which formed the heat bath, and (iii) an external energy source which couples to the vibratory units. Long-range Coulomb interaction between the oscillatory units produces a narrow band of frequencies, $\omega_i(\omega_0 \leqslant \omega_i \leqslant \omega_{\max})$, corresponding to the normal modes of the electromagnetic oscillations. Utilizing these assumptions, Fröhlich deduced that the average rate of change of ith mode quanta is [2]

$$\langle \dot{n}_i \rangle = S - \phi[\langle n_i \rangle \exp(\hbar\omega_i/kT) - (1 + \langle n_i \rangle)] - \chi \sum_j [\langle n_i \rangle (1 + \langle n_j \rangle) \exp[\hbar(\omega_i - \omega_j)/kT] - \langle n_j \rangle (1 + \langle n_i \rangle)], \tag{1}$$

where S is the rate of energy supplied, and ϕ and χ are coupling constants to the heat bath for the one- and two-quantum processes respectively.

Lifshits claims that included in the interaction hamiltonian should be "two-quantum" terms which allow the simultaneous creation and destruction of the quanta (i) and (j). Thus, according to Lifshits, a modification of the Fröhlich formula is required which yields for the average rate of change of ith mode quanta [6]:

$$\langle \dot{n}_i \rangle = S - \phi[\langle n_i \rangle \exp(\hbar\omega_i/kT) - (1 + \langle n_i \rangle)] - \sum_j \chi_j [\langle n_i \rangle (1 + \langle n_j \rangle) \exp(\hbar\omega_i/kT) \tag{2}$$

$$- \langle n_j \rangle (1 + \langle n_i \rangle) \exp(\hbar\omega_j/kT) - (1 + \langle n_i \rangle)(1 + \langle n_j \rangle) + \langle n_i \rangle \langle n_j \rangle \exp[\hbar(\omega_i + \omega_j)/kT]]$$

$$= S - B_i[\langle n_i \rangle \exp(\hbar\omega_i/kT) - (1 + \langle n_i \rangle)], \tag{3}$$

where $\chi_j = \chi \exp(-\hbar\omega_j/kT)$, $B_i = \Sigma_j \chi_j[1 + \langle n_j\rangle + \langle n_j\rangle \exp(\hbar\omega_j/kT)] + \phi$. Therefore, the two-quantum term is of the same form as the one-quantum term and no Bose condensation occurs.

To confirm the weakness of Lifshits' conclusions, the problem must be treated microscopically. Assigning creation and destruction operators to each mode associated with the oscillating subunits (a_i^+, a_i), heat bath (b_k^+, b_k), and the energy source (p_p^+, p_p), it is possible to write the hamiltonian of the biological system as:

$$H = \sum_i \hbar\omega_i a_i^+ a_i + \sum_k \hbar\Omega_k b_k^+ b_k + \sum_p \hbar\bar{\Omega}_p p_p^+ p_p + \sum_{i,j,k} (\lambda a_i b_j^+ b_k + \lambda^* a_i^+ b_j b_k^+)$$
$$+ \sum_{i,j,k}' (\chi a_j^+ a_i b_k^+ + \chi^* a_j a_i^+ b_k) + \frac{1}{2}\sum_{i,j,k} (\beta a_j a_i b_k^+ + \beta^* a_j^+ a_i^+ b_k) + \sum_{p,i} (\xi p_p a_i^+ + \xi^* p_p^+ a_i), \tag{4}$$

where Ω_k and $\bar{\Omega}_p$ are the frequencies associated with excitations in the heat bath and energy source respectively and λ, χ, and ξ are coupling constants for the one-quantum process, for the Fröhlich two-quantum process, and for the energy supply to the oscillating units respectively.

β is the coupling constant for the simultaneous creation and destruction two-quantum terms suggested by Lifshits. Using this hamiltonian and perturbation theory [10] yielded for the $\langle \dot{n}_i\rangle$, the average rate of change of quanta with frequency ω_i in the biological system:

$$\langle \dot{n}_i\rangle = S - \phi(T,\omega_i)[\langle n_i\rangle \exp(\hbar\omega_i/kT) - (1 + \langle n_i\rangle)] - \sum_j \Lambda(T,\omega_i,\omega_j)[\langle n_i\rangle(1+\langle n_j\rangle)\exp(\hbar(\omega_i-\omega_j)/kT) - \langle n_j\rangle(1+\langle n_i\rangle)]$$
$$- \sum_j \Gamma(T,\omega_i,\omega_j)[\langle n_i\rangle\langle n_j\rangle \exp(\hbar(\omega_i+\omega_j)/kT) - (1+\langle n_i\rangle)(1+\langle n_j\rangle)],$$

where

$$\phi(T,\omega_i) = \frac{4\pi|\lambda|^2}{\hbar}\sum_j N(\hbar\Omega_j)N(\hbar\omega_i + \hbar\Omega_j)\exp(\hbar\Omega_j/kT),$$
$$\Lambda(T,\omega_i,\omega_j) = \frac{2\pi|\chi|^2}{\hbar}\times\begin{cases} 1 + N(\hbar\omega_j - \hbar\omega_i), & \text{for } \omega_j > \omega_i, \\ N(\hbar\omega_i - \hbar\omega_j), & \text{for } \omega_j < \omega_i, \end{cases} \tag{6}$$
$$S = \frac{4\pi|\xi|^2}{\hbar}\sum_i \langle p_i^+ p_i\rangle_0, \qquad \Gamma(T,\omega_i,\omega_j) = \frac{2\pi|\beta|^2}{\hbar}N(\hbar\omega_i + \hbar\omega_j),$$

and $N(\hbar\omega)$ is the number of excitations with energy $\hbar\omega$ in the heat bath.

If $\Lambda(T,\omega_i,\omega_j)\exp(-\hbar\omega_j/kT) = \Gamma(T,\omega_i,\omega_j)$ as Lifshits presumes, then eq. (5) can be reduced to Lifshits' form. However, as seen in eq. (6), allowing equality of $\Lambda\exp(-\hbar\omega_j/kT)$ and Γ is incorrect. Nonetheless, presupposing that the coupling constants are in the same order of magnitude for each type of two-quantum interaction, the coefficient, $\Lambda(T,\omega_i,\omega_j)$, is much larger than the coefficient, $\Gamma(T,\omega_i,\omega_j)$. This can be demonstrated readily for biological systems where ω_i is of the order of 10^{11} sec^{-1}. At room temperature $\hbar\omega_i/kT \doteq 10^{-2}$, thus Γ and Λ can be approximately written as:

$$\Gamma \doteq (2\pi|\beta|^2 kT/\hbar^2)(\omega_i + \omega_j)^{-1} \quad \text{and} \quad \Lambda \doteq (2\pi|\chi|^2 kT/\hbar)(|\omega_j - \omega_i|)^{-1}. \tag{7a, b}$$

For the Γ term, since $\omega_i \doteq \omega_j$ due to the very narrow range of normal frequencies, let $\omega_i \doteq \omega_j = \bar{\omega}$. For the Λ term, let $|\omega_j - \omega_i| = \Delta\omega$, the width of the frequency band. Thus eqs. (7) become:

$$\Gamma \doteq (\pi|\beta|^2/\hbar)(kT/\hbar\bar{\omega}) \quad \text{and} \quad \Lambda \doteq (2\pi|\chi|^2/\hbar)(kT/\hbar\Delta\omega). \tag{8a, b}$$

Since the range of normal frequencies of the oscillations is very small, $\Delta\omega \ll \bar{\omega}$. Therefore, the terms in eq. (8b) are much larger than those in eq. (8a). The simultaneous creation and destruction of quanta proposed by Lifshits can be regarded as negligible. Thus, the predominant "two-quantum" process is precisely the one postulated by

Fröhlich, and the addition of the Lifshits term does not cancel out the Bose condensation phenomenon predicted by Fröhlich.

As Fröhlich has pointed out to us, oscillations as introduced in refs. [7–9] and by the above authors form only a part of the degrees of freedom of the heat bath. Very important for the relevant energy transfer are non-oscillating systems, e.g. free ions, mobile ionic groups (dipoles), and certain low-lying electronic levels. For all of these it can be shown in a trivial way that Lifshits' contention is incorrect. In fact some of them may permit excitations in the energy range $(0, \hbar(\omega_{max} - \omega_0))$ but not in the range $(2\hbar\omega_0, 2\hbar\omega_{max})$, thus making two-phonon absorption or emission impossible.

(Received 7 May 1973)

This is the first in a series of papers on the large-order behavior of perturbation theory for coupled anharmonic oscillators. We exploit previously published dispersion techniques to convert the calculation of perturbation theory in large order into a barrier-penetration problem. We then introduce new semiclassical methods for describing tunneling through nonspherically symmetric, N-dimensional potentials. To illustrate our new methods, we calculate the large-order behavior of perturbation theory for a simple system of two equal-mass oscillators with quartic coupling. Our predictions are in complete agreement with computer calculations. We then extend our results to oscillators with x^{2N} coupling, N-oscillator systems, and some infinite-oscillator systems.

I. INTRODUCTION

In a recent paper Adler[1] argues that α, the physical charge on the electron, is an essential singularity of the Gell-Mann–Low function. Since the location of an essential singularity cannot be affected by the low-order terms in a perturbation expansion, an asymptotic study of perturbation theory for quantum electrodynamics in extremely large order seems indicated.

There has already been much work on the large-order behavior of perturbation series in quantum

field theory.[2] However, these papers are concerned with determining whether diagrammatic perturbation theory converges or diverges and are satisfied with order-by-order bounds on the terms in the perturbation series. What is required now is a precise analytic study of the behavior of perturbation theory in large order and not just upper and lower bounds.

Our general approach to perturbation theory in large order is guided by recent successful studies (which we review later) of perturbation theory for the anharmonic oscillator. We hope to extend and apply this work to the perturbation series encountered in quantum field theory. A $(\phi^4)_2$ quantum field theory is a good model with which to begin because, unlike four-dimensional quantum electrodynamics, its perturbation series are finite order by order. Moreover, Glimm and Jaffe[3] have shown that, with spatial and ultraviolet cutoffs, this field theory is equivalent to a finite system of coupled anharmonic oscillators (modes). Our goal is to find the large-order behavior of perturbation theory for this system as a function of the two cutoffs, remove the ultraviolet and spatial cutoffs, and, assuming that this limit exists (we see no reason why it should not), thereby obtain the answer. We have not solved this problem, but we do report major progress toward that goal. We have developed new mathematical techniques for investigating the large-order behavior of perturbation theory for coupled oscillator systems. Specifically, we have developed very general *multidimensional* semiclassical techniques[4] for treating nonspherically symmetric potentials such as those encountered in the cutoff $(\phi^4)_2$ model.

The purpose of the first paper in this series is to explain our new methods in detail in the limited context of equal-mass oscillators. (Our second paper deals with the more difficult problem of unequal-mass oscillators.) We begin by solving the two-mode oscillator defined by

$$\left[-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2 +\lambda(ax^4+by^4+2cx^2y^2)/4-E(\lambda)\right]\psi(x,y)=0, \tag{1.1}$$

where

$$\lim_{|\vec{r}|\to\infty}\psi(x,y)=0, \quad \vec{r}=(x,y). \tag{1.2}$$

We assume that $a>0$, $b>0$, and $c\geq -\sqrt{ab}$, making the potential bounded below. Then it is possible to satisfy Eq. (1.2) and ψ is a bound-state wave function with $E(\lambda)$ its associated energy eigenvalue. The perturbation series for the ground-state energy is given by[5]

$$E(\lambda)=1+\sum_{n=1}^{\infty}A_n\lambda^n. \tag{1.3}$$

Our goal is to predict the behavior of A_n for large n as a function of a, b, and c. We solve this problem in Secs. II–VI. The solution is a discontinuous function of a, b, and c, and the discontinuities have an interesting physical explanation. In Sec. VII we hope to whet the reader's appetite by giving a partial solution of the N-mode oscillator defined by

$$\left[\sum_{i=1}^{N}\left(-\frac{\partial^2}{\partial x_i^2}+\tfrac{1}{4}x_i^2\right) +\tfrac{1}{4}\lambda\sum_{i,j=1}^{N}a_{ij}x_i^2x_j^2-E(\lambda)\right]\psi(x_i)=0. \tag{1.4}$$

In addition, we exhibit some matrices $\{a_{ij}\}$ for which the limit $N\to\infty$ may be taken, and explicitly compute the large-order behavior of the ground-state energy perturbation series for those infinite systems.

Before discussing more fully the content and results of this paper, we briefly review what is known about the one-oscillator problem so that this paper will be reasonably self-contained. In early computer studies[6,7] of the ground-state energy of the anharmonic oscillator, an extraordinarily simple behavior was observed for perturbation theory in large order. In particular, for the anharmonic oscillator defined by

$$[-d^2/dx^2+x^2/4+\lambda x^4/4-E(\lambda)]\psi(x)=0 \tag{1.5}$$

and

$$\lim_{|x|\to\infty}\psi(x)=0, \tag{1.6}$$

and the ground-state energy perturbation series defined by

$$E(\lambda)=\tfrac{1}{2}+\sum_{n=1}^{\infty}A_n\lambda^n, \tag{1.7}$$

a numerical fit to A_n for large n was found to be

$$A_n=-\frac{\sqrt{6}}{\pi^{3/2}}(-3)^n\,\Gamma(n+\tfrac{1}{2})\left[1+O\left(\frac{1}{n}\right)\right]. \tag{1.8}$$

Later, methods were developed that explain this behavior analytically.[8,9] Indeed, two completely independent techniques were developed which predict formulas similar to Eq. (1.8) for *all* energy levels of *all* anharmonic oscillators having λx^{2N} interactions. Analogous results for anharmonic oscillators with arbitrary polynomial interactions were also obtained and the effect of Wick ordering on perturbation theory in large order was determined.[10] Moreover, higher-order corrections [$O(1/n)$ terms] were also calculated and these also agree with computer calculations.[8,9]

The anharmonic oscillator suggests how perturbation theory might behave in a $(\phi^4)_2$ field theory because it is also a quantum field theory. Equations (1.5) and (1.6) can be reinterpreted as describing a ϕ^4 field theory in one-dimensional space-time.[11] For more complicated systems such as those defined in Eqs. (1.1) and (1.2) and in Eq. (1.4), A_n behaves for large n very much like the A_n in Eq. (1.8). We would not be very surprised to find that the ground-state energy perturbation series for a $(\phi^4)_2$ field theory behaves similarly.

We now give a more detailed outline of this paper. Section II employs dispersion techniques to reduce the problem of finding the leading large-n behavior of A_n to that of solving a quantum-mechanical barrier-penetration problem. The barrier penetration is then treated semiclassically. In Secs. III and IV we develop those semiclassical methods needed to solve Eqs. (1.1) and (1.2) for the special case where $a=b=1$. In Sec. III we solve the problem approximately using geometrical optics, and in Sec. IV we find the precise leading behavior of A_n for large n using physical optics. The notions of geometrical and physical optics are discussed in detail. The results are as follows: For $-1 \leq c < 1$,

$$A_n \sim -[48c/\sin(\pi\nu)]^{1/2}(-3)^n \Gamma(n+\tfrac{1}{2})/\pi, \tag{1.9}$$

where $\nu(\nu+1)=2c$; for $c>1$,

$$A_n \sim -[48\bar{c}/\sin(\pi\bar{\nu})]^{1/2}[(-3c-6)/2]^n \Gamma(n+\tfrac{1}{2})/\pi, \tag{1.10}$$

where $\bar{\nu}(\bar{\nu}+1)=2\bar{c}=(3-c)/(1+c)$; and for $c=1$,

$$A_n \sim 2(-3)^{n+1}\Gamma(n+1)/\pi. \tag{1.11}$$

The discontinuity at $c=1$ is caused by a kind of constructive interference.

The calculation for the special spherically symmetric case ($c=1$) is done in Appendix A. Appendix A actually treats the more general case of N oscillators with spherically symmetric coupling. In Appendix B we repeat the calculations of Sec. IV for a system of two coupled oscillators with $2N$ order rather than quartic coupling.

The predictions in Eqs. (1.9)–(1.11) are compared with computer calculations in Sec. V and we observe spectacular agreement. Section VI generalizes the results in Eqs. (1.9)–(1.11) to the case where a and b are not 1. Again the theoretical and numerical calculations agree. Finally, in Sec. VII we investigate Eq. (1.4). In Appendix C we discuss some properties of equal-mass N-oscillator systems that are more general than those in Eq. (1.4).

II. DISPERSION RELATION

In this section we reduce the problem of finding the large-order behavior of the Rayleigh-Schrödinger coefficients to a semiclassical barrier-penetration problem. This reduction is necessary because, as we explain below, a direct analysis of the difference equation which generates the perturbation series is too difficult.

In general, the Rayleigh-Schrödinger coefficients [such as those defined in Eq. (1.3)] for a perturbation problem in quantum mechanics may be computed from a recursion relation which gives the nth coefficient in terms of its predecessors and integrals over all the lower-order contributions to the wave function. The special form of the unperturbed wave function for the harmonic oscillator and our choice of a polynomial perturbing potential [see Eqs. (1.1) and (1.4)] enable us to reduce the recursion relation to a single nonlinear partial difference equation. This difference equation, which we derive and discuss in detail in Secs. V and VI, may be solved on a computer.

The corresponding but much simpler difference equation for a single anharmonic oscillator can actually be solved approximately.[8,9] However, for a system of coupled anharmonic oscillators, the indices in the difference equation proliferate and the relevant approximation techniques become unwieldy, even for the two-mode oscillator. With this difficulty in mind, we have developed in a previous paper a rather indirect, but physically intuitive, method for computing the large-n behavior of A_n which generalizes immediately to the many-coupled oscillator problem. This method rests on Eq. (2.4).

Equation (2.4) may be derived by assuming a once-subtracted dispersion relation for $E(\lambda)$:

$$F(\lambda) = \frac{1}{2\pi i}\int_{-\infty}^{0} \frac{D(x)}{x-\lambda}\,dx, \tag{2.1}$$

where

$$F(\lambda) \equiv [E(\lambda)-E(0)]/\lambda \tag{2.2}$$

and

$$D(\lambda) \equiv \lim_{\epsilon\to 0}[F(\lambda+i\epsilon)-F(\lambda-i\epsilon)]. \tag{2.3}$$

From Eq. (2.1) we obtain an exact expression for the nth Rayleigh-Schrödinger coefficient after expanding $(x-\lambda)^{-1}$ and comparing with Eq. (1.3). We find that

$$A_n = \frac{1}{2\pi i}\int_{-\infty}^{0} D(x)x^{-n}\,dx. \tag{2.4}$$

The proof of Eq. (2.1) for the one-mode oscillator is outlined in Sec. II of BW II. Although there is

as yet no proof, it is intuitively reasonable that Eq. (2.1) is valid for the N-mode oscillator. However, a proof would require that $E(\lambda)$ be analytic in the cut λ plane. Analyticity has only been proved[12] in the region shown in Fig. 1. Fortunately, analyticity in this region is sufficient to rigorously establish Eq. (2.4) for large n.[12]

Equation (2.4) may be understood as follows. When λ is negative, the perturbing potential in Eq. (1.1) becomes repulsive. The states that were found for $\lambda > 0$ now decay. Decaying states have complex eigenvalues and the imaginary part of the eigenvalue is inversely proportional to the lifetime of the state. Equation (2.4) relates A_n to the inverse moments of the imaginary part of $E(\lambda)$ and thus to the lifetime of the decaying state. For large n, the integral is dominated by small negative values of x. Thus, the large-order behavior of A_n is related to the imaginary part of $E(\lambda)$ for small negative coupling constant.

It is interesting to note that if the perturbing potential is dominated by the unperturbed potential when λ gets small enough, all states will be bound for such values of λ. We then have $\mathrm{Im}E(\lambda) = 0$ for $|\lambda|$ sufficiently small. In this case, Eq. (2.4) tells us that $\lim_{n\to\infty} A_n = 0$, and the perturbation series converges. Thus, Eq. (2.4) quantifies Dyson's[13] old argument about the divergence of perturbation theory. We emphasize the similarity between the above discussion and that given by Adler in Sec. V A of Ref. 1.

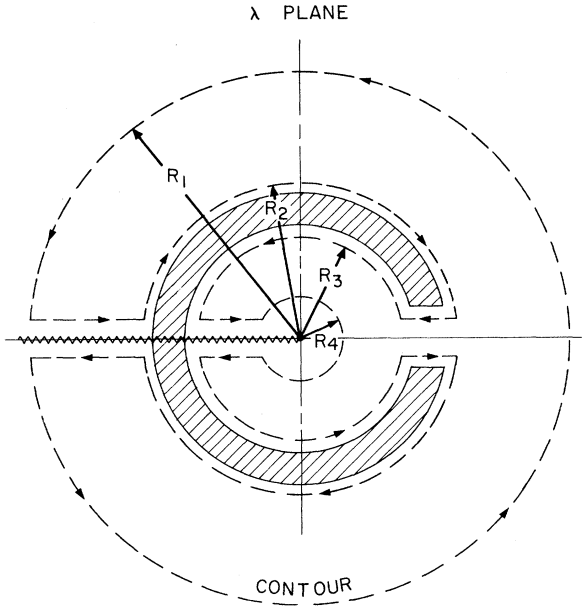

FIG. 1. The domain of analyticity of $E(\lambda)$ rigorously established by Simon. $E(\lambda)$ is analytic except on the cut along the negative real axis and in the shaded region. The contour appropriate for proving Eq. (2.4) is indicated by a dashed line.

Equation (2.4) relates the computation of A_n to the familiar quantum-mechanical barrier-penetration problems as follows. Generalizing the arguments of the Appendix in Ref. 9 we can express $\mathrm{Im}E(\lambda)$ as

$$\mathrm{Im}E = \frac{\int_{S_V} \vec{\mathbf{J}} \cdot d\vec{\mathbf{S}}}{\int_V \psi^* \psi \, dV}, \tag{2.5}$$

where $\vec{\mathbf{J}}$ is the probability current,

$$\vec{\mathbf{J}} \equiv \tfrac{1}{2} i(\psi^* \vec{\nabla} \psi - \psi \vec{\nabla} \psi^*), \tag{2.6}$$

and S is the boundary of volume V. We take S to lie outside the barrier so that there are no points outside of S where the probability current can reflect back toward the origin. Thus $\vec{\mathbf{J}}$ measures decay of the state by expressing the flow of probability density out to $|\vec{\mathbf{r}}| = \infty$.

Equations (2.4) and (2.5) relate A_n to the perturbed wave function for small negative λ.

III. GEOMETRICAL OPTICS

A. Discussion of Method of Solution

In Sec. II we reduced the calculation of the large-order behavior of perturbation theory to the familiar quantum-mechanical problem of tunneling through a nonspherical N-dimensional potential barrier. We propose a method for solving this problem which rests on a simple physical picture. A particle in an unstable state centered at the origin will ultimately penetrate the barrier and escape to infinity. The total amplitude for escape is the sum of the amplitudes over all possible paths of escape. We will show that there exist most probable escape paths (MPEP's) and that the relative amplitude to escape along other paths is exponentially small. The dominant contribution to the escape amplitude comes from regions, which we call tubes, surrounding the MPEP's. The probability current is negligible outside of these tubes during tunneling and flows outward in narrow beams. We will show that for a system without a rotational symmetry the number of tubes is finite and that they are well separated. We will then use semiclassical (WKB-related) methods to approximate the solutions to the Schrödinger equation [Eq. (1.1)] within these tubes.

We have introduced the notion of a tube in order to reduce our nonspherical multidimensional problem to one which is approximately one-dimensional. It is natural to try to solve a tunneling problem using WKB techniques.[14] There has been much work on the problem of WKB approximations to many-dimensional systems.[14] The zeroth-order WKB

equation for the phase S of a wave function with energy E is[15]

$$(\vec{\nabla}S)^2 = V - E\,. \tag{3.1}$$

This is just the Hamilton-Jacobi equation for a classical system with Hamiltonian $\vec{p}^2 + V$. In one dimension it reduces to $(dS/dx)^2 = V - E$, whose solution is $S = \pm\int (V-E)^{1/2}$. For the general multidimensional case it is a nonlinear partial differential equation. Of course, if the Hamiltonian has a continuous symmetry, Eq. (3.1) will be separable. However, Eq. (3.1) is nontrivial in general. The new multidimensional techniques which we have discovered simplify the problem of solving Eq. (3.1) because now we need to solve it only in a small, approximately one-dimensional region. Our technique is expressly designed to deal with problems which do *not* have continuous symmetries, and is thus *complementary* to the separation of variables idea.

We briefly review the path-integral formalism. The amplitude for a particle of energy E to take a particular path P in a potential V is

$$\frac{1}{N}\exp\left[-\int_P (V-E)^{1/2}\right], \tag{3.2}$$

where $\int_P (E-V)^{1/2}$ is the classical action and the normalization factor N depends only on the end points of the path. The total amplitude is just the sum of Eq. (3.2) over all paths P.

In the tunneling region, $(V-E)$ is positive, and the amplitude is exponentially damped. Therefore, the dominant contribution to the amplitude comes from regions near the paths which minimize the action integral and thus satisfy

$$\delta\int (V-E)^{1/2} = 0\,. \tag{3.3}$$

The Euler-Lagrange equations following from Eq. (3.3) are[16]

$$2(V-E)\frac{d^2x_i}{ds^2} + \frac{dx_i}{ds}\left[\sum_j \frac{dx_j}{ds}\frac{dV}{dx_j}\right] = \frac{\partial V}{\partial x_i}\,, \tag{3.4}$$

where s is the path length. All solutions of Eq. (3.4) are local stationary points of the action. However, we are interested in the *global* minima. This will eliminate all except a discrete[17] set of paths which are just the MPEP's.

Once we have found a set of MPEP's, we must find approximate solutions to the Schrödinger equation along these trajectories. As in any semiclassical or ray description of a wave phenomenon, we must distinguish two levels of approximation. At the first level, called geometrical optics or the eikonal approximation, the phase of the wave function is approximated by a line integral along the trajectory, while its amplitude is assumed to be constant. This is just zeroth-order WKB. The second level, called physical optics or first-order WKB, takes into account the variation of the amplitude and the spread of the wave function into the region around the trajectory. Thus, physical optics is characterized by a set of tubes through which most of the probability current flows.

These two levels of approximation are clearly distinguished in our results for the large-order behavior of perturbation theory. We find that in general for large n

$$A_n \sim KL^n\,\Gamma(Mn+J)[\,1+O(1/n)]\,. \tag{3.5}$$

The constants L, M, and J are determined by geometrical optics alone. Physical optics is needed to find the value of K.

B. Determination of Most Probable Escape Paths

The program we outlined in part A of this section for finding the MPEP's is of course very difficult. It involves actually finding closed-form solutions to Eq. (3.4) and explicitly selecting those solutions which minimize $\int (V-E)^{1/2}$. Fortunately, in many cases, a heuristic argument enables us to guess the most probable paths without solving Eq. (3.4) and these turn out to be straight lines. In fact, it is generally true that the MPEP's for the equal-mass oscillators defined in Eq. (1.4) are straight lines. The more difficult problem of unequal-mass oscillators, which have curved MPEP's, will be discussed in the next paper of this series.[18] It is easy to show that the straight MPEP's satisfy Eq. (3.4), but we have no way of proving that they are global minima of the action. The only convincing evidence we have for this is the excellent agreement of our results with our computer calculations.

In this section we use geometrical optics to treat the special case of Eq. (1.1) for which $a = b = 1$. This simplifies the notation without obscuring any of the important features of the problem. In Sec. IV we use physical optics to treat this same case. Equation (1.1) is solved in general in Sec. VI.

We expect a straight MPEP to satisfy certain reasonable criteria. It should be a "path of least resistance" to tunneling and thus should pass through a saddle point of the potential $V = \frac{1}{4}x^2 + \frac{1}{4}y^2 - \frac{1}{4}\epsilon(x^4 + y^4 + 2cx^2y^2)$. The saddle point should be oriented along the path (which is a radial line). A saddle point of V satisfies the equations

$$\begin{aligned}\frac{\partial V}{\partial x} &= \tfrac{1}{2}x - \epsilon(x^3 + cxy^2) = 0\,,\\ \frac{\partial V}{\partial y} &= \tfrac{1}{2}y - \epsilon(y^3 + cx^2y) = 0\,.\end{aligned} \tag{3.6}$$

Equations (3.6) have nine solutions, namely,

$$(x, y) = (0, 0),$$
$$(\pm(2\epsilon)^{-1/2}, 0), \quad (0, \pm(2\epsilon)^{-1/2}), \tag{3.7}$$

and

$$\pm([2(c+1)\epsilon]^{-1/2}, \pm[2(c+1)\epsilon]^{-1/2}).$$

To identify those critical points in Eq. (3.7) which are radially oriented saddle points, we compute the Hessian matrix H (matrix of second partial derivatives). We demand that H have one positive and one negative eigenvalue at the critical point and further require that the eigenvector having negative eigenvalue must lie along the radial line connecting the critical point with the origin. We find that

$$H = \begin{bmatrix} \frac{1}{2} - \epsilon(3x^2 + cy^2) & -2c\epsilon xy \\ -2c\epsilon xy & \frac{1}{2} - \epsilon(3y^2 + cx^2) \end{bmatrix}. \tag{3.8}$$

It follows that $(0, 0)$ is not a saddle point, that $(\pm(2\epsilon)^{-1/2}, 0)$ and $(0, \pm(2\epsilon)^{-1/2})$ are acceptable saddle points when $-1 \leq c < 1$, and $\pm([2(c+1)\epsilon]^{-1/2}, \pm[2(c+1)\epsilon]^{-1/2})$ are acceptable saddle points when $c > 1$. When $c = 1$, there are no saddle points. This is the spherically symmetric case where all straight-line paths contribute equally to the amplitude and it is treated separately in Appendix A.

It is now easy to show that radial lines through the saddle points are solutions of Eq. (3.4).[19] Equation (3.4) reduces to

$$\frac{dx}{ds}\left(\frac{dx}{ds}\frac{\partial V}{\partial x} + \frac{dy}{ds}\frac{\partial V}{\partial y}\right) = \frac{\partial V}{\partial x},$$
$$\frac{dy}{ds}\left(\frac{dx}{ds}\frac{\partial V}{\partial x} + \frac{dy}{ds}\frac{\partial V}{\partial y}\right) = \frac{\partial V}{\partial y}, \tag{3.9}$$

because our straight-line paths have the property that

$$\frac{d^2x}{ds^2} = \frac{d^2y}{ds^2} = 0.$$

Equation (3.9) is satisfied by $(dx/ds, dy/ds) = (0, \pm 1), (\pm 1, 0)$, and $(\pm\sqrt{2}/2, \pm\sqrt{2}/2)$ because of three properties of V:

$$\left.\frac{\partial V}{\partial y}\right|_{y=0} = 0,$$
$$\left.\frac{\partial V}{\partial x}\right|_{x=0} = 0, \tag{3.10}$$
$$\frac{\partial V}{\partial x} = \pm\frac{\partial V}{\partial y}, \quad \text{when } x = \pm y.$$

C. Geometrical Optics

We outline here a brief and heuristic treatment. A careful and mathematically detailed approach is given in Sec. IV. We follow method 2 of the Appendix of BW II. Up to multiplicative constants the wave function $\psi(x, y)$ in the tunneling region on the MPEP is given by

$$e^{-\int_{s_0}^{(x,y)}(V-E)^{1/2}\,ds}.$$

We are ignoring all paths except the four MPEP's. E is the unperturbed value of the energy, namely, unity. The integral is taken along the MPEP from the inner turning point $s_0 = O(1)$ (solution of $V - E = 0$) to the argument of $\psi(x, y)$.

We are interested in computing the current flowing out to infinity. Since the distant turning point $s_1 = O(\epsilon^{-1/2})$ is the last place where the current can be reflected back toward the origin, we compute the current at a point just beyond s_1. The total current J is the sum of the currents along each MPEP. J is proportional to

$$\exp\left[-2\int_{s_0}^{s_1}(V-E)^{1/2}ds\right]$$

for each MPEP. This reduces to

$$\exp\left\{-2\int_{s_0}^{s_1}[\tfrac{1}{4}s^2 - \tfrac{1}{4}\epsilon s^4\alpha - 1]^{1/2}ds\right\},$$

where $\alpha = \cos^4\theta + \sin^4\theta + 2c\sin^2\theta\cos^2\theta$, and θ is the angle between the MPEP and the x axis. Computing the above integral approximately gives

$$J \propto \epsilon^{-1/2}\, e^{-1/(3\epsilon\alpha)}$$

for each MPEP. From Eqs. (2.4) and (2.5) we thus obtain

$$A_n \propto \int_{-\infty}^{0} d\epsilon(-\epsilon)^{-n-3/2}\, e^{1/(3\epsilon\alpha)}$$
$$\propto \Gamma(n+\tfrac{1}{2})(-3\alpha)^n. \tag{3.11}$$

When $-1 \leq c < 1$, the MPEP's are along the axes and $\alpha = 1$. When $c > 1$, the MPEP's are at 45° to the axes and $\alpha = \frac{1}{2}(c+1)$. Thus, for large n,

$$A_n \propto (-3)^n\,\Gamma(n+\tfrac{1}{2}), \quad -1 \leq c < 1,$$

and (3.12)

$$A_n \propto [-3(c+1)/2]^n\,\Gamma(n+\tfrac{1}{2}), \quad c > 1.$$

Equation (3.12) is continuous in c at $c = 1$.

Equation (3.12) clearly illustrates the phenomenon of *decoupling* that takes place in the large-order behavior of perturbation theory. When the coupling of the oscillators is strong enough ($c > 1$), A_n depends on the coupling term. But when $-1 \leq c < 1$, the system seems to behave as if the oscillators were completely uncoupled. Actually, when $c < 1$ the multiplicative constant K, which we will determine in Sec. IV, still depends on c. Nevertheless, the decoupling of the *dominant* behavior of A_n for large n is quite remarkable and is typical of the simplification that we observe in large order.

IV. PHYSICAL OPTICS

In this section we use physical optics to approximate the imaginary part of the ground-state energy for the system

$$\left\{-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2 -\tfrac{1}{4}\epsilon(x^4+y^4+2cx^2y^2)-E\right\}\psi=0. \quad (4.1)$$

We will solve the problem explicitly only for $-1 \leq c<1$. When $c>1$ we use the following symmetry transformation to reduce the problem back to the $c<1$ case[20]:

$$x\to\bar{x}=\frac{x+y}{\sqrt{2}}, \qquad y\to\bar{y}=\frac{x-y}{\sqrt{2}}. \quad (4.2)$$

Equation (4.2) converts Eq. (4.1) into

$$\left\{-\frac{\partial^2}{\partial\bar{x}^2}-\frac{\partial^2}{\partial\bar{y}^2}+\tfrac{1}{4}\bar{x}^2+\tfrac{1}{4}\bar{y}^2 -\tfrac{1}{4}\epsilon\left(\frac{1+c}{2}\right)\left(\bar{x}^4+\bar{y}^4+2\frac{3-c}{1+c}\bar{x}^2\bar{y}^2\right)-E\right\}\psi=0. \quad (4.3)$$

We then make the additional transformations

$$c\to\bar{c}=(3-c)/(1+c), \qquad \epsilon\to\bar{\epsilon}=\epsilon(1+c)/2, \quad (4.4)$$

and observe that $c>1$ implies that $|\bar{c}|<1$.

A. The Physical-Optics Approximation

We will solve Eq. (4.1) in a tube of thickness $O(1)$ surrounding the positive x axis. (The x axis is an MPEP when $|c|<1$.) To do so, we break the tube into two regions: Region I, where $y=O(1)$ and $x<\epsilon^{-1/4}$, and Region II, where $y=O(1)$ and $\epsilon^{-1/6}<x\ll\epsilon^{-1/2}$. Notice that the regions overlap.

In Region I we approximate Eq. (4.1) by

$$\left[-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2-1\right]\psi=0, \quad (4.5)$$

whose solution is the unperturbed ground-state wave function

$$\psi_{\mathrm{I}}=e^{-(x^2+y^2)/4}. \quad (4.6)$$

We have freely chosen the normalization of ψ_{I}.

In Region II, we approximate Eq. (4.1) by

$$\left[-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2-\tfrac{1}{4}\epsilon(x^4+2cx^2y^2)-1\right]\psi=0, \quad (4.7)$$

where we have neglected ϵy^4 compared with y^2. As in BW II, we seek a solution which is exponentially decaying with increasing x in the tunneling region. Thus, we factor off a decreasing WKB-type function of the x variable:

$$\psi=\chi(\tfrac{1}{4}x^2-\tfrac{1}{4}\epsilon x^4-\tfrac{1}{2})^{-1/4} \times\exp\left[-\int_{\sqrt{2}}^{x}(\tfrac{1}{4}t^2-\tfrac{1}{4}\epsilon t^4-\tfrac{1}{2})^{1/2}dt\right]. \quad (4.8)$$

We have chosen the lower end point of the integral arbitrarily. The new equation satisfied by χ is

$$(x^2-\epsilon x^4)^{1/2}\chi_x-\chi_{yy}+(\tfrac{1}{4}y^2-\tfrac{1}{2}-\tfrac{1}{2}\epsilon cx^2y^2)\chi=0. \quad (4.9)$$

The change of scale

$$\epsilon x^2=z^2 \quad (4.10)$$

eliminates all reference to ϵ from Eq. (4.9) and gives

$$z(1-z^2)^{1/2}\chi_z-\chi_{yy}+(\tfrac{1}{4}y^2-\tfrac{1}{2}-\tfrac{1}{2}cy^2z^2)\chi=0. \quad (4.11)$$

In Eq. (4.8) we factored off the rapidly changing geometrical optics behavior. Equation (4.11) contains the next-order correction to this behavior which we have referred to as physical optics; that is, Eq. (4.11), when solved, will provide the multiplicative constants that were missing in Eq. (3.12). However, there are no further approximations to be made because all quantities in Eq. (4.11) are of order unity. Equation (4.11) must now be solved exactly.

The change of variables

$$w=(1-z^2)^{1/2} \quad (4.12)$$

is useful because the resulting equation,

$$(w^2-1)\chi_w-\chi_{yy}+[\tfrac{1}{4}y^2-\tfrac{1}{2}-\tfrac{1}{2}cy^2(1-w^2)]\chi=0, \quad (4.13)$$

no longer contains a square-root term.

One strategy for solving Eq. (4.13) is to transform the dependent variable so that a Fourier transform in the y variable gives a (hopefully soluble) first-order partial differential equation. Of course, an immediate Fourier transform of Eq. (4.13) is useless because of the y^2 term. We are thus led to the substitution

$$\chi=e^{-y^2f(w)/4}A. \quad (4.14)$$

The undetermined function $f(w)$ will be chosen to eliminate the y^2 term from the differential equation for A. It will then be profitable to Fourier transform that equation because the highest power of y will be one. The above constraint on $f(w)$ takes the form of a Riccati equation:

$$-(w^2-1)f'(w)-f^2(w)+1-2c+2cw^2=0. \quad (4.15)$$

When Eq. (4.15) is satisfied, the equation for A simplifies to

$$(w^2-1)A_w - A_{yy} + yf(w)A_y + \tfrac{1}{2}[f(w)-1]A = 0. \tag{4.16}$$

First we solve Eq. (4.15). A standard substitution which linearizes the Riccati equation is

$$f(w) = (w^2-1)u'(w)/u(w). \tag{4.17}$$

We obtain

$$(1-w^2)u'' - 2wu' + u\left(2c - \frac{1}{1-w^2}\right) = 0. \tag{4.18}$$

We gratefully recognize that Eq. (4.18) is the associated Legendre equation.[21] Solutions to this equation are

$$u(w) = P_\nu^\mu(w),\ Q_\nu^\mu(w), \tag{4.19}$$

where

$$\nu(\nu+1) = 2c, \quad \mu^2 = 1. \tag{4.20}$$

For definiteness we choose[22]

$$u(w) = P_\nu^{-1}(w). \tag{4.21}$$

Next, we return to Eq. (4.16) and complete its solution. It is clear that the strategy of the substitution in Eq. (4.14) has succeeded; that is, if we Fourier transform in the y variable, the resulting equation will be first order and should yield to the method of characteristics. However, we are fortunate that there is an even simpler approach. We change to new independent variables

$$(w, y) \to (w,\ s = y/u(w)). \tag{4.22}$$

In terms of these variables, Eq. (4.16) becomes

$$(w^2-1)u^2(w)A_w + \tfrac{1}{2}u^2(w)[f(w)-1]A = A_{ss}, \tag{4.23}$$

which is separable.

We now argue that the separation constant for Eq. (4.23) is 0. To justify this contention explicitly we separate

$$A(w, s) = B(w)C(s). \tag{4.24}$$

For separation constant α^2, the equation for $C(s)$ is $C''(s) = \alpha C(s)$, whose solution is $C(s) \propto \cosh(\alpha s) = \cosh[\alpha y/u(w)]$. Here we have kept only the even solution in y because only an even solution can be matched to $\psi_{\rm I}$ in Eq. (4.6). However, $u(w)$ in Eq. (4.21) vanishes [see Eq. (4.29)] at $w = 1$ and $w \lesssim 1$ is in the overlap of Regions I and II [see Eqs. (4.10) and (4.12)]. Therefore, there is no asymptotic match of ψ across Regions I and II unless, of course, $\alpha^2 = 0$.

Having shown that $\alpha^2 = 0$ and thus that $C(s)$ is constant, it is straightforward to solve for $B(w)$. We obtain (omitting a multiplicative constant)

$$B(w) = u^{-1/2}[(1-w)/(1+w)]^{1/4}. \tag{4.25}$$

Note that as $w \to 1$, $B(w) \to$ a finite constant [see Eq. (4.31)]. Thus, it is possible to match $\psi_{\rm I}$ and $\psi_{\rm II}$ asymptotically in the overlap region.

We have now solved Eq. (4.1) in Region II up to an over-all multiplicative constant β. Our final result is

$$\psi_{\rm II} = \beta(\tfrac{1}{4}x^2 - \tfrac{1}{4}\epsilon x^4 - \tfrac{1}{2})^{-1/4} \times \exp\left[-\int_{\sqrt{2}}^{x} (\tfrac{1}{4}t^2 - \tfrac{1}{4}\epsilon t^4 - \tfrac{1}{2})^{1/2} dt\right] \times \exp[-y^2 f(w)/4][u(w)]^{-1/2} \times [(1-w)/(1+w)]^{1/4}. \tag{4.26}$$

It is easy to identify the physical meaning of the three types of terms in Eq. (4.26). There is a rapidly varying term from geometrical optics and several slowly varying terms that do not depend on y. These describe the amplitude along the MPEP. Finally, the term $\exp[-y^2 f(w)/4]$ describes the falloff of probability current in the tube surrounding the x axis. A quick calculation shows that as x approaches the turning line [the line along which $V(x, y) - E = 0$] at the end of the tunnel near $x = \epsilon^{-1/2}$, w approaches 0, and, for positive c, the tube gradually widens. At the turning line the tube flares out like the bell of a trumpet. When $-1 \leq c < 0$, the tube narrows as $w \to 0$. When $c = 0$, the thickness of the tube is constant along its length.

It might appear that our solution Eq. (4.26) is the result of an amazing sequence of lucky substitutions whose application is rather limited. Actually these techniques immediately generalize to *all* straight-line path problems [see Secs. V–VII and Appendix B]. Moreover, when we study an arbitrary curved-path problem in our next paper[23] we show that factoring off the geometrical optics behavior always leads to a Riccati equation whose solution is related to the thickness of the tube. So, on the contrary, the substitutions we have made are both natural and general.

B. Asymptotic Matching of Regions I and II

We now determine β by requiring that $\psi_{\rm I}$ in Eq. (4.6) and $\psi_{\rm II}$ in Eq. (4.26) become asymptotically equal in the overlap of Regions I and II. In this overlap region, x is large compared with 1 but small compared with $\epsilon^{-1/2}$. Thus, we approximate

$$(\tfrac{1}{4}x^2 - \tfrac{1}{4}\epsilon x^4 - \tfrac{1}{2})^{-1/4} \sim (\tfrac{1}{2}x)^{-1/2}, \tag{4.27}$$

$$-\int_{\sqrt{2}}^{x}(\tfrac{1}{4}t^2-\tfrac{1}{4}\epsilon t^4-\tfrac{1}{2})^{1/2}dt \sim -\tfrac{1}{2}\int_{\sqrt{2}}^{x}(t^2-2)^{1/2}dt-\tfrac{1}{4}x^2+\tfrac{1}{2}\ln x+\tfrac{1}{4}+O\left(\frac{1}{x^2}\right). \tag{4.28}$$

Also, in the overlap of Regions I and II, $w\sim 1$. Thus, we use[24]

$$u(w)=P_\nu^{-1}(w)\sim 2^{-1/2}(1-w)^{1/2}, \quad \text{when } w\sim 1. \tag{4.29}$$

Equation (4.29) implies that

$$f(w)=\frac{(w^2-1)u'(w)}{u(w)}\sim 1, \tag{4.30}$$

$$u^{-1/2}\left(\frac{1-w}{1+w}\right)^{1/4}\sim 1. \tag{4.31}$$

Combining Eqs. (4.26)–(4.31) gives

$$\psi_{II}\sim \beta e^{-(x^2+y^2)/4}e^{1/4\sqrt{2}}. \tag{4.32}$$

Thus, comparing Eqs. (4.32) and Eq. (4.6) gives

$$\beta=2^{-1/2}e^{-1/4}. \tag{4.33}$$

Now ψ in Region II is completely determined relative to the normalization of ψ in Region I.

C. Determination of the Probability Current $J(x)$

In the Appendix of BW II we developed a trick (referred to there as Method 2) for evaluating the probability current for values of x further from the origin than the turning line without ever doing turning-point analysis. Without further explanation we use this technique to obtain the magnitude of the probability current emerging from the end of the tube along the positive x axis:

$$J(y)=\beta^2 e^{-y^2 f(0)/2}u^{-1}(0)\times\exp\left[-\int_{\sqrt{2}}^{x_1}(t^2-\epsilon t^4-2)^{1/2}dt\right]. \tag{4.34}$$

x is the distant zero of the integrand. Note that J is a function of y only.

The evaluation of the integral is given in BW II as

$$\exp\left[-\int_{\sqrt{2}}^{x_1}(t^2-\epsilon t^4-2)^{1/2}dt\right]\sim e^{-1/3\epsilon}2(e/\epsilon)^{1/2}. \tag{4.35}$$

To compute $u(0)$ and $f(0)$ we use the formulas[25]

$$u(0)=P_\nu^{-1}(0)=\tfrac{1}{2}\pi^{-1/2}\sin(\tfrac{1}{2}\pi\nu)\Gamma(\tfrac{1}{2}\pi\nu)/\Gamma(\tfrac{3}{2}+\tfrac{1}{2}\nu),$$
$$u'(0)=\frac{d}{dw}P_\nu^{-1}(w)\Big|_{w=0} =-\pi^{-1/2}\cos(\tfrac{1}{2}\pi\nu)\,\Gamma(\tfrac{1}{2}+\tfrac{1}{2}\nu)/\Gamma(1+\tfrac{1}{2}\nu). \tag{4.36}$$

From Eqs. (4.17) and (4.36) we have

$$\frac{f(0)}{2}=\frac{\cos(\frac{1}{2}\pi\nu)\,\Gamma(\frac{1}{2}+\frac{1}{2}\nu)\Gamma(\frac{3}{2}+\frac{1}{2}\nu)}{\sin(\frac{1}{2}\pi\nu)\,\Gamma(\frac{1}{2}\nu)\Gamma(1+\frac{1}{2}\nu)}. \tag{4.37}$$

Finally, we combine Eqs. (4.33)–(4.35) and obtain

$$J(y)=e^{-1/3\epsilon}\epsilon^{-1/2}\exp[-y^2 f(0)/2]/u(0), \tag{4.38}$$

with $u(0)$ and $f(0)/2$ given above.

D. Computation of ImE

To calculate ImE, we use Eq. (2.5) and proceed to evaluate the integrals in the denominator and numerator in turn.

The integral in the denominator is done by replacing ψ with ψ_I in Eq. (4.6) and allowing V, the region of integration, to be unbounded. This is a good approximation because the dominant contribution comes from Region I. We obtain

$$\int_V \psi^*\psi\,dV\sim 2\pi. \tag{4.39}$$

The integral in the numerator is a surface integral which reduces to an integral over y. We allow the end points of the integral to be unbounded, use Eq. (4.38), and find that

$$\int_{S_V}\vec{J}\cdot d\vec{S}\sim\frac{e^{-1/3\epsilon}\epsilon^{-1/2}}{u(0)}\int_{-\infty}^{\infty}dy\,e^{-y^2 f(0)/2} \sim e^{-1/3\epsilon}\left[\frac{2\pi}{\epsilon f(0)u^2(0)}\right]^{1/2}. \tag{4.40}$$

After using Eqs. (4.36) and (4.37), Eq. (4.40) simplifies drastically. From this result and Eqs. (2.5) and (4.39) we have finally

$$\text{Im}E=2\sqrt{2}\,e^{-1/3\epsilon}[\nu(\nu+1)/\epsilon\sin(\pi\nu)]^{1/2}. \tag{4.41}$$

We have multiplied by an extra factor of 4 to obtain Eq. (4.41) because the contributions to the integral for ImE come from four equal tubes. As much current flows out along the positive x axis as along the negative x axis and symmetrically along the y axis in both directions.

E. Perturbation Theory in Large Order

From Eqs. (2.4) and (4.41), we have for large n

$$A_n=\left[\frac{\nu(\nu+1)\pi}{\sin(\pi\nu)}\right]^{1/2}\times\frac{2\sqrt{2}}{\pi^{3/2}}\int_0^\infty d\epsilon\,e^{-1/3\epsilon}\epsilon^{-n-3/2}(-1)^{n+1} =2\left[\frac{2c\pi}{\sin(\pi\nu)}\right]^{1/2}\frac{\sqrt{6}}{\pi^{3/2}}(-1)^{n+1}3^n\Gamma(n+\tfrac{1}{2}). \tag{4.42a}$$

Equation (4.42a) is valid for $c<1$, $\nu(\nu+1)=2c$.

When $c>1$, we use Eqs. (1.3) and (4.4) to obtain

$$A_n \sim 2\left[\frac{2\bar{c}\pi}{\sin(\pi\bar{\nu})}\right]^{1/2}\frac{\sqrt{6}}{\pi^{3/2}}(-1)^{n+1}\left(\frac{3c+6}{2}\right)^n\Gamma(n+\tfrac{1}{2}), \tag{4.42b}$$

where $\bar{\nu}(\bar{\nu}+1)=2\bar{c}=(3-c)/(1+c)$.

For $c=1$, we cite the result in Eq. (A18), to wit:

$$A_n \sim (-1)^{n+1}\frac{6}{\pi}3^n\Gamma(n+1). \tag{4.42c}$$

F. Discussion

We can immediately verify Eq. (4.42a) for the case $c=0\Rightarrow\nu=0$. As $\nu\to 0$, the quantity in square brackets approaches unity and we obtain exactly twice the result in Eq. (1.8). This is because now we have two uncoupled anharmonic oscillators.

The other and more interesting limit to investigate is $c\to 1\Rightarrow\nu\to 1$. Now the term in square brackets blows up. This singularity corresponds with the onset of spherical symmetry. Recall that our analytical procedures necessarily break down for that case because there are no isolated MPEP's—all radial paths are equally probable. The sudden increase from four to an infinite number of MPEP's allows the probability current to escape to infinity faster, reducing the lifetime of the unstable state. We thus observe a constructive interference phenomenon which causes an enhancement in the rate of divergence of perturbation theory—A_n in Eq. (4.42c) is larger than A_n in Eqs. (4.42a) and (4.42b) by a factor of $n^{1/2}$.

One encounters many similar phenomena in optics. Consider, for example, a light beam parallel to the z axis and incident upon a flat elliptical plate centered about and perpendicular to the z axis. We use ray tracing to determine the amplitude of the scattered wave at a point on the z axis behind the ellipse. Only two rays scattering off the edge of the ellipse, namely, those at the ends of the minor axes, contribute appreciably to the amplitude. However, when the lengths of the major and minor axes become equal, the scattering amplitude suffers a discontinuous jump because of constructive interference. All rays scattering off the edge of the now circular disk contribute equally to the scattered wave.

We describe the numerical verification of Eq. (4.42) in Sec. V.

V. COMPARISON WITH NUMERICAL DATA

In this section we verify the theoretical predictions in Eqs. (4.42a) and (4.42b). We have run a computer program which calculates A_n to 55th order in perturbation theory by solving a difference equation. It then fits (to six significant figures) the raw Rayleigh-Schrödinger coefficients to a formula similar to but slightly less general than that in Eq. (3.5):

$$A_n = -\frac{\sqrt{6}}{\pi^{3/2}}\alpha(-3\beta)^n\Gamma(n+\tfrac{1}{2})\left(1+\frac{\gamma_1}{n}+\frac{\gamma_2}{n^2}+\frac{\gamma_3}{n^3}+\frac{\gamma_4}{n^4}\right). \tag{5.1}$$

The relevant numerical techniques are discussed in BW I, Appendixes D and E.

The actual difference equation that was solved is

$$\begin{aligned}(2i+2j)C_{n,i,j} &= (i+1)(2i+1)C_{n,i+1,j}\\ &\quad +(j+1)(2j+1)C_{n,i,j+1}\\ &\quad +aC_{n-1,i-2,j}+bC_{n-1,i,j-2}\\ &\quad +2cC_{n-1,i-1,j-1}-\sum_{k=1}^{n-1}D_{n-k}C_{k,i,j},\end{aligned} \tag{5.2}$$

where

$$C_{n,1,0}+C_{n,0,1}=D_n=(-1)^{n+1}A_n, \tag{5.3}$$

and

$$C_{0,0,0}=1,$$

$$C_{n,0,0}=0 \quad \text{for } n>0,$$

$$C_{n,i,j}=0 \quad \text{for } i+j>2n,$$

$$C_{n,i,j}=0 \quad \text{for } i<0 \text{ or } j<0.$$

Equation (5.2) is derived by substituting

$$E(\lambda)=1-\sum_{n=1}^{\infty}D_n(-\lambda)^n, \tag{5.4}$$

$$\psi(x)=e^{-(x^2+y^2)/4}\left\{1+\sum_{n=1}^{\infty}B_n(x,y)(-\lambda)^n\right\}, \tag{5.5}$$

$$B_n(x,y)=\sum_{i,j=0}^{2n}(\tfrac{1}{2}x^2)^i(\tfrac{1}{2}y^2)^jC_{n,i,j} \tag{5.6}$$

into Eq. (1.1) and collecting powers of $(\frac{1}{2}x^2)^i$, $(\frac{1}{2}y^2)^j$, and λ^n.

The numerical predictions for α and β for various values of a, b, and c are given in Table I. The predictions in Eq. (4.42) are as follows: For $-1\leq c<1$, $a=b=1$,

$$\begin{aligned}\alpha &= \{-8\pi c/\cos[\tfrac{1}{2}\pi(1+8c)^{1/2}]\}^{1/2},\\ \beta &= 1,\end{aligned} \tag{5.7}$$

where we have eliminated ν in favor of c using Eq. (4.20). For $c>1$, $a=b=1$,

$$\begin{aligned}\alpha &= \left\{\frac{8\pi(c-3)}{(1+c)\cos[\pi(25-7c)^{1/2}(4+4c)^{-1/2}]}\right\}^{1/2},\\ \beta &= (c+1)/2,\end{aligned} \tag{5.8}$$

where we have used Eq. (4.4). For $a=b=1$ the values of α and β in Table I agree to six places with

TABLE I. Numerical values of α and β in Eq. (5.1) for various values of a, b, and c in Eq. (1.1). The theoretical predictions in Eqs. (4.42a) and (4.42b) and the numerical calculations of α and β agree to six figures, which was the available limit of computer accuracy. Some values of α were not computed.

the expressions in Eqs. (5.7) and (5.8). Note that when the argument of the cosine function becomes imaginary, cos is replaced by cosh. The function in the curly brackets is always positive.

We have done one further and rather amusing numerical calculation which does not appear in Table I. We computed A_n for $c=-5$. This problem has no apparent physical significance because the Hamiltonian is not bounded below, and therefore has no discrete eigenvalues. Nevertheless, the perturbation series is still well defined and we found that $\beta=-2.000\,00$. This result agrees with β in Eq. (5.8).

In Sec. VI we obtain theoretical values for α and β when $a, b \neq 1$ and compare these with the data in Table I.

VI. THE CASE $a, b \neq 1$

The generalization of the discussion of Secs. III and IV to the case where $a, b \neq 1$ in Eq. (1.1) is entirely straightforward. As before, we find the saddle points of V by solving

$$\frac{\partial V}{\partial x}=\tfrac{1}{2}x-\epsilon(ax^3+cxy^2)=0,$$

$$\frac{\partial V}{\partial y}=\tfrac{1}{2}y-\epsilon(by^3+cx^2y)=0$$

and requiring that the Hessian matrix

$$H=\begin{bmatrix} \frac{1}{2}-\epsilon(3ax^2+cy^2) & -2cxy\epsilon \\ -2cxy\epsilon & \frac{1}{2}-\epsilon(3by^2+cx^2) \end{bmatrix}$$

have negative determinant.

The critical points are $(0,0)$, $(0,\pm(2b\epsilon)^{-1/2})$, $(\pm(2a\epsilon)^{-1/2},0)$, and $\pm[2\epsilon(c^2-ab)]^{-1/2}((c-b)^{1/2}, \pm(c-a)^{1/2})$. $(0,\pm(2b\epsilon)^{-1/2})$ are saddle points if $c/b<1$ and $(\pm(2a\epsilon)^{-1/2},0)$ are saddle points if $c/a<1$. If $c>\max(a,b)$ then the off-axis critical points are saddle points. (Recall that for the Hamiltonian to be bounded below we must have $a\geq 0$, $b\geq 0$, and $c\geq -\sqrt{ab}$.) All of the saddle points are radially directed.

As in Sec. IV, the off-axis case can be reduced to the case $c/a<1$ by a rotation. To simplify the algebra we introduce the following notation:

$$D=ab-c^2=\mathrm{Det}\begin{vmatrix} a & c \\ c & b \end{vmatrix}, \tag{6.1a}$$

$$D_1=b-c=\mathrm{Det}\begin{vmatrix} 1 & c \\ 1 & b \end{vmatrix}, \tag{6.1b}$$

$$D_2=a-c=\mathrm{Det}\begin{vmatrix} a & 1 \\ c & 1 \end{vmatrix}, \tag{6.1c}$$

$$S=D_1+D_2=a+b-2c. \tag{6.1d}$$

Then a suitable rotation is

$$\begin{aligned} x&=(D_1/S)^{1/2}\bar{x}\pm(D_2/S)^{1/2}\bar{y}, \\ y&=\mp(D_2/S)^{1/2}\bar{x}+(D_1/S)^{1/2}\bar{y}. \end{aligned} \tag{6.2}$$

In terms of the new variables the potential is

$$V=\tfrac{1}{4}(\bar{x}^2+\bar{y}^2)-\tfrac{1}{4}\epsilon(\bar{a}\bar{x}^4+\bar{b}\bar{y}^4+2\bar{c}\,\bar{x}^2\bar{y}^2), \tag{6.3}$$

where

$$\begin{aligned} \bar{a}&=D/S, \\ \bar{b}&=[(D_1-D_2)^2+D]/S, \\ \bar{c}&=3D/S-2c. \end{aligned} \tag{6.4}$$

Observe that

$$\bar{c}-\bar{a}=2D/S-2c=\frac{2D_1D_2}{S}<0,$$

when $a>0$, $b>0$, and $c>\max(a,b)$.

Without loss of generality, then, we assume $c<a$. We will solve the Schrödinger equation in a narrow tube surrounding the x axis. In Region I where $0\leq x<\epsilon^{-1/4}$ we have

$$\psi_{\mathrm{I}}\sim e^{-(x^2+y^2)/4}. \tag{6.5}$$

In Region II, $\epsilon^{-1/8} < x < \epsilon^{-1/2}$ and we can approximate the differential equation by

$$\left[-\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial y^2} + \tfrac{1}{4}x^2 - \tfrac{1}{4}\epsilon(ax^4 + 2cx^2y^2) - E \right] \psi_{\rm II} = 0 . \tag{6.6}$$

The substitutions

$$\begin{aligned} a\epsilon &\to \epsilon , \\ c/a &\to c \end{aligned} \tag{6.7}$$

reduce Eq. (6.6) to Eq. (4.7), which has already been solved.

We therefore immediately deduce that the large-order behavior of perturbation theory is

$$A_n = -\frac{\sqrt{6}}{\pi^{3/2}} \alpha (-3\beta)^n \, \Gamma(n + \tfrac{1}{2}) , \tag{6.8}$$

where

$$\begin{aligned} \alpha &= \left\{ \frac{8\pi(2ac + 2bc - 3ab - c^2)}{(ab - c^2)\cos[\tfrac{1}{2}\pi(25 - 16c(a+b-2c)/(ab-c^2))^{1/2}]} \right\}^{1/2} , \\ \beta &= \frac{ab - c^2}{a + b - 2c} , \end{aligned} \tag{6.11}$$

where $a > 0$, $b > 0$, $c > \max(a, b)$.

The results in Eqs. (6.9)–(6.11) agree to six places with the numbers in Table I.

$$\begin{aligned} \alpha &= \left\{ \frac{-2\pi c}{a \cos[\tfrac{1}{2}\pi(1 + 8c/a)^{1/2}]} \right\}^{1/2} , \\ \beta &= a , \end{aligned} \tag{6.9}$$

for the case $a > b > 0$, $a > c \geq -\sqrt{ab}$.

There is a factor of 2 missing from the expression for α in Eq. (6.9) relative to Eq. (5.7) because the contribution from the tube along the y axis is negligible when $a > b$. When $b > a$, we have similar results:

$$\begin{aligned} \alpha &= \left\{ \frac{-2\pi c}{b \cos[\tfrac{1}{2}\pi(1 + 8c/b)^{1/2}]} \right\}^{1/2} , \\ \beta &= b , \end{aligned} \tag{6.10}$$

where $b > a > 0$, $b > c \geq -\sqrt{ab}$.

For the off-axis case we use Eq. (6.4) to deduce that

VII. GENERALIZATION TO N DIMENSIONS

It is natural to try to extend the techniques we have developed for two-mode oscillators to more complicated problems. In this section we will show that such an extension is possible for a large class of N-mode equal-mass oscillator systems. Our aim will be to present a brief overview of what can be accomplished in N dimensions, and we will not dwell on algebraic or numerical details.

We begin by studying systems having potentials of the form

$$V = \sum_{i=1}^{N} \tfrac{1}{4} x_i^{\,2} + \tfrac{1}{4}\lambda \sum_{i,j=1}^{N} a_{ij} \, x_i^{\,2} x_j^{\,2} , \tag{7.1}$$

where a_{ij} is a real symmetric matrix. The Hamiltonian in (7.1) must be bounded below, and therefore a must satisfy

$$\sum_{i,j} a_{ij} \, y_i \, y_j \geq 0 \text{ for } y_i \geq 0 . \tag{7.2}$$

When $\lambda = -\epsilon (\epsilon > 0)$ the critical points of V are the solutions of

$$\begin{aligned} 0 &= \frac{\partial V}{\partial x_i} \\ &= \tfrac{1}{2} x_i - \epsilon x_i \sum_{j=1}^{N} a_{ij} \, x_j^{\,2} . \end{aligned} \tag{7.3}$$

Thus

$$x_i = 0 ,$$

or

$$\frac{1}{2\epsilon} = \sum_{j=1}^{N} a_{ij} \, x_j^{\,2} . \tag{7.4}$$

We will first consider the case where all $x_i \neq 0$. Then Eq. (7.4) has a solution if a is nonsingular. We define D_i to be the determinant of the matrix obtained from a by replacing each element of the ith column by one. Then $\sum_j a_{ij} D_j = \det(a)$ for all i, and

$$x_j^{\,2} = \frac{1}{2\epsilon} \frac{D_j}{\det(a)} . \tag{7.5}$$

If this is to correspond to a point in real space we must have

$$\frac{D_i}{\det(a)} > 0 , \quad 1 \leq i \leq N . \tag{7.6}$$

Of course there are 2^{N-1} vectors which satisfy Eq. (7.5) because we can choose the sign of each component of x_i independently.

The Hessian matrix at the critical point is

$$H_{ij} = \tfrac{1}{2}\delta_{ij} - \epsilon \delta_{ij} \sum_k a_{ik} \, x_k^{\,2} - 2\epsilon x_i \, x_j a_{ij} . \tag{7.7}$$

Using Eq. (7.5) we can rewrite this as

$$H_{ij} = -2\epsilon x_i x_j a_{ij}$$

$$= -\frac{\sigma_i \sigma_j}{\det(a)} (D_i D_j)^{1/2} a_{ij}, \tag{7.8}$$

where σ_i is the sign of x_i. Note that $D_i D_j$ is always positive [see Eq. (7.6)]. Equations (7.3) and (7.8) imply that

$$\sum_j H_{ij} \sigma_j (D_j)^{1/2} = -\sigma_i (D_i)^{1/2}, \tag{7.9}$$

which means that the radial line through each critical point is one of the critical point's principal axes. Furthermore, the minus sign in Eq. (7.9) implies that along this radial line, V has a maximum at the critical point. Thus if all the other eigenvalues of H at the critical point are positive, we have a radially directed saddle point.

A necessary condition for H to have one negative and $N-1$ positive eigenvalues is

$$\det H < 0. \tag{7.10}$$

But,

$$\det H = [-\det(a)]^{-N} \det[\sigma_i \sigma_j (D_i D_j)^{1/2} a_{ij}]$$

$$= -[-\det(a)]^{-N-1} \prod_{i=1}^{N} D_i.$$

Using Eq. (7.6) we see that

$$\det H < 0 \Longleftrightarrow (-1)^N \det(a) < 0. \tag{7.11}$$

In two dimensions, Eq. (7.11) is indeed satisfied by the off-axis saddle points that we discussed in Sec. VI. In fact this condition and Eq. (7.6) imply that $c > \max(a, b)$, which we have shown to be a necessary and *sufficient* condition for an off-axis saddle point in two dimensions. In higher dimensions however, we can have $\det H < 0$ without having one negative and $N-1$ positive eigenvalues. It is difficult to give a simple necessary and sufficient condition for saddle points in the general N-dimensional case.

If several of the x_i are zero the procedure for finding a saddle point is slightly more complicated. We choose to label the axes so that the first M x_i are zero. Then, the condition for a critical point becomes

$$x_i = 0, \quad i = 1, \ldots, M$$

$$\frac{1}{2\epsilon} = \sum_{j=M+1}^{N} a_{ij} x_j^2, \quad i = M+1, \ldots, N. \tag{7.12}$$

The discussion proceeds as before in the subspace of nonzero components. We find that the Hessian matrix is given by

$$\begin{bmatrix} \frac{1}{2} - \epsilon \sum_{k=M+1}^{N} a_{1k} x_k^2 & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \frac{1}{2} - \epsilon \sum_{k=M+1}^{N} a_{Mk} x_k^2 & 0 \\ 0 & \cdots & 0 & -2\epsilon x_i x_j a_{ij} \end{bmatrix},$$

where the x_i's are the solutions of Eq. (7.12). Thus, in addition to the usual conditions on the N-M dimensional matrix $x_i x_j a_{ij}$, we must have

$$\frac{1}{2} - \epsilon \sum_{M+1}^{N} a_{ik} x_k^2 > 0, \quad i = 1, \ldots, M.$$

The special case of an on-axis critical point, where all but one of the x_i vanish, is important because any other configuration can be reduced to this one by a rotation. Here the condition for a saddle point becomes

$$\frac{1}{2} - \epsilon a_{iN} x_N^2 > 0, \quad i = 1, \ldots, N-1$$

where

$$x_N^2 = \frac{1}{2\epsilon a_{NN}}. \tag{7.13}$$

It is now easy to generalize the arguments of Secs. IV and VI to compute the contribution to the large-order behavior of perturbation theory from this saddle point. We observe that in the tube where $\epsilon^{-1/6} < x_N < \epsilon^{-1/2}$, $x_i = O(1)$, $i \neq N$, we can make the approximation

$$\frac{1}{4}\epsilon \sum_{i,j} a_{ij} x_i^2 x_j^2 \sim \frac{1}{4}\epsilon x_N^2 \sum_{j=1}^{N-1} a_{Nj} x_j^2 + \frac{1}{4}\epsilon a_{NN} x_N^4.$$

Following the procedure of Sec. IV, we factor a rapidly varying WKB function of the x_N variable [see Eq. (4.8)] out of the wave function and neglect all terms in the resulting equation which vanish as $\epsilon \to 0$. After a simple change of variables [see Eq. (4.12)], we obtain a partial differential equation which must be solved exactly:

$$(w^2 - 1)\chi_w + \sum_{i=1}^{N-1} \left[-\frac{\partial^2}{\partial x_i^2} + \frac{1}{4} x_i^2 - \frac{1}{2} - \frac{a_{iN}}{2a_{NN}} x_i^2 (1 - w^2) \right] \chi = 0.$$

The ansatz

$$\chi = A\exp\left[-\tfrac{1}{4}\sum_{i=1}^{N-1} f_i(w)x_i^2\right]$$

generates $N-1$ Riccati equations whose solutions govern the thickness of the tube of probability current in the directions perpendicular to the MPEP. Then the change of variables

$$w = w\,,$$

$$s_i = x_i/u_i(w)\,, \quad 1 \leq i \leq N-1$$

with

$$f_i = (w^2-1)u_i'(w)/u_i(w)$$

reduces the equation for A to one that is separable:

$$(w^2-1)A_w + \tfrac{1}{2}\sum_{i=1}^{N-1}[f_i(w)-1]A = \sum_{i=1}^{N-1}\frac{1}{u_i^2(w)}\frac{\partial^2}{\partial x_i^2}A\,.$$

Finally, we require that the wave function in the tunneling region match to a harmonic-oscillator wave function (the solution of the Schrödinger equation near the origin). As in Sec. IV, this implies that A is a function only of w. It is then easy to determine the probability current and evaluate the dispersion integral. The resulting contribution to the large-order behavior of perturbation theory is

$$A_n = -\left\{\prod_{i=1}^{N-1}\left[\frac{8\pi a_{iN}}{a_{NN}\sin(\pi\nu_i)}\right]^{1/2}\right\} \times\sqrt{6}\,\pi^{-3/2}(-3a_{NN})^n\,\Gamma(n+\tfrac{1}{2})\,, \tag{7.14}$$

where $\nu_i(\nu_i+1) = 2a_{iN}/a_{NN}$.

This expression will be equal to the true large-order behavior if the x_N axis is the MPEP. However, as we mentioned above, we can use Eq. (7.14) even if the dominant saddle point does not lie on this axis. As an example, let us consider the case of a dominant critical point whose coordinates are nonvanishing. Then the following rotation will align the radial line through the saddle point with the $\bar{x}_N$ axis:

$$x_i = \sum_{j=1}^{N} R_{ij}\bar{x}_j\,, \tag{7.15}$$

$$R = \begin{bmatrix} a_{11} & \cdots & a_{N-1\,1} & \left(D_1/\sum_{i=1}^{N} D_i\right)^{1/2} \\ \vdots & & \vdots & \vdots \\ a_{1N} & \cdots & a_{N-1\,N} & \left(D_N/\sum_{i=1}^{N} D_i\right)^{1/2} \end{bmatrix}.$$

We choose the first $N-1$ column vectors of R to lie along the other principal axes of the saddle point. In the new coordinate system V will no longer have the simple form in Eq. (7.1). It will contain terms like $\bar{x}_i^3\bar{x}_j$. However, it is easy to see that there are no terms of the form $\bar{x}_N^3\bar{x}_j$ $(j\neq N)$ or $\bar{x}_N^2\bar{x}_i\bar{x}_j$ $(i,j\neq N)$. Such terms would give a nonvanishing contribution to $\partial^2 V/\partial\bar{x}_N\partial\bar{x}_j$ or to $\partial^2 V/\partial\bar{x}_i\partial\bar{x}_j$ at the critical point. (The coordinates of the critical point are $\bar{x}_j = 0$, $1\leq j\leq N-1$, $\bar{x}_N\neq 0$.) Thus V has the form

$$V = \sum_{i=1}^{N}\tfrac{1}{4}\bar{x}_i^2 - \tfrac{1}{4}\epsilon\left(\bar{a}_{NN}\bar{x}_N^4 + \sum_{i=1}^{N-1}\bar{a}_{iN}x_i^2x_N^2 + b\right),$$

where b depends at most linearly on $\bar{x}_N$. In the tube where $\bar{x}_i = O(1)$, $1\leq i\leq N-1$, and $\epsilon^{-1/6}\leq\bar{x}_N\leq\epsilon^{-1/2}$, we can clearly approximate V by neglecting b entirely.

We then use Eq. (7.14) to compute the large-order behavior of perturbation theory as before. The computation of $\bar{a}_{iN}$ for all i is a tedious algebraic problem. Still it is easy to find the value of $\bar{a}_{NN}$, the coefficient of $\bar{x}_N^4$ in $\sum_{i,j}a_{ij}x_i^2x_j^2$. Using Eq. (7.15) it is

$$\begin{aligned}\bar{a}_{NN} &= \sum_{i,j} a_{ij}\frac{D_iD_j}{(\sum_j D_j)^2} \\ &= \frac{1}{(\sum_j D_j)^2}\sum_j D_j\det(a) \\ &= \frac{\det(a)}{\sum_j D_j}\,.\end{aligned}$$

Thus, the large-order behavior of perturbation theory is

$$A_n \sim -\sqrt{6}\,\pi^{-3/2}2^{N-1}K_N\left[\frac{-3\det(a)}{\sum_j D_j}\right]^n\Gamma(n+\tfrac{1}{2})\,. \tag{7.16}$$

The constant K_N may be determined from Eq. (7.14) once we have computed $\bar{a}_{iN}$ for $i\neq N$. The factor 2^{N-1} reflects the possible choices of the sign of x_j in Eq. (7.5). Similar formulas exist for the case where some of the x_i vanish at the dominant saddle point.

Equation (7.14) may also be used to find the large-order behavior of the perturbation series for systems having an infinite number of degrees of freedom. As an example, consider the sequence of potentials

$$V^{(N)} = \tfrac{1}{4}\sum_{i=1}^{N}x_i^2 - \tfrac{1}{4}\epsilon\sum_{\substack{i,j=1\\ i\neq j}}^{N}x_i^2x_j^2\,. \tag{7.17}$$

The critical points of $V^{(N)}$ are given by

$$0 = \frac{\partial V^{(N)}}{\partial x_i} = \tfrac{1}{2}x_i - \tfrac{1}{4}\epsilon x_i\sum_{j\neq i}x_j^2\,, \tag{7.18}$$

whose solutions are

$$x_i = 0 \text{ or } x_i{}^2 = [2\epsilon(M-1)]^{-1}. \tag{7.19}$$

M is the number of nonzero x_i. Note that M can never be one, so Eq. (7.19) always makes sense. The Hessian matrix is

$$H_{ij}^{(N)} = -\frac{\delta_{ij}}{2(M-1)} - 2\epsilon x_i x_j + 3\epsilon\delta_{ij}(x_i{}^2). \tag{7.20}$$

Observe from Eq. (7.20) that we cannot have a saddle point if any of the x_i vanish because Eq. (7.13) is violated. Hence, all $x_i \neq 0$ and

$$H_{ij}^{(N)} = \frac{\delta_{ij}}{2(N-1)} - \frac{\sigma_i\sigma_j}{(N-1)},$$

where σ_i is the sign of x_i. The eigenvalues of this matrix are $\frac{1}{2} - N/(N-1)$, which is negative, and $2/(N-1)$, the latter having multiplicity $N-1$. Therefore, we have a saddle point. There is a different saddle point for each of the 2^{N-1} choices of sign for x_i.

To determine the large-order behavior of perturbation theory for this system, we must compute $D_i^{(N)}$ and $\det[a^{(N)}]$ [see Eq. (7.16)]. The matrix $a^{(N)}$ is given by

$$\begin{bmatrix} 0 & 1 & 1 & 1 & \cdots \\ 1 & 0 & 1 & 1 & \cdots \\ 1 & 1 & 0 & 1 & \cdots \\ 1 & 1 & 1 & 0 & \\ \cdots & \cdots & \cdots & & \ddots \end{bmatrix}.$$

Thus,

$$\det[a^{(N)}] = (N-1)(-1)^{N-1}$$

and

$$D_i^{(N)} = (-1)^{N-1}, \quad 1 \leq i \leq N.$$

We can also compute $\bar{a}_{iN}^{(N)}$ because the potential is so symmetric. We find that

$$\begin{aligned} \bar{a}_{iN}^{(N)} &= \frac{N-3}{N}, \quad 1 \leq i \leq N-1 \\ \bar{a}_{NN}^{(N)} &= \frac{N-1}{N}. \end{aligned} \tag{7.21}$$

Therefore, from Eqs. (7.14) and (7.21), the large-order behavior of perturbation theory is

$$A_n^{(N)} = -\sqrt{6}\,\pi^{-3/2}\left[\frac{-8\pi(N-3)/(N-1)}{\cos\frac{3}{2}\pi(1-16/9(N-1))^{1/2}}\right]^{(N-1)/2}\left(-3\frac{N-1}{N}\right)^n\Gamma(n+\tfrac{1}{2}). \tag{7.22}$$

Now consider the limit as $N\to\infty$. This limit defines an infinite-mode oscillator system which, strictly speaking, is some nonlocal field theory. The leading contribution to Eq. (7.22) which comes from geometrical optics remains finite in this limit:

$$\left(-3\frac{N-1}{N}\right)^n\Gamma(n+\tfrac{1}{2}) \to (-3)^n\Gamma(n+\tfrac{1}{2}).$$

However, the constant from physical optics blows up. The divergence of this constant derives from two sources. The factor $(\sqrt{8\pi})^{N-1}$ occurs in any N-mode problem in which no axis passes through the dominant saddle point. The vanishing of the cosine term as $N\to\infty$ is a more singular divergence of the form $N^{N/2}$. It reflects the disappearance of the saddle point. The extreme symmetry of the potential makes the saddle become flat as N becomes large. This kind of symmetry is not present in potentials arising from $(\phi^N)_2$ quantum field theories.

It is amusing that we can eliminate this divergence by a mass renormalization. We will argue that by adding a lower-order mass term to the potential we can ensure that the $N\to\infty$ limit of $A_n^{(N)}$ exists. Consider the effect of adding a term of the form

$$\epsilon R^{(N)}\sum_{i=1}^{N}\tfrac{1}{4}x_i{}^2.$$

Because this term is at most $O(1)$ in the tunneling region, it cannot affect the determination of the MPEP. This term is merely a correction of $O(\epsilon)$ to the mass, and thus can actually be viewed as a mass renormalization. Following the scaling arguments of Sec. VII, Ref. 9, we find that this term contributes an over-all multiplicative constant (independent of n) to the large-order growth of perturbation theory, namely,

$$\exp\left[\frac{-NR^{(N)}}{2(N-1)}\right].$$

On the other hand, we easily determine from Eq. (7.22) that the two large-N divergences which we discussed give precisely

$$[6(N-3)]^{(N-1)/2}.$$

Hence, if we choose

$$R^{(N)} = \frac{(N-1)^2}{N}\ln(6N-18), \tag{7.23}$$

then the limit $N\to\infty$ may be taken. We obtain the remarkable result that the large-order behavior of the Rayleigh-Schrödinger coefficients A_n for the

ground-state energy perturbation series of the infinite-mode system described by the potential

$$V=\lim_{N\to\infty}\left\{\tfrac{1}{4}[1-\lambda R^{(N)}]\sum_{i=1}^{N}x_i{}^2+\tfrac{1}{4}\lambda\sum_{\substack{i,j=1\\ i\neq j}}^{\infty}x_i{}^2x_j{}^2\right\} \tag{7.24}$$

is

$$A_n\sim-\sqrt{6}\,\pi^{-3/2}(-3)^n\,\Gamma(n+\tfrac{1}{2}), \tag{7.25}$$

where $N\to\infty$ in such a way that λN is small. This is precisely the result in Eq. (1.8) for the one-mode anharmonic oscillator. Of course, it can be argued that the choice of the potential in Eq. (7.24) is somewhat contrived. Nonetheless, we feel that Eq. (7.25) is just one more example of the extraordinary simplification that takes place in the large-order limit of perturbation theory.

APPENDIX A: OSCILLATORS WITH SPHERICAL SYMMETRY

Here we investigate the ground-state-energy perturbation series for spherically coupled oscillators. This special case obtains when we choose $c=1$ in Eq. (1.4). However, a spherically symmetric configuration of oscillators is so easy to treat that we immediately generalize from the two-mode problem of Eq. (1.4) to the N-mode problem, which we define by the equation

$$\left\{\sum_{i=1}^{N}\left(-\frac{\partial^2}{\partial x_i{}^2}+\tfrac{1}{4}x_i{}^2\right)+\tfrac{1}{4}\lambda\left(\sum_{i=1}^{N}x_i{}^2\right)^2-E(\lambda)\right\}\psi(x_i)=0, \tag{A1}$$

where $\lim_{|x_i|\to\infty}\psi=0$.

We use spherical symmetry to transform Eq. (A1) to N-dimensional spherical coordinates. Moreover, we seek a wave function ψ which depends only on r, the radial coordinate, because the ground-state wave function has no angular dependence. We thus reduce Eq. (A1) to the ordinary differential equation

$$\left[-\frac{d^2}{dr^2}-\frac{N-1}{r}\frac{d}{dr}+\tfrac{1}{4}r^2+\tfrac{1}{4}\lambda r^4-E(\lambda)\right]\psi(r)=0, \tag{A2}$$

where

$$r^2=\sum_{i=1}^{N}x_i{}^2.$$

Our problem is to compute the eigenvalue $E(\lambda)$ perturbatively in large order. We expand $E(\lambda)$ into the perturbation series

$$E(\lambda)=\tfrac{1}{2}N-\sum_{n=1}^{\infty}(-\lambda)^nC_n. \tag{A3}$$

We could solve this problem by removing the first derivative term from Eq. (A2) by making a suitable transformation and then using WKB in the same manner as in the body of this paper. However, we prefer a much simpler approach. We will convert Eq. (A2) into a partial difference equation which has already been solved asymptotically in BW II.

To transform Eq. (A2) into a partial difference equation, we substitute the expression

$$\psi(r)=e^{-r^2/4}\left\{1+\sum_{n=1}^{\infty}(-\lambda)^n\sum_{j=1}^{2n}(\tfrac{1}{2}r^2)^jC_{n,j}\right\} \tag{A4}$$

and Eq. (A3) into Eq. (A2) and collect powers of $r^2/2$ and $-\lambda$. The coefficient of $(\frac{1}{2}r^2)^j$ and $(-\lambda)^n$ is the desired difference equation:

$$2jC_{n,j}=(j+1)(2j+N)C_{n,j+1}+C_{n-1,j-2}-\sum_{p=1}^{n-1}C_{p,1}C_{n-p,j}, \tag{A5}$$

with initial value $C_{0,0}=1$ and boundary condition $C_{n,j}\neq0$ for $n>1$ and $1\leq j\leq 2n$; $C_{n,j}=0$ otherwise. C_n is related to $C_{n,j}$ by

$$C_n=NC_{n,1}. \tag{A6}$$

Following Sec. VI A of BW II, we approximate Eq. (A5) by dropping the nonlinear convolution term. As was argued there, the neglected term does not affect the leading asymptotic behavior of $C_{n,1}$ for large n. Thus, the equation to be solved is

$$2jC_{n,j}=(j+1)(2j+N)C_{n,j+1}+C_{n-1,j-2}. \tag{A7}$$

We put Eq. (A7) into a more useful form by substituting

$$C_{n,j}=D_{n,j}/[j\Gamma(j+\tfrac{1}{2}N)]. \tag{A8}$$

The equation satisfied by $D_{n,j}$ is

$$D_{n,j}=D_{n,j+1}+\frac{(j+\frac{1}{2}N-1)(j+\frac{1}{2}N-2)}{2(j-2)}D_{n-1,j-2}. \tag{A9}$$

Next, we replace Eq. (A9) by a new approximate equation satisfied by a new dependent variable $E_{n,j}$:

$$E_{n,j}=E_{n,j+1}+\tfrac{1}{2}(j+N-1)E_{n-1,j-2}. \tag{A10}$$

Equation (A10) is derived by approximating the coefficient of $D_{n-1,j-2}$ in Eq. (A9) for large j, keeping terms of orders j and 1 and neglecting terms of order j^{-1}.

We must introduce an extra condition which fixes the multiplicative scale of $E_{n,j}$ because Eq. (A10) is homogeneous; to wit, we require that

$$\lim_{n\to\infty}E_{n,2n}/D_{n,2n}=1. \tag{A11}$$

From Eq. (A10) we easily deduce that

$$E_{n,2n} = E_{0,0}\Gamma(n+\tfrac{1}{2}(N+1))/\Gamma(\tfrac{1}{2}(N+1)). \quad \text{(A12)}$$

$E_{0,0}$ is the multiplicative factor which adjusts the scale of $E_{n,j}$. Also, from Eqs. (A7) and (A8) we have

$$D_{n,2n} = 2n\Gamma(2n+\tfrac{1}{2}N)4^{-n}/n! \,. \quad \text{(A13)}$$

Combining Eqs. (A11)–(A13) gives

$$E_{0,0} = \Gamma(\tfrac{1}{2}(N+1))2^{N/2}\pi^{-1/2}. \quad \text{(A14)}$$

Finally, we recall that Sec. VI H of BW II gives a complete treatment of the asymptotic behavior of solutions for difference equations like that in Eq. (A10). It is shown there that for large n,

$$E_{n,1} \sim E_{0,0}\frac{3^{n+N/2}\Gamma(n+\tfrac{1}{2}N)}{2\sqrt{\pi}\,\Gamma(\tfrac{1}{2}(N+1))}. \quad \text{(A15)}$$

Thus, we combine Eqs. (A6), (A8), and (A15) to obtain

$$C_n \sim \Gamma(n+\tfrac{1}{2}N)3^n 6^{N/2}\pi^{-1}/\Gamma(\tfrac{1}{2}N). \quad \text{(A16)}$$

This is the precise leading asymptotic behavior of C_n for large n and is the general result we have sought.

Two special cases of this equation are noteworthy. For the one-mode oscillator ($N=1$), the coefficients of the ground-state-energy perturbation series grow like

$$C_n \sim 6^{1/2}\pi^{-3/2}3^n\,\Gamma(n+\tfrac{1}{2}), \quad \text{(A17)}$$

which agrees with Eq. (1.8).

Second, the coefficients for the two-mode oscillator ($N=2$) diverge like

$$C_n \sim \frac{2}{\pi}\,3^{n+1}n! \,, \quad \text{(A18)}$$

as in Eqs. (1.11) and (4.42c).

Observe also that the rate of divergence of perturbation theory increases with increasing N: $\Gamma(n+\frac{1}{2}N) \sim \Gamma(n)n^{N/2}$. This is a phenomenon characteristic only of spherically symmetrically coupled oscillators. As is shown in Sec. IV, it results physically from a kind of constructive interference.

APPENDIX B: NONQUARTIC COUPLING

To demonstrate that the analytical methods of Sec. IV are easily generalized to more difficult problems, we treat the two-mode, nonquartically coupled oscillator. This system is defined by the equation

$$\left[-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2+\lambda 2^{-N}(x^{2N}+cx^{2N-2}y^2+dx^{2N-4}y^4+\cdots+dx^4y^{2N-4}+cx^2y^{2N-2}+y^{2N})-E(\lambda)\right]\psi=0. \quad \text{(B1)}$$

Corresponding to Eq. (4.1) we have

$$\left[-\frac{\partial^2}{\partial x^2}-\frac{\partial^2}{\partial y^2}+\tfrac{1}{4}x^2+\tfrac{1}{4}y^2-\epsilon^{N-1}2^{-N}(x^{2N}+cx^{2N-2}y^2+\cdots)-1\right]\psi=0. \quad \text{(B2)}$$

As in Sec. IV, we solve Eq. (B2) in a tube surrounding the positive x axis. In Region I we obtain the same result as in Eq. (4.6) and in Region II we make a substitution similar to that in Eq. (4.8):

$$\psi = \chi(\tfrac{1}{4}x^2-\epsilon^{N-1}2^{-N}x^{2N}-\tfrac{1}{2})^{-1/4}\exp\left[-\int_{\sqrt{2}}^{x}(\tfrac{1}{4}t^2-\epsilon^{N-1}2^{-N}t^{2N}-\tfrac{1}{2})^{1/2}dt\right]. \quad \text{(B3)}$$

In the resulting differential equation for χ we let

$$\epsilon x^2 = z^2 \quad \text{(B4)}$$

and obtain

$$z(1-2^{2-N}z^{2N-2})^{1/2}\chi_z - \chi_{yy} + \left(\tfrac{1}{4}y^2-\frac{c}{2^N}z^{2N-2}y^2-\tfrac{1}{2}\right)\chi=0. \quad \text{(B5)}$$

Equation (B5), like Eq. (4.11), must be solved *exactly*—there are no further approximations.

To simplify Eq. (B5), we let

$$\omega = (1-2^{2-N}z^{2N-2})^{1/2}, \quad \text{(B6)}$$

which gives

$$(N-1)(\omega^2-1)\chi_\omega - \chi_{yy} + [\tfrac{1}{4}y^2-\tfrac{1}{2}-\tfrac{1}{4}c(1-\omega^2)y^2]\chi=0. \quad \text{(B7)}$$

The substitution

$$\chi = e^{-y^2 f(\omega)/4}A \quad \text{(B8)}$$

leads to a Riccati equation that is almost identical to that in Eq. (4.15):

$$-(N-1)(\omega^2-1)f'(\omega)-f^2(\omega)+1-c+c\omega^2=0. \quad \text{(B9)}$$

To linearize Eq. (B9), we let

$$f(\omega) = (N-1)(\omega^2-1)u'(\omega)/u(\omega). \quad \text{(B10)}$$

As in Sec. IV, $u(\omega)$ satisfies a Legendre equation:

$$u(\omega)=P_\nu^\mu(\omega), \tag{B11}$$

where $\mu=-1/(N-1)$ and $\nu(\nu+1)=c/(N-1)^2$.

When Eq. (B9) is satisfied, A solves a much simpler equation than Eq. (B7), namely,

$$(N-1)(\omega^2-1)A_\omega-A_{yy}+yf(\omega)A_y+\tfrac{1}{2}[f(\omega)-1]A=0. \tag{B12}$$

The substitution $(\omega, y)\to(\omega, s=y/u(\omega))$ reduces Eq. (B12) to one that is separable:

$$(N-1)(\omega^2-1)u^2(\omega)A_\omega+\tfrac{1}{2}u^2(\omega)[f(\omega)-1]A=A_{ss}. \tag{B13}$$

The argument given in Sec. IV that the separation constant for Eq. (4.23) vanishes also holds for Eq. (B13). It follows that, up to an arbitrary multiplicative constant β,

$$A=\beta[u(\omega)]^{-1/2}[(1-\omega)/(1+\omega)]^{1/(4N-4)}. \tag{B14}$$

This completes the solution of Eq. (B2).

We determine β by asymptotically matching ψ in Region II to ψ in Region I. In the matching region, $\omega\sim1$, and we have[24]

$$P_\nu^{-1/(N-1)}(\omega)\sim(\tfrac{1}{2}-\tfrac{1}{2}\omega)^{(N-1)/2}/\Gamma(N/(N-1)). \tag{B15}$$

From Eq. (B15) we have for $\omega\sim1$

$$A\sim\beta\Gamma^{1/2}(N/(N-1)),\qquad f(\omega)\sim1. \tag{B16}$$

In the matching region we also have formulas similar to those in Eqs. (4.27) and (4.28) from which we conclude that [see Eq. (B3)]

$$\psi/\chi\sim2^{1/2}e^{1/4}e^{-x^2/4}. \tag{B17}$$

From Eqs. (B16) and (B17) and Eq. (4.6), we obtain the generalization of Eq. (4.33):

$$\beta=e^{-1/4}\{2\Gamma(N/(N-1))\}^{-1/2}. \tag{B18}$$

Continuing to follow Sec. IV, we use the formulas[25]

$$P_\nu^\mu(0)=2^\mu\pi^{-1/2}\cos\frac{\pi(\nu+\mu)}{2}\,\frac{\Gamma(\frac{1}{2}+\frac{1}{2}\nu+\frac{1}{2}\mu)}{\Gamma(1+\frac{1}{2}\nu-\frac{1}{2}\mu)}, \tag{B19}$$

$$\frac{d}{dx}P_\nu^\mu(x)\Big|_{x=0}=2^{\mu+1}\pi^{-1/2}\times\sin\frac{\pi(\nu+\mu)}{2}\,\frac{\Gamma(1+\frac{1}{2}\nu+\frac{1}{2}\mu)}{\Gamma(\frac{1}{2}+\frac{1}{2}\nu-\frac{1}{2}\mu)}, \tag{B20}$$

from which it follows that

$$f(0)=2(1-N)\times\frac{\sin[\pi(\nu+\mu)/2]\Gamma(1+\frac{1}{2}\nu+\frac{1}{2}\mu)\Gamma(1+\frac{1}{2}\nu-\frac{1}{2}\mu)}{\cos[\pi(\mu+\nu)/2]\Gamma(\frac{1}{2}+\frac{1}{2}\nu-\frac{1}{2}\mu)\Gamma(\frac{1}{2}+\frac{1}{2}\nu+\frac{1}{2}\mu)}. \tag{B21}$$

Equations (B19) and (B21) are now used to determine $J(x)$, and then ImE, and finally the behavior of A_n for large n. We jump immediately to the final answer because the calculation is relatively easy and the techniques are described in Sec. IV. Our result is that for large n,

$$A_n\sim-(2K)\frac{N-1}{\pi^{3/2}}(-2)^{-n}\Gamma(nN-n+\tfrac{1}{2})\times\left[\frac{\Gamma(2N/(N-1))}{\Gamma^2(N/(N-1))}\right]^{nN-n+1/2}, \tag{B22}$$

where

$$K=\left[\frac{\Gamma(1+\nu-\mu)\Gamma(-\nu-\mu)}{\Gamma(1-\mu)\Gamma(-\mu)}\right]^{1/2}. \tag{B23}$$

Finally, we check (B22) and (B23) in three important limiting cases. First, we let $\nu\to0$. In this limit K in Eq. (B23) is 1. Thus, A_n in Eq. (B22) is exactly *twice* the theoretical prediction for the large-order behavior of perturbation theory for the x^{2N} oscillator.[8] This is reasonable because when $\nu=0$, $c=0$, and we have two noninteracting x^{2N} oscillators.

Second, we pick $N=2$, when $\mu=-1$. In this case

$$K=[\Gamma(2+\nu)\Gamma(1-\nu)]^{1/2},$$

which further simplifies to

$$K=[\nu(\nu+1)\pi/\sin(\pi\nu)].$$

Here we recover the same result as in Eq. (4.42a).

Third, we expect to find a singularity in K when Eq. (B1) has spherical symmetry because of constructive interference. Hence we investigate the limit $C\to N$. Solving $\nu(\nu+1)=N/(N-1)^2$ gives

$$\nu_{1,2}=1/(N-1),\ -N/(N-1).$$

But, $\mu=-1/(N-1)$, so

$$u+\nu_1=0,\quad 1+\nu_2-\mu=0.$$

Thus, one of the two Γ functions in Eq. (B23) blows up and K is indeed singular.

We conclude that the results in Eqs. (B22) and (B23) are quite reasonable and attest to the generalizability of the methods introduced in Sec. IV.

APPENDIX C

Our discussion of N-dimensional oscillators in Sec. VII was incomplete because we did not show that straight lines through radially directed saddle points were solutions of the classical orbit equa-

tions, and we did not give criteria for the existence of saddle points. The purpose of this appendix is to remedy these omissions.

Consider an N-dimensional potential of the form

$$V=\sum_i \tfrac{1}{4}x_i{}^2+\frac{\lambda}{2M}\sum_{i_1,\ldots,i_{2M}} A_{i_1\cdots i_{2M}}x_{i_1}\cdots x_{i_{2M}}. \tag{C1}$$

The interaction term is the most general $2M$th-order homogeneous polynomial, subject to the restriction that V be bounded below for $\lambda>0$. Then we have the following theorem: If $\lambda=-\epsilon$, $\epsilon>0$, then the radial line through any critical point of V is a solution of the classical equations [Eq. (3.4)]. Furthermore, this radial line is a principal axis of the critical point and V reaches a maximum at the critical point along this line.

Proof: Let $a=(a_1,\ldots,a_n)$ be a critical point of V. Then,

$$\left.\frac{\partial V}{\partial x_i}\right|_{x_i=a_i}=\tfrac{1}{2}a_i-\epsilon\sum_{i_2,\ldots,i_{2M}} A_{ii_2\cdots i_{2M}}a_{i_2}\cdots a_{i_{2M}}=0. \tag{C2}$$

The radial line through a_i is

$$x_i(s)=\frac{a_i}{|a|}s. \tag{C3}$$

Using Eqs. (C2) and (C3) we can evaluate the expressions in Eq. (3.4) in terms of s:

$$\begin{aligned}V_iV(x_i(s))&=\frac{a_i}{2|a|s}-\epsilon\sum_{i_2,\ldots,i_{2M}} A_{ii_2\cdots i_{2M}}\left(\frac{s}{|a|}\right)^{2M-1}\\&=\frac{a_is}{2|a|s}-\frac{a_i}{s}\left(\frac{s}{|a|}\right)^{2M-1}\end{aligned} \tag{C4}$$

and

$$\sum_i x_i'(s)\nabla_i x_i(s)=\tfrac{1}{2}s-\frac{s^{2M-1}}{|a|^{2M-2}}. \tag{C5}$$

Thus

$$x_i'(s)\sum_j x_j'(s)\nabla_j x_i(s)=\nabla_i V(x_i(s)),$$

and $x_i(s)$ satisfies Eq. (3.4), the equation of motion.

Next, to show that the radial line $x_i(s)$ is a principal axis of the critical point, we compute the Hessian matrix H_{ij}:

$$\begin{aligned}H_{ij}&=\frac{\partial^2 V}{\partial x_i\,\partial x_j}(a)\\&=\tfrac{1}{2}\delta_{ij}-\epsilon^{(2M-1)}\sum_{i_3,\ldots,i_{2M}} A_{iji_3\cdots i_{2M}}a_{i_3}\cdots a_{i_{2M}}.\end{aligned} \tag{C6}$$

Thus,

$$\sum_j H_{ij}x_j(s)=\frac{sa_i}{|a|}(1-M);$$

that is, $x_i(s)$ is an eigenvector of H with eigenvalue $1-M$ and by definition it is a principal axis of the critical point. Because $1-M$ is less than 0, the critical point is a maximum along the x_i direction. This completes the proof.

Next we will show that for almost all values of the parameters of V in Eq. (C1) there is at least one radially directed saddle point.

Let us first review the results that we obtained in two dimensions. For the potential $V=\frac{1}{4}(x^2+y^2)-\frac{1}{4}\epsilon(ax^4+2cx^2y^2+by^4)$, there are three distinct possibilities:

$$c\neq a,\quad c\neq b, \tag{C7a}$$

$$a=b=c, \tag{C7b}$$

$$a=c>b. \tag{C7c}$$

In the first case we found that V always has a radial saddle point. The second case is spherically symmetric and is treated by separation of variables in Appendix A. The third case was not treated in Sec. VI, but it is easy to see that there is a degenerate critical point along the x axis (the Hessian has a zero eigenvalue). We will see that a similar trichotomy occurs for the general potential in Eq. (C1).

Let us consider an arbitrary unit vector $\hat{u}$ and study the variation of V along the radial line through $\hat{u}$:

$$V=\tfrac{1}{4}r^2-\frac{\epsilon}{2M}r^{2M}T(\hat{u}), \tag{C8}$$

where $x_j=r\hat{u}_j$ and

$$T(\hat{u})=\sum_{i_1,\ldots,i_{2M}} A_{i_1\cdots i_{2M}}\hat{u}_{i_1}\cdots\hat{u}_{i_{2M}}.$$

Then

$$\frac{\partial V}{\partial r}=\tfrac{1}{2}r-\epsilon r^{2M-1}T(\hat{u}), \tag{C9}$$

and

$$\frac{\partial^2 V}{\partial r^2}=\tfrac{1}{2}-\epsilon(2M-1)r^{2M-2}T(\hat{u}). \tag{C10}$$

Thus V has a maximum on this radial line at

$$r=\left(\frac{1}{2\epsilon T(\hat{u})}\right)^{1/(2M-2)} \tag{C11}$$

Equation (C11) defines an $N-1$ dimensional hypersurface B. It is easy to show that V attains a minimum on B. If $T(u)$ does not vanish anywhere, then the hypersurface is compact and, because V is continuous, a minimum exists. If T does vanish,

it can only do so for a finite number of vectors $\hat{u}$. Therefore consider a small cone of solid angles around each such $\hat{u}$. These cones will intersect B in a finite number of small patches, and the complement of these patches B' is compact. Thus V has a minimum on B'. Since we can choose the opening angle of the cones to be as small as we wish, the point where V has a minimum is separated from the patches by a finite distance. (Otherwise the minimum would lie along one of the directions where T vanishes; but this would be absurd because $V \to +\infty$ in such a direction.)

There are now two possibilities. Either the minimum of V is isolated or else V attains its minimum on some connected subset of V. The latter case corresponds to Eq. (C7b) and is exceptional in the sense that we can make the minimum isolated by changing the interaction term $A_{i_1 \cdots i_{2M}}$ infinitesimally and we will therefore not consider it further.

If the minimum is isolated, then we have a radially directed saddle point because, by construction, V has a maximum along the radial direction and a minimum in all other directions. As we have shown above, the radial direction is one of the principal axes of the saddle point. The saddle point may of course be degenerate as in Eq. (C7c). (The WKB methods which we have introduced depend on the existence of a nondegenerate saddle point.) However, since degeneracy is also extremely exceptional, there is almost always a saddle point.

We conclude finally that the straight-line WKB methods which we have introduced in this paper are applicable to almost all potentials of the form in Eq. (C1).

[10]T. I. Banks and C. M. Bender, J. Math. Phys. 13, 1320 (1972).

[11]The equivalence is demonstrated in BWI, Appendix A. In addition to the usual quantum-mechanical perturbative methods, Feynman rules and diagrams can be used to calculate the terms in the series in Eq. (1.7). A_n is the sum of all connected bubble diagrams having n vertices (see BWI, Appendix B). The topology of diagrams for ϕ^4 field theories in any space-time dimension is the same.

[12]To prove Eq. (2.4) we use two rigorous results of B. Simon as given in Ann. Phys. (N.Y.) 58, 79 (1970). Simon proved that $E(\lambda)$ is analytic in the domain shown in Fig. 1 and that the Rayleigh-Schrödinger series is asymptotic in the cut plane for sufficiently small λ. We can use the Cauchy theorem to write

$$F(\lambda) = \frac{1}{2\pi i} \oint_C \frac{F(z)}{z-\lambda}\, dz,$$

where C is the dashed contour shown in Fig. 1. A simple scaling argument (the Symanzik transformation) shows that $F(\lambda) \sim \lambda^{-2/3}$ as $|\lambda| \to \infty$. Thus as $R_1 \to \infty$, the contribution from the large circle vanishes. Furthermore, since the Rayleigh-Schrödinger series is asymptotic, the integral along the small circle $\to 0$ as $R_4 \to 0$. Expanding the denominator as in the text gives the formula

$$A_n = \frac{1}{2\pi i} \int_{-\infty}^{-R_2} D(x) x^{-n}\, dx + \frac{1}{2\pi i} \int_B F(z) z^{-n}\, dz + \frac{1}{2\pi i} \int_{-R_3}^{0} D(x) x^{-n}\, dx,$$

where B is the contour around the boundary of the open annulus. We now let n get large and observe that the first two integrals contributing to A_n are overwhelmed by the third, assuming that $D(x) \neq 0$ for $-R_3 < x < 0$. This establishes Eq. (2.4) for large n.

[13]F. J. Dyson, Phys. Rev. 85, 631 (1952).

[14]A discussion of the WKB approach to tunneling problems may be found in L. D. Landau and E. M. Lifshitz, *Quantum Mechanics: Nonrelativistic Theory* (Pergamon, London, 1958), p. 171 et seq. For multidimensional WKB see V. P. Maslov, *Théorie des Perturbations et Méthodes Asymptotiques* (Dunod, Gauthier-Villars, Paris, 1972) and A. Sommerfeld, *Optics: Lectures on Theoretical Physics* (Academic, New York, 1964), Vol. 4.

[15]See, for example, L. I. Schiff, *Quantum Mechanics* (McGraw-Hill, New York, 1949), p. 179.

[16]Equation (3.4) has a classical analogy. It is formally identical to classical equations for the orbit of a particle in the potential V. Of course, for classical motion to occur we must have $E > V$, while in the quantum-mechanical tunneling problem $E < V$. Thus our most probable escape paths are analytic continuations of the classical orbits.

[17]In a problem with a continuous symmetry, such as spherical symmetry, the set of MPEP's will of course be continuous. This happens in our problem only when $c = 1$. When $c \neq 1$ (and $a = b = 1$) we have four paths because of reflection symmetry in x and y.

[18]T. Banks and C. M. Bender, following paper, Phys. Rev. D8, 3366 (1973).

[19]It is also easy to show that these are the only straight-line solutions of Eq. (3.4).

[20]This transformation is of course motivated by the direction of the MPEP's for $c > 1$ (they meet the x axis at 45° angles). See Sec. III.

[21]See the Bateman Manuscript Project, *Higher Transcendental Functions*, edited by A. Erdélyi (McGraw-Hill, New York, 1953), Vol. 1, p. 121, Eq. (1). This work is referred to hereafter as BMP.

[22]We are of course free to choose any linear combination of $P_\nu^{-1}(w)$ and $P_\nu^1(w)$. It is most convenient and simplest to make the choice in Eq. (4.21) because it is easy to argue that α^2, the separation constant for Eq. (4.23), vanishes. For choices other than that in Eq. (4.21) there may be an integral over separation constants.

[23]See Ref. 18, Sec. II.

We develop a general formalism for calculating the large-order behavior of perturbation theory for quantized systems of unequal-mass coupled anharmonic oscillators. Our technique is based on a generalization of the semiclassical approximation which was used to study equal-mass oscillators in the first paper of this series. The unequal-mass problem is much more difficult because the path which minimizes the classical action is not a straight line. Assuming that this tunneling path is known, we derive a general expression for the physical-optics approximation to the wave function of a tunneling particle. This derivation rests on the construction of a WKB approximation in curved space. We thus completely reduce the general quantum problem to the much simpler classical one of determining the path. Then we present a perturbation scheme for finding the classical path for systems of oscillators whose masses only differ by a small amount. Finally, we illustrate our techniques by solving a two-mode unequal-mass oscillator and comparing these results with a computer calculation. Our theoretical predictions and numerical calculations agree.

I. INTRODUCTION

In the first paper of this series,[1] we developed a method for computing the large-order behavior of the perturbation series for the ground-state energy of a system of N equal-mass coupled anharmonic oscillators. The method employs an extension of the semiclassical (WKB) approximation to multidimensional systems. However, before we can make the WKB approximation we must find the particular solutions of the classical orbit equations which make the action integral $\int (V-E)^{1/2}$ both a local and global minimum.[2] In general, it is very difficult to solve the classical equations, but in BBW I it was shown that for equal-mass oscillators the MPEP's are straight lines. In the present paper we will investigate the more difficult problem of computing the large-order behavior of perturbation theory for systems whose MPEP's are *not* straight lines. To demonstrate that our techniques work in such situations, we completely reduce the calculation of the large-order behavior of perturbation theory to the classical task of finding the MPEP.

Our interest in curved-path problems is not merely academic, for we are ultimately interested in quantum field theoretic perturbation series. The $(\phi^4)_N$ field theory with spatial and ultraviolet cutoffs is equivalent[3] to a system of unequal mass anharmonic oscillators. The "masses" in this case are just the energies of the modes of the field. It therefore seems likely that any attempt

Dielectric constant of biological systems

(Received 29 November 1983; revised manuscript received 24 February 1984)

In this paper we follow the Fröhlich model of long-range coherence in biological systems and use the field-theoretic Hamiltonian of Wu and Austin. We calculate the complex dielectric constant of the metabolically active dipolar parts in the cell. The actual computation proceeds in two stages. In the first stage the imaginary part of the dielectric constant is obtained by the method of continued fractions. In the second stage the real part of the dielectric constant is calculated by an application of the Kramers-Kronig theorem. The main objective of the work presented in this paper is the real part of the dielectric constant. We also discuss the contributions from water which constitutes the majority of the cell content. Our results confirm the predictions of Fröhlich, and we give analytical expressions which can be utilized in the Fröhlich potential.

I. THE FRÖHLICH MODEL

In a series of papers Fröhlich points out certain physically intriguing features of biological membranes:

(i) the various components possess a high degree of organization and cooperation;
(ii) there exists a strong transmembrane electric field;
(iii) the many types of dipoles present in a membrane are capable of high-frequency vibrations (10^{11}–10^{12} Hz);
(iv) in order to support metabolic activity the energy supply must exceed a critical value.

Based on these precepts Fröhlich[1–7] developed a mathematical model in which a chain of coupled dipole moments interact with their environment consisting of a heat bath and an energy supply. To illustrate the principles involved let us consider just two neighboring dipolar molecules which vibrate initially at frequencies ω_1 and ω_2, respectively. Then, due to their coupling, modified frequencies of dipole vibrations, ω_+ and ω_-, arise:

$$\omega_\pm = \left[\tfrac{1}{2}(\omega_1^2+\omega_2^2) \pm \left[\tfrac{1}{4}(\omega_1^2-\omega_2^2)^2 + \frac{\beta_0^4}{(\epsilon'_\pm)^2} \right]^{1/2} \right]^{1/2}, \quad (1)$$

where $\beta_0^2=\gamma e^2\sqrt{z_1 z_2}/MR^3$ and γ is a size- and shape-dependent coupling parameter, z_1 and z_2 are the numbers of elementary charges within each of the molecules, R is the equilibrium chain spacing, M is the molecule's mass, and $\epsilon'_\pm \equiv \epsilon'(\omega_\pm)$ is the real part of the complex dielectric constant of the system. The interaction energy

$$\Delta E = \frac{\hbar}{2}[(\omega_+ + \omega_-) - (\omega_1+\omega_2)] \quad (2)$$

is calculated by expanding the external square root in Eq. (1) as

$$\Delta E \cong \frac{\hbar}{2}\left[[2(\omega_1^2+\omega_2^2)]^{1/2} - (\omega_1+\omega_2) + \frac{\left[(\omega_1^2-\omega_2^2)^2 + \frac{4\beta_0^4}{(\epsilon'_+)^2} \right]^{1/2} - \left[(\omega_1^2-\omega_2^2)^2 + \frac{4\beta_0^4}{(\epsilon'_-)^2} \right]^{1/2}}{[8(\omega_1^2+\omega_2^2)]^{1/2}} \right]. \quad (3)$$

It is only when the two original frequencies are close to resonance, i.e., for $|\omega_1^2-\omega_2^2| \ll 4\beta_0^2/\epsilon'_\pm$, that we can expand the internal square root in a series in which the first term will be proportional to R^{-3}. Otherwise, the suitable expansion contains terms falling off as R^{-6}, R^{-12}, etc. At resonance then ($\omega_1=\omega_2=\bar{\omega}$)

$$\Delta E = \frac{A}{R^3} - \frac{B}{R^6}. \quad (4)$$

Here B is the van der Waals constant and A is the long-range constant given by

$$A = \left[\frac{\hbar e^2 z \gamma}{\sqrt{8}\bar{\omega} M} \right] \left[\frac{1}{\epsilon'(\omega_+)} - \frac{1}{\epsilon'(\omega_-)} \right], \quad (5)$$

where $z=z_1=z_2$. The constant A vanishes when either

(i) ω_1 and ω_2 differ significantly or

 ©1984 The American Physical Society

(ii) $\epsilon'(\omega_+)=\epsilon'(\omega_-)$, i.e., the medium is frequency independent in the region considered.

Moreover, A depends on the rate of energy supply S through the value of the resonance frequency $\bar{\omega}$. It is clear that by considering the energy supply time dependent, the harmonic oscillators driven by it will attain the frequency of the driving force. In addition, A is size and shape dependent as a function of γ. If ω_- (ω_+) is excited, then the interaction is a selective attraction (repulsion). All these properties make this mechanism very appealing from the point of view of growth- and division-control effects in biology.

The only unknown parameter in Eq. (5) has been the dielectric constant $\epsilon'(\bar{\omega})$. This paper is devoted to solving this problem.

II. THE WU-AUSTIN HAMILTONIAN

Wu and Austin[8–11] proposed the following second-quantized Hamiltonian as a model Hamiltonian of the Fröhlich theory:

$$H=\sum_i \tilde{\omega}_i a_i^\dagger a_i+\sum_k \Omega_k b_k^\dagger b_k+\sum_l \theta_l P_l^\dagger P_l+\tfrac{1}{2}\sum_{i,j,k}(\chi a_i^\dagger a_j b_k^\dagger+\chi^* a_j a_i^\dagger b_k)+\sum_{i,k}(\lambda b_k a_i^\dagger+\lambda^* b_k^\dagger a_i)+\sum_{i,l}(\xi P_l a_i^\dagger+\xi^* P_l^\dagger a_i)\,. \tag{6}$$

Here $(a_i^\dagger,a_i)$, $(b_k^\dagger,b_k)$, and $(P_l^\dagger,P_l)$ are the dipole, heat-bath, and energy-pump creation and annihilation operators, respectively. The first three terms in Eq. (6) describe the three constituent parts of the system in the harmonic approximation and the remaining terms relate to the interactions between the subsystems. The commutation relations for the operators involved in Eq. (6) are those of the Bose-Einstein statistics:

$$[a_i,a_j^\dagger]=[b_i,b_j^\dagger]=[P_i,P_j^\dagger]=\delta_{ij}\,, \tag{7}$$

$$[a_i,a_j]=[b_i,b_j]=[P_i,P_j]=0\,, \tag{8}$$

$$[a_i^\dagger,a_j^\dagger]=[b_i^\dagger,b_j^\dagger]=[P_i^\dagger,P_j^\dagger]=0\,. \tag{9}$$

All operators of different types commute. For the present purposes, the Wu-Austin Hamiltonian is approximated by excluding the effects of the pump and linear dipole—heat-bath coupling. These changes, however, can be accommodated by modifying the dipole frequencies from $\tilde{\omega}_i$ to ω_i. Following Wu and Austin,[10] the effective Hamiltonian is adopted in the form

$$H=H_0+H_1\,, \tag{10}$$

where H_0 is the unperturbed cell Hamiltonian

$$H_0=\sum_i \omega_i a_i^\dagger a_i \tag{11}$$

and the interaction operator H_1 contains only the dominant, second-order dipole—heat-bath coupling

$$H_1=\tfrac{1}{2}\sum_{i,j,k}(\chi a_i^\dagger a_j b_k^\dagger+\chi^* a_j a_i^\dagger b_k)\,. \tag{12}$$

A similar Hamiltonian was used by Mishra *et al.*[12] to calculate the interaction potential between two collections of bosons. The effective Hamiltonian, Eq. (10), will be later used to evaluate the dielectric constant of the biological cell.

III. THE COMPLEX DIELECTRIC CONSTANT

In this section we outline a well-established[13] approach to the frequency-dependent complex dielectric constant. We have

$$\epsilon(\omega)=\epsilon'(\omega)-i\epsilon''(\omega)\,, \tag{13}$$

where $\epsilon'(\omega)$ and $\epsilon''(\omega)$ are the real and imaginary parts, respectively. The Kramers-Kronig[14] theorem relates the two parts through

$$\epsilon'(\omega)=1+\frac{1}{\pi}\mathrm{P}\int_{-\infty}^{\infty}\frac{\epsilon''(\nu)}{\nu-\omega}d\nu \tag{14}$$

and

$$\epsilon''(\omega)=-\frac{1}{\pi}\mathrm{P}\int_{-\infty}^{\infty}\frac{\epsilon'(\nu)}{\nu-\omega}d\nu\,, \tag{15}$$

where $\epsilon_\infty=\epsilon(\infty)$ and P denotes taking the principal part of the integral. Moreover, the imaginary part of $\epsilon(\omega)$ is proportional to the band-shape function $I(\omega)$ which is an observable quantity

$$\epsilon''(\omega)=\frac{4\pi^2(1-e^{-\beta\hbar\omega})}{V\hbar}I(\omega)\,, \tag{16}$$

where V is the volume, $\hbar$ is Planck's constant, and $\beta=(kT)^{-1}$ with k the Boltzmann constant and T the absolute temperature. The band-shape function, in turn, is derived from the dipole-dipole autocorrelation function by the Fourier transformation

$$I(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{-i\omega t}\langle\hat{\vec{\mathrm{M}}}\cdot\hat{\vec{\mathrm{M}}}(t)\rangle dt\,. \tag{17}$$

Here, $\vec{\mathrm{M}}$ is the total-dipole-moment operator of the sample:

$$\hat{\vec{\mathrm{M}}}=\sum_{i=1}^{N}\hat{\vec{\mu}}_i \tag{18}$$

and t is time. The angular brackets $\langle\ \rangle$ imply a thermal average of the operators within, i.e.,

$$\langle\hat{\vec{\mathrm{M}}}\cdot\hat{\vec{\mathrm{M}}}(t)\rangle\equiv\mathrm{Tr}\left[\left(\frac{e^{-\beta H}}{Z}\right)\hat{\vec{\mathrm{M}}}\cdot\hat{\vec{\mathrm{M}}}(t)\right]\,, \tag{19}$$

where H is the Hamiltonian of the system and Z is the canonical partition function. The time development of the operator $\hat{\vec{\mathrm{M}}}(t)$ is given by

$$\hat{\vec{\mathrm{M}}}(t)=e^{i\hat{L}t}\hat{\vec{\mathrm{M}}}\,, \tag{20}$$

where $\hat{L}$ is the Liouville operator defined by

$$\hat{L}\hat{\vec{M}} \equiv \frac{1}{\hbar}[H,\hat{\vec{M}}] . \tag{21}$$

Furthermore, the average $\langle \hat{\vec{M}} \cdot \hat{\vec{M}}(t) \rangle$ is related to the causal Green's function $\bar{G}(t)$ since

$$\bar{G}(t) \equiv -i\Theta(t)\langle \hat{\vec{M}}(t) \cdot \hat{\vec{M}} \rangle - i\Theta(-t)\langle \hat{\vec{M}} \cdot \hat{\vec{M}}(t) \rangle , \tag{22}$$

where $\Theta(t)$ is the Heaviside step function. Denoting the Fourier transform of $\bar{G}(t)$ by $\bar{G}(\omega)$ we arrive at

$$I(\omega) = \frac{-1}{1-e^{-\beta\hbar\omega}} \mathrm{Im}\bar{G}(\omega) . \tag{23}$$

Defining the binary product of two arbitrary operators $\hat{B}$ and $\hat{C}$ as

$$(\hat{B}^{\dagger} | \hat{C}) \equiv \mathrm{Tr}\left[\left[\frac{e^{-\beta H}}{Z} \right] [\hat{B},\hat{C}] \right] \tag{24}$$

and employing the complex frequency variable $z = i\omega \pm \eta$, $\bar{G}(z)$ acquires a very compact form:

$$\frac{2\pi}{i}\bar{G}(z) = \left(\hat{\vec{M}}^{\dagger} \left| \frac{1}{z - iL} \right| \hat{\vec{M}} \right) . \tag{25}$$

The operator $\hat{\vec{M}}$ can be written in a second-quantized form as

$$\hat{\vec{M}} = \sum_{j,l} \langle j | \hat{\vec{\mu}} | l \rangle a_j^{\dagger} a_l , \tag{26}$$

where the creation and annihilation operators $a_j^{\dagger}$ and a_l span the complete and orthonormal space of many-body states $| n_1, n_2, \ldots \rangle$:

$$a_i^{\dagger} | n_1, n_2, \ldots, n_i, \ldots \rangle = \sqrt{n_i + 1} | n_1, n_2, \ldots, n_i + 1, \ldots \rangle , \tag{27}$$

$$a_i | n_1, n_2, \ldots, n_i, \ldots \rangle = \sqrt{n_i} | n_1, n_2, \ldots, n_i - 1, \ldots \rangle , \tag{28}$$

where n_i is the occupation number in the ith state ϕ_i. Substituting Eq. (26) into Eq. (25) yields

$$\bar{G}(z) = \sum_{j,l,m,n} \langle j | \hat{\vec{\mu}} | l \rangle \langle m | \hat{\vec{\mu}} | n \rangle G_{jlmn}(z) , \tag{29}$$

where $G_{jlmn}(z)$ is a Green's function in terms of the field operators alone,

$$\frac{2\pi}{i} G_{jlmn}(z) \equiv \left(F_{jl} \left| \frac{1}{z - i\hat{L}} \right| F_{mn} \right) , \tag{30}$$

where $F_{ij} \equiv a_i^{\dagger} a_j$. Equation (30) can be equivalently written in a matrix notation as

$$\frac{2\pi}{i} \underline{\underline{G}}(z) = \left(\underline{\underline{F}} \left| \frac{1}{z - i\hat{L}} \right| \underline{\underline{F}} \right) . \tag{31}$$

By introducing a projection operator P,

$$P \equiv | \underline{\underline{F}}) \cdot \underline{\underline{\alpha}} \cdot (\underline{\underline{F}} | , \tag{32}$$

where $\underline{\underline{\alpha}} = (\underline{\underline{F}} | \underline{\underline{F}})^{-1}$ and P's complement $Q \equiv 1 - P$ and following the prescription due to Mori,[15] the Green's function, Eq. (31), can be converted into a continued fraction expression

$$\frac{2\pi}{i} \underline{\underline{G}}(z) = \cfrac{(\underline{\underline{F}} | \underline{\underline{F}})}{z\underline{\underline{1}} - (\underline{\underline{F}} | i\hat{L} | \underline{\underline{F}}) \cdot \underline{\underline{\alpha}} + \cfrac{(\underline{\underline{G}} | \underline{\underline{G}}) \cdot \underline{\underline{\alpha}}}{z\underline{\underline{1}} - (\underline{\underline{G}} | iL_1 | \underline{\underline{G}}) \cdot \underline{\underline{\beta}} + \cdots}} , \tag{33}$$

where the following symbols have been used:

$$| \underline{\underline{G}}) \equiv QiL | \underline{\underline{F}}) , \tag{34}$$

$$\hat{L}_1 \equiv Q\hat{L}Q , \tag{35}$$

$$\underline{\underline{\beta}} \equiv (\underline{\underline{G}} | \underline{\underline{G}})^{-1} , \tag{36}$$

and $\underline{\underline{1}}$ is an identity matrix.

Equation (33) is the central equation of this paper. Its Fourier transform will be used to calculate the band-shape function $I(\omega)$ via Eq. (23). This, in turn, will enable us to evaluate both imaginary and real parts of the dielectric constant, using Eqs. (16) and (14), respectively. However, the continued fraction expression, Eq. (33), is just another way of formally representing the Green's function $\underline{\underline{G}}(z)$. It is an exact result which, unless further simplifications are given, must not be viewed as a solution to the problem. In Sec. IV we employ an effective Hamiltonian, Eq. (10), and carry out approximate calculations of the continued fraction expression, Eq. (33).

IV. APPROXIMATE CALCULATIONS OF THE GREEN'S FUNCTION

In order to calculate the Green's function of the Hamiltonian, Eq. (10), we rewrite Eq. (33) as

$$\frac{2\pi}{i} \underline{\underline{G}}(z) = [z\underline{\underline{1}} - (\underline{\underline{F}} | i\hat{L} | \underline{\underline{F}}) \cdot \underline{\underline{\alpha}} - \underline{\underline{\sigma}}(z)]^{-1} \cdot (\underline{\underline{F}} | \underline{\underline{F}}) , \tag{37}$$

where

$$\underline{\underline{\sigma}}(z) \equiv -\left(\underline{\underline{G}} \left| \frac{1}{z - i\hat{L}_1} \right| \underline{\underline{G}} \right) \cdot \underline{\underline{\alpha}} \tag{38}$$

and $\underline{\underline{\sigma}}(z)$ must be approximated. The details of our calculations involved in Eq. (37) are presented in Appendix A and here we just summarize the results of subsequent stages of these calculations.

(i) Matrix $(\underline{\underline{F}} | \underline{\underline{F}})$ is given by

$$(F_{jl} | F_{mn}) = (n_l - n_m)\delta_{j,m}\delta_{l,n} , \tag{39}$$

where n_i denotes the number of dipolar phonons in the state i

$$n_i = [\exp(\omega_i / kT) - 1]^{-1} \tag{40}$$

according to the Bose-Einstein statistics.

(ii) Matrix $\underline{\underline{\alpha}}$ is the inverse of $(\underline{\underline{F}} | \underline{\underline{F}})$. Since the latter matrix is diagonal, so is $\underline{\underline{\alpha}}$:

$$\alpha_{jlmn} = (n_l - n_m)^{-1}\delta_{j,m}\delta_{l,n} . \tag{41}$$

(iii) Matrix $(\underline{F}\,|\,i\hat{L}\,|\,\underline{F})$ contains the following elements:

$$(F_{jl}\,|\,i\hat{L}\,|\,F_{mn})=\frac{i}{\hbar}(\omega_m-\omega_n)(n_l-n_m)\delta_{j,m}\delta_{l,n}\ . \tag{42}$$

(iv) Matrix $(\underline{G}\,|\,(z-i\hat{L}_1)^{-1}\,|\,\underline{G})$ equals $(\underline{F}\,|\,i\hat{L}Q\times(z-i\hat{L}_1)^{-1}Qi\hat{L}\,|\,\underline{F})$. However, its elements cannot be obtained exactly. The approximate calculations carried out in Appendix A yield

$$\begin{aligned}\left[F_{jl}\left|i\hat{L}Q\frac{1}{z-i\hat{L}_1}Qi\hat{L}\right|F_{mn}\right]=\frac{|\chi|^2}{\hbar}\Bigg[&\sum_{p,r}\frac{\rho_r(n_l-n_p)-\bar{n}_l n_p}{z+i\hbar^{-1}\omega_{p,l}-i\hbar^{-1}\Omega_r}\delta_{l,n}-\sum_r\frac{\rho_r(n_l-n_m)-\bar{n}_l n_m}{z+i\hbar^{-1}\omega_{m,l}-i\hbar^{-1}\Omega_r}\\&-\sum_r\frac{\rho_r(n_n-n_j)-\bar{n}_n n_j}{z+i\hbar^{-1}\omega_{j,n}-i\hbar^{-1}\Omega_r}+\sum_{p,r}\frac{\rho_r(n_p-n_m)-\bar{n}_p n_m}{z+i\hbar^{-1}\omega_{m,p}-i\hbar^{-1}\Omega_r}\delta_{j,m}\\&+\sum_{p,r}\frac{\bar{\rho}_r(n_l-n_p)-\bar{n}_l n_p}{z+i\hbar^{-1}\omega_{p,l}+i\hbar^{-1}\Omega_r}\delta_{l,n}-\sum_r\frac{\bar{\rho}_r(n_l-n_m)+\bar{n}_l n_m}{z+i\hbar^{-1}\omega_{m,l}+i\hbar^{-1}\Omega_r}\\&-\sum_r\frac{\bar{\rho}_r(n_n-n_j)+\bar{n}_n n_j}{z+i\hbar^{-1}\omega_{j,n}+i\hbar^{-1}\Omega_r}+\sum_{p,r}\frac{\rho_r(n_p-n_m)+\bar{n}_p n_m}{z+i\hbar^{-1}\omega_{m,p}+i\hbar^{-1}\Omega_r}\delta_{j,m}\Bigg]\ .\end{aligned} \tag{43}$$

The following symbols have been used:

$$\omega_{i,j}\equiv\omega_i-\omega_j\ , \tag{44}$$

$$\bar{n}_i\equiv 1+n_i\ , \tag{45}$$

$$\rho_i\equiv[\exp(\Omega_i/kT)-1]^{-1}\ , \tag{46}$$

$$\bar{\rho}_i\equiv 1+\rho_i\ . \tag{47}$$

At this point we have calculated all the matrices that are required in Eq. (37), but we still must carry out a matrix inversion. This inversion is preceded by deriving a Dyson equation which is then solved by a variational technique. The details of this computation are given in Appendix B. Based on this, the approximate Green's function is

$$\begin{aligned}\frac{2\pi}{i}G_{jlmn}(z)=\Bigg[z-i\hbar^{-1}\omega_{j,l}-\frac{|\chi|^2}{\hbar^2(n_m-n_n)}\Bigg[&\sum_{p,r}\frac{\rho_r(n_l-n_p)-\bar{n}_l n_p}{z+i\hbar^{-1}\omega_{p,l}-i\hbar^{-1}\Omega_r}-\sum_p\frac{\bar{\rho}_p(n_l-n_m)-\bar{n}_l n_m}{z+i\hbar^{-1}\omega_{m,l}-i\hbar^{-1}\Omega_p}\\&-\sum_p\frac{\bar{\rho}_p(n_n-n_j)-\bar{n}_n n_j}{z+i\hbar^{-1}\omega_{j,n}-i\hbar^{-1}\Omega_p}+\sum_{p,r}\frac{\rho_r(n_p-n_m)-\bar{n}_p n_m}{z+i\hbar^{-1}\omega_{m,p}-i\hbar^{-1}\Omega_r}\\&+\sum_{p,r}\frac{\rho_r(n_l-n_p)-\bar{n}_l n_p}{z+i\hbar^{-1}\omega_{p,l}+i\hbar^{-1}\Omega_r}-\sum_p\frac{\bar{\rho}_p(n_l-n_m)+\bar{n}_l n_m}{z+i\hbar^{-1}\omega_{m,l}+i\hbar^{-1}\Omega_p}\\&-\sum_p\frac{\bar{\rho}_p(n_n-n_j)+\bar{n}_n n_j}{z+i\hbar^{-1}\omega_{j,n}+i\hbar^{-1}\Omega_p}\\&+\sum_{p,r}\frac{\rho_r(n_p-n_m)+\bar{n}_p n_m}{z+i\hbar^{-1}\omega_{m,p}+i\hbar^{-1}\Omega_r}\Bigg]\Bigg]^{-1}(n_n-n_m)\delta_{j,m}\delta_{l,n}\ .\end{aligned} \tag{48}$$

This complicated equation can be written in a compact form:

$$\frac{2\pi}{i}G_{jlmn}(z)\equiv\left[z-ih^{-1}\omega_{j,l}-\frac{|\chi|^2}{\hbar^2(n_m-n_n)}\sum_{Q=1}^{8}\sigma^{(Q)}_{jlmn}(z)\right]^{-1}(n_l-n_j)\delta_{j,m}\delta_{l,n}\ . \tag{49}$$

The precise definition of the eight quantities $\sigma^{(Q)}_{jlmn}(z)$ can be obtained by comparing the right-hand sides of Eqs. (48) and (49).

The Green's function given by Eq. (49) depends upon the complex frequency variable z. The corresponding function dependent upon the real frequency ω is obtained by the method outlined in Appendix C. The final form of the required Green's function is

$$G_{jlmn}(\omega)=\frac{1}{2\pi}\frac{(n_l-n_j)\delta_{j,m}\delta_{l,n}}{\omega-\hbar^{-1}\omega_{j,l}\pm[i\,|\chi|^2/\pi\hbar^2(n_l-n_j)]\Gamma_{jl}(\omega)}\ . \tag{50}$$

The function $\Gamma_{jl}(\omega)$ is the frequency-dependent linewidth function. Note that the line shift function $S(\omega)$ has been

neglected since the resonance frequencies are usually determined from experiment anyhow. The form of the linewidth function will be discussed in Sec. V.

V. CALCULATIONS OF THE COMPLEX DIELECTRIC CONSTANT

Having found the explicit form of the frequency-dependent correlation function, Eq. (50), we use Eqs. (23) and (16) to obtain the imaginary (absorptive) part of $\epsilon(\omega)$ and then, applying the Kramers-Kronig formula, Eq. (14), the real (nonabsorptive) part of $\epsilon(\omega)$ will be calculated. We start with the imaginary part of $G_{jlmn}(\omega)$,

$$\mathrm{Im}G_{jlmn}(\omega)=\frac{1}{2\pi}\frac{(|\chi|^2/\pi\hbar^2)\Gamma_{jl}(\omega)\delta_{j,m}\delta_{l,n}}{(\omega-\hbar^{-1}\omega_{j,l})^2+[|\chi|^4/\pi\hbar^2(n_l-n_j)^2]\Gamma_{j,l}^2(\omega)} . \tag{51}$$

Assuming the dipole moment matrix elements in the phonon states in Eq. (26), $\langle i|\hat{\vec{\mu}}|j\rangle$, to be real quantities, we obtain

$$\begin{aligned}\mathrm{Im}\bar{G}(\omega)&=\sum_{j,l,m,n}\langle j|\hat{\vec{\mu}}|l\rangle\langle m|\hat{\vec{\mu}}|n\rangle\mathrm{Im}G_{jlmn}(\omega)\\&=\sum_{j,l}|\langle j|\hat{\vec{\mu}}|l\rangle|^2\frac{(|\chi|^2/\pi\hbar^2)\Gamma_{jl}(\omega)}{(\omega-\hbar^{-1}\omega_{j,l})^2+[|\chi|^4/\pi^2\hbar^4(n_l-n_j)]\Gamma_{jl}^2(\omega)} .\end{aligned} \tag{52}$$

This, together with Eqs. (23) and (16), is used to evaluate the imaginary part of the dielectric constant:

$$\epsilon''(\omega)=\frac{4\pi^2(1-e^{-\beta\hbar\omega})}{V\hbar(1+e^{-\beta\hbar\omega})}\sum_{j,l}|\langle j|\hat{\vec{\mu}}|l\rangle|^2\frac{(|\chi|^2/\pi\hbar^2)\Gamma_{jl}(\omega)}{(\omega-\hbar^{-1}\omega_{j,l})^2+[|\chi|^4/\pi^2\hbar^4(n_l-n_j)^2]\Gamma_{jl}^2(\omega)} . \tag{53}$$

If the imaginary part of the dielectric constant is to have any practical value, an explicit form for the quantity $\Gamma_{jl}(\omega)$ must be obtained. The mathematical details have been relegated to Appendix D and we outline only the most important points here.

(i) If, in Eq. (48), the coupling constant χ between the dipolar and the bath phonons is allowed to vanish, a very simple formula is obtained:

$$\frac{2\pi}{i}G_{jlmn}(z)\cong\frac{(n_n-n_m)\delta_{j,m}\delta_{l,n}}{z-i\hbar^{-1}\omega_{j,l}} . \tag{54}$$

Now, applying the principles discussed in Appendix C, we find

$$\mathrm{Im}G_{jlmn}(\omega)=\pi(n_n-n_m)\hbar\delta_{j,m}\delta_{l,n}\delta(\hbar\omega-(\omega_j-\omega_l)) . \tag{55}$$

Thus the absorptive part of the dielectric constant calculated from this equation displays a sharp (narrow) line corresponding to a dipolar frequency transition given by $\omega_l\rightarrow\omega_j$, where $\omega_j>\omega_l$. An absorption line will be observed at an experimental frequency $\omega=\hbar^{-1}(\omega_j-\omega_l)$.

(ii) As the effects of the bath phonons are introduced ($\chi\neq0$), the situation described in (i) is altered as both shifting and broadening of the absorption line is observed. Focusing on the transitions between the modes j and l, two types of terms in Eq. (48) can be distinguished.

(a) The bath directly influences the modes j and l:

$$\text{Bath}\rightarrow\begin{cases}\text{mode } j\\ \text{mode } l\end{cases} .$$

This coupling scheme corresponds to those terms in Eq. (48) that contain a single summation over p.

(b) The bath influences a dipolar mode other than the modes j and l and the result of this is fed into the modes j and l:

$$\text{Bath}\rightarrow\text{intermediate dipolar mode}\rightarrow\begin{cases}\text{mode } j\\ \text{mode } l\end{cases} .$$

This coupling scheme corresponds to all those terms in Eq. (48) that contain a double summation over p and r.

(iii) The summations involved in terms of category (a) can be easily carried out but some difficulty is associated with the terms of category (b). To simplify, it is assumed that there exists only one dipolar mode k other than modes j and l participating in processes (b) and that the bath phonons are acoustic phonons with sound velocity v. The function $\Gamma_{jl}(\omega)$ is now evaluated (see Appendix D for details) as

$$\begin{aligned}\Gamma_{jl}(\omega)=\frac{V\hbar}{2\pi^2v^3}\{&w_1^2(n_l-n_k)[\rho(w_1)+\rho(-w_1)]\\&+w_2^2(n_k-n_j)[\rho(w_2)+\rho(-w_2)]\\&-2\bar{w}_1^2(n_l-n_j)[\bar{\rho}(\bar{w}_1)+\bar{\rho}(-\bar{w}_1)]\} ,\end{aligned} \tag{56}$$

where

$$w_1\equiv\hbar\omega+\omega_{k,l} , \tag{57}$$

$$w_2\equiv\hbar\omega+\omega_{j,k} , \tag{58}$$

$$\bar{w}_1\equiv\hbar\omega+\omega_{j,l} . \tag{59}$$

We now calculate the real part of the dielectric constant using the Kramers-Kronig formula, Eq. (14), and the expression for $\epsilon''(\omega)$, Eq. (53). In order to simplify the result we make the following two approximations:

(i) the resonance approximation, $\omega\cong\hbar^{-1}\omega_{j,l}$, and
(ii) the high-temperature limit, $kT\gg\hbar\omega$.

The necessary integration is carried out with the aid of a contour in the complex plane (see Appendix E). The final expression for the real part of the dielectric constant is obtained as

$$\epsilon'(\omega)=1+\frac{2\pi}{VkT}\sum_{j,l}|\langle j|\hat{\vec{\mu}}|l\rangle|^2(n_l-n_j)\frac{\left[\hbar^{-2}\omega_{j,l}^2+\left[\frac{|\chi|^4}{\pi^2\hbar^4(n_l-n_j)^2}\right]\Gamma_{jl}^2(\hbar^{-1}\omega_{j,l})-\hbar^{-1}\omega_{j,l}\omega\right]}{\left[(\omega-\hbar^{-1}\omega_{j,l})^2+\frac{|\chi|^4}{\pi^2\hbar^4(n_l-n_j)^2}\Gamma_{jl}^2(\hbar^{-1}\omega_{j,l})\right]}. \tag{60}$$

VI. DISCUSSION

In our Hamiltonian the coupling constant χ is an unknown parameter. The equations that have been derived for ϵ' and ϵ'', which are measurable quantities, should provide a means for estimating this parameter. Since both Eqs. (53) and (60) are fairly complicated, we introduce two additional assumptions:

(i) the resonance condition, $\omega=\omega_0\cong\hbar^{-1}\omega_{j,l}$, and
(ii) the high-temperature limit, $\exp(-\beta\hbar\omega)\cong 1-\beta\hbar\omega$.

As a result, an approximate expression for $\epsilon''(\omega)$ is obtained:

$$\epsilon''(\omega_0)\cong\frac{2\pi^3\hbar^2\omega_0}{VkT|\chi|^2}\sum_{j,l}\frac{|\langle j|\vec{\mu}|l\rangle|^2}{\Gamma_{jl}(\omega_0)}(n_l-n_j)^2. \tag{61}$$

Furthermore, we approximate the remaining summation by

$$\sum_{j,l}\frac{|\langle j|\vec{\mu}|l\rangle|^2}{\Gamma_{jl}(\omega_0)}(n_l-n_j)^2\cong\frac{N|\vec{\mu}|^2}{\Gamma(\omega_0)}, \tag{62}$$

where N is the total number of phonons and $|\vec{\mu}|$ is the mean dipole moment of the sample. Hence, the final form of $\epsilon''(\omega)$ is

$$\epsilon''(\omega_0)\cong\frac{2\pi^3\hbar^2\rho|\vec{\mu}|^2\omega_0}{|\chi|^2kT\Gamma(\omega_0)}, \tag{63}$$

where ρ is the density of the material.

Similarly, the real part of the dielectric constant, $\epsilon'(\omega)$ of Eq. (60), can be evaluated close to the resonance, i.e., for $\omega=\omega_0\pm\delta\omega$, as

$$\epsilon'(\omega_0\pm\delta\omega)=1+\frac{2\pi}{kT}\rho|\vec{\mu}|^2\frac{1\mp\omega_0\Delta\,\delta\omega}{1-\Delta(\delta\omega)^2}, \tag{64}$$

where $\Delta\cong\pi^2\hbar^4N/|\chi|^4\Gamma^2(\omega_0)$. Therefore, $\epsilon'(\omega)$ is of an asymmetric shape whose value at ω_0 is equal to the static value

$$\epsilon'(\omega_0)=1+\frac{2\pi}{kT}\rho|\vec{\mu}|^2=\epsilon'(0) \tag{65}$$

and $\epsilon'(\pm\infty)=1$. Equation (65) resembles the Debye equation in the case of ϵ resulting from the existence of permanent dipole moments. Within this approximation the real part, $\epsilon'(\omega_0)$, is strongly frequency dependent, confirming the assumption of Fröhlich. We can therefore conclude that the point dipoles do contribute to the long-range attraction predicted by Fröhlich. The imaginary part, $\epsilon''(\omega_0)$, is proportional to ω_0 and inversely proportional to the coupling constant $|\chi|^2$. The real part becomes frequency independent as $|\chi|\to 0$. Both ϵ' and ϵ'' decrease with the absolute temperature and increase with the density of the substance.

Our calculations of the complex dielectric constant of a biological cell have been based on a number of assumptions which have to be scrutinized.

(i) The omission of energy-pump and linear cell—heat-bath coupling can be justified as causing a constant shift of eigenfrequencies $\omega_i\to\tilde{\omega}_i$ which are not known beforehand.

(ii) Similar argument applies to neglecting the line-shift function $S(\omega)$.

(iii) The continued fraction expression, Eq. (48), is approximate. However, it is still complicated enough for our purposes.

(iv) In dealing with the heat-bath modes we have adopted continuum approximation and Debye model, both realistic in view of the large size of the heat bath.

(v) The high-temperature limit seems appropriate as $T\cong 300$ K is a typical temperature necessary for life processes.

(vi) Finally, taking only one excited mode k into consideration in Eq. (56) is yet to be verified but it seems compatible with the tenets of the Fröhlich model.

It should be realized that the derived complex dielectric constant, Eqs. (53) and (60), covers the giant dipoles present in the cell membrane. It does not include the bulk of a cell which is free and bound water. This fact must be accounted for when attempting to correlate our theory with experiment. Unfortunately, no satisfactory theory on the role of water content in the dielectric properties of organic materials exists. It is well known[16] that water affects the value of ϵ'' more profoundly than ϵ'. For pure water ϵ'' reaches 30 while dry organic material has ϵ'' in the range 10^{-3}—10^{-1} (microwave frequencies considered). Since moist materials achieve ϵ'' in the order of 1, both water and organic molecules seem to be involved strongly in dielectric processes.

Based on the excellent treatise on aqueous dielectrics by Hasted,[16] we write the expression for the dielectric constant of an entire tissue approximately as

$$\epsilon=v_m\epsilon_m+v_b\epsilon_b+(1-v_m-v_b)\epsilon_w, \tag{66}$$

where v_m and v_b are the volume fractions of the membrane dipolar complexes and bound water, respectively, and ϵ_m,ϵ_b are the corresponding dielectric constants. The values of v_m and v_b vary from substance to substance, but for muscle tissue,[16] for example, $v_m=25\%$. The dielectric constant of free water ϵ_w can be assumed to obey the Debye-Drude equations

$$\epsilon'(\omega)=\epsilon_\infty+\frac{\epsilon_s-\epsilon_\infty}{1+\omega^2\tau^2}, \tag{67}$$

$$\epsilon''(\omega)=\frac{(\epsilon_s-\epsilon_\infty)\omega\tau}{1+\omega^2\tau^2}, \tag{68}$$

where $\epsilon_s=\epsilon(0)$, $\epsilon_\infty=\epsilon(\infty)$, and τ is the single relaxation time. At 20°C, the most appropriate temperature for considering living organisms, the free-water parameters, are[16]

$$\epsilon_s\cong 78.5,\quad \epsilon_\infty\cong 4.5,\quad \tau=0.9\times 10^{-11}\text{ s}.$$

The dipole moment of H_2O molecules is $|\vec{\mu}|=1.84$ D whereas for various protein molecules it ranges between 150 and 400 D depending on the type of the protein and the pH of the electrolyte.

The dielectric properties of bound water are not known in detail but are presumed to be between those of ice and liquid water. Its volume fraction v_b is much smaller than that of free water and it relaxes at much lower frequencies with almost no contribution to the dielectric loss at microwave frequencies.

Finally, the dielectric constant of the membrane dipolar complexes ϵ_m is given in Eqs. (53) and (60) or their estimates, Eqs. (63) and (65). We believe that it should be possible to experimentally detect these unusual dielectric properties of biological substances. We expect that in the 10^{10}–10^{12} Hz region there should be resonance peaks clearly distinguishable from the water background. After all, the membrane content in the tissue is by no means negligible. At this stage of development we are not prepared to offer any numerical values, which is simply due to the scarcity of relevant experimental data. Nevertheless we recognize the importance of this question and will deal with it in our future work.

APPENDIX A

(i) In order to calculate the matrix elements of $(\underline{F}\,|\,\underline{F})$ we evaluate the commutator

$$[F_{ik},F_{jl}]=\delta_{kj}a_i^\dagger a_l-\delta_{il}a_j^\dagger a_k \tag{A1}$$

and use Eq. (24) to find

$$(F_{jl}\,|\,F_{mn})=(n_l-n_m)\delta_{j,m}\delta_{l,n}\ , \tag{A2}$$

where we have approximated H by H_0.

(ii) The calculations of $(\underline{F}\,|\,i\hat{L}\,|\,\underline{F})$ require applying the Liouville operator $\hat{L}$ of Eq. (21) to the element F_{mn}:

$$i\hat{L}F_{mn}=\frac{i}{\hbar}\left[(\omega_m-\omega_n)a_m^\dagger a_n+\sum_{p,r}\chi^*(a_p^\dagger a_n-a_n^\dagger a_p)b_r+\sum_{p,r}\chi(a_p^\dagger a_n-a_m^\dagger a_p)b_r^\dagger\right]. \tag{A3}$$

Taking the inner product of the "ket" produced from this result with the "bra" $(F_{jl}|$ yields

$$(F_{jl}\,|\,i\hat{L}\,|\,F_{mn})=\frac{i}{\hbar}(\omega_m-\omega)(n_l-n_m)\delta_{j,m}\delta_{l,n}\ . \tag{A4}$$

(iii) The matrix $(\underline{G}\,|\,(z-i\hat{L}_1)^{-1}\,|\,\underline{G})$ is calculated in several steps.

(a) Using $Q=1-P$ and Eq. (32) for P, we write Q explicitly as

$$Q=1-\sum_{q,r}|\,a_q^\dagger a_r)\frac{1}{(n_r-n_q)}(a_q^\dagger a_r|\ . \tag{A5}$$

(b) The definition of $|\,\underline{G})$, Eq. (34), applied in conjunction with Eq. (A5) gives

$$|\,G_{mn})=\frac{i}{\hbar}\sum_{p,r}|\,(\chi^*b_r+\chi b_r^\dagger)(F_{pn}-F_{mp}))\ . \tag{A6}$$

(c) Similarly, utilizing Eq. (A5) in the definition of $\hat{L}_1$, Eq. (35) yields

$$i\hat{L}_1=i\hat{L}-\sum_{s,t}i\hat{L}\,|\,a_s^\dagger a_t)\frac{1}{n_t-n_s}(a_s^\dagger a_t|-\sum_{q,r}|\,a_q^\dagger a_r)\frac{1}{(n_r-n_q)}(a_q^\dagger a_r\,|\,i\hat{L}+\sum_{q,r,s,t}|\,a_q^\dagger a_r)\frac{1}{(n_r-n_q)}(a_q^\dagger a_r\,|\,i\hat{L}\,|\,a_s^\dagger a_t)\frac{1}{(n_t-n_s)}(a_s^\dagger a_t|\ . \tag{A7}$$

(d) Making use of Eq. (A6) we obtain

$$\left[G_{jl}\left|\frac{1}{z-i\hat{L}_1}\right|G_{mn}\right]=\left[-\frac{i}{\hbar}\right]\left[\frac{i}{\hbar}\right]\sum_{p,q,r,s}\left[(\chi^*b_s+\chi b_s^\dagger)(F_{rl}-F_{jr})\left|\frac{1}{z-i\hat{L}_1}\right|(\chi^*b_q+\chi b_q^\dagger)(F_{pn}-F_{mp})\right] \tag{A8}$$

and upon expanding the right-hand side, eight terms arise, each of which is of the form

$$\left[b_iF_{jk}\left|\frac{1}{z-i\hat{L}_1}\right|b_lF_{mn}\right]\equiv G^{(1)}_{ijklmn}(z)\ , \tag{A9}$$

$$\left[b_i^\dagger F_{jk}\left|\frac{1}{z-i\hat{L}_1}\right|b_l^\dagger F_{mn}\right]\equiv G^{(2)}_{ijklmn}(z)\ . \tag{A10}$$

These new Green's functions involve the new variables bF and $b^\dagger F$ which implies that as we proceed further down the continued fraction, the bath variables begin to make their appearance. It is convenient to introduce the vectors $\underline{A}$ and $\underline{B}$ of which bF and $b^\dagger F$ are the components. Thus we have $b_iF_{jk}\in\underline{A}$ and $b_i^\dagger F_{jk}\in\underline{B}$. Hence the right-hand sides of Eqs. (A9) and (A10) are the elements of the following matrices: $G^{(1)}_{ijklm}(z)\in\underline{\underline{G}}^{(1)}(z)$, $G^{(2)}_{ijklmn}(z)\in\underline{\underline{G}}^{(2)}(z)$. Formally, these new Green's functions resemble Eq. (37) since

$$\underline{\underline{G}}^{(1)}(z)=[z\underline{\underline{1}}-(\underline{A}\,|\,i\hat{L}_1\,|\,\underline{A})-\underline{\underline{\Sigma}}^{(1)}(z)]^{-1}\cdot(\underline{A}\,|\,\underline{A}) \tag{A11}$$

and

$$\underline{\underline{G}}^{(2)}(z)=[z\underline{\underline{1}}-(\underline{B}\,|\,i\hat{L}_1\,|\,\underline{B})-\underline{\underline{\Sigma}}^{(2)}(z)]^{-1}\cdot(\underline{B}\,|\,\underline{B})\ . \tag{A12}$$

Here, the two functions $\underline{\underline{\Sigma}}^{(1)}(z)$ and $\underline{\underline{\Sigma}}^{(2)}(z)$ represent the third stage in the continued fraction development and are set equal to zero as an approximation:

$$\underline{\underline{\Sigma}}^{(1)}(z)=\underline{\underline{\Sigma}}^{(2)}(z)=0 . \tag{A13}$$

With this approximation Eqs. (A11) and (A12) may be written as

$$\underline{\underline{G}}^{(1)}(z)\simeq(\underline{A}\mid\underline{A})\cdot[\underline{\underline{\Delta}}^{(1)}(z)]^{-1}\cdot(\underline{A}\mid\underline{A}) , \tag{A14}$$

$$\underline{\underline{G}}^{(2)}(z)\simeq(\underline{B}\mid\underline{B})\cdot[\underline{\underline{\Delta}}^{(2)}(z)]^{-1}\cdot(\underline{B}\mid\underline{B}) , \tag{A15}$$

where

$$\underline{\underline{\Delta}}^{(1)}(z)\equiv[z(\underline{A}\mid\underline{A})-(\underline{A}\mid i\hat{L}_1\mid\underline{A})] , \tag{A16}$$

$$\underline{\underline{\Delta}}^{(2)}(z)\equiv[z(\underline{B}\mid\underline{B})-(\underline{B}\mid i\hat{L}_1\mid\underline{B})] . \tag{A17}$$

The final forms of the matrix elements are written as follows:

$$G^{(1)}_{ijklmn}(z)=\frac{\rho_i(n_k-n_m)-\bar{n}_k n_m}{z+i\hbar^{-1}\omega_{m,n}-i\hbar^{-1}\Omega_1}\delta_{il}\delta_{jm}\delta_{kn} , \tag{A18}$$

$$G^{(2)}_{ijklmn}(z)=\frac{\bar{\rho}_i(n_k-n_m)+\bar{n}_k n_m}{z+i\hbar^{-1}\omega_{m,n}+i\hbar^{-1}\Omega_1}\delta_{il}\delta_{jm}\delta_{kn} . \tag{A19}$$

The various quantities appearing in these equations are defined in Sec. IV [see Eqs. (40) and (44)—(47)].

APPENDIX B

In this appendix we calculate the inverse required in Eq. (37) using a variational technique.[15] For convenience we extract from Eq. (37) the part that has to be inverted and represent it by the matrix $\underline{\underline{g}}(z)$,

$$\underline{\underline{g}}(z)\equiv[z\underline{\underline{1}}-(\underline{F}\mid i\hat{L}\mid\underline{F})\cdot\underline{\underline{\alpha}}-\underline{\underline{\sigma}}(z)]^{-1} . \tag{B1}$$

We first convert Eq. (B1) into a Dyson equation defining a zero-order diagonal Green's function:

$$\underline{\underline{g}}_0^{-1}(z)=z\underline{\underline{1}}-(\underline{F}\mid i\hat{L}\mid\underline{F})\cdot\underline{\underline{\alpha}} . \tag{B2}$$

Therefore

$$\underline{\underline{g}}^{-1}(z)=\underline{\underline{g}}_0^{-1}(z)-\underline{\underline{\sigma}}(z) . \tag{B3}$$

Multiplying both sides of this equation by $\underline{\underline{g}}(z)$ and then from the left by $\underline{\underline{g}}_0(z)$ and rearranging we obtain the desired Dyson equation

$$\underline{\underline{g}}(z)=\underline{\underline{g}}_0(z)+\underline{\underline{g}}_0(z)\cdot\underline{\underline{\sigma}}(z)\cdot\underline{\underline{g}}(z) . \tag{B4}$$

Since $\underline{\underline{\sigma}}$ is large we use a variational approach to solve the Dyson equation instead of the iterative method which employs

$$\underline{\underline{g}}(z)=\underline{\underline{g}}_0(z)+\underline{\underline{g}}_0(z)\cdot\underline{\underline{\sigma}}(z)\cdot\underline{\underline{g}}_0(z)+\underline{\underline{g}}_0(z)\cdot\underline{\underline{\sigma}}(z)\cdot\underline{\underline{g}}_0(z)\cdot\underline{\underline{\sigma}}(z)\cdot\underline{\underline{g}}_0(z)+\cdots . \tag{B5}$$

Dyson's equation can be written as a functional-matrix equation:

$$\underline{\underline{F}}(\underline{\underline{g}})\equiv\underline{\underline{F}}=\underline{\underline{g}}_0+\underline{\underline{g}}_0\cdot\underline{\underline{\sigma}}\cdot\underline{\underline{g}}-\underline{\underline{g}}=\underline{\underline{0}} \tag{B6}$$

and the problem is to obtain a solution of this equation for the unknown matrix $\underline{\underline{g}}$. If we start with a trial solution $\underline{\underline{g}}^t$ and expand $\underline{\underline{F}}$ about this solution and retain only the first-order terms then we will obtain

$$\underline{\underline{F}}(\underline{\underline{g}})=\underline{\underline{F}}(\underline{\underline{g}}^t)+\left[\frac{\delta\underline{\underline{F}}(\underline{\underline{g}})}{\delta\underline{\underline{g}}}\right]_{\underline{\underline{g}}^t}\cdot(\underline{\underline{g}}-\underline{\underline{g}}^t)=\underline{\underline{0}} . \tag{B7}$$

Equation (B7) can be immediately solved to give an approximate result $\underline{\underline{g}}^a$,

$$\underline{\underline{g}}^a=\underline{\underline{g}}^t-\left[\frac{\delta\underline{\underline{F}}}{\delta\underline{\underline{g}}}\right]^{-1}_{\underline{\underline{g}}^t}\cdot\underline{\underline{F}}(\underline{\underline{g}}^t) . \tag{B8}$$

The matrix inverse required in Eq. (B8) can be easily found:

$$(\delta\underline{\underline{F}}\mid\delta\underline{\underline{q}})^{-1}=-(\underline{\underline{1}}+\underline{\underline{g}}\cdot\underline{\underline{\sigma}}) . \tag{B9}$$

Since Eq. (B9) contains the unknown $\underline{\underline{g}}$ which must be replaced by $\underline{\underline{g}}^t$ that appears in Eq. (B8), we replace it by another trial function $\underline{\underline{g}}^\tau$ and then substitute the result in Eq. (B8), thereby producing another approximation which we call $\underline{\underline{g}}^v$:

$$\underline{\underline{g}}^v=\underline{\underline{g}}_0+\underline{\underline{g}}_0\cdot\underline{\underline{\sigma}}\cdot\underline{\underline{g}}^t+\underline{\underline{g}}^\tau\cdot\underline{\underline{\sigma}}\cdot\underline{\underline{g}}_0+\underline{\underline{g}}^\tau\cdot\underline{\underline{R}}\cdot\underline{\underline{g}}^t , \tag{B10}$$

where $\underline{\underline{R}}\equiv\underline{\underline{\sigma}}\cdot\underline{\underline{g}}_0\cdot\underline{\underline{\sigma}}-\underline{\underline{\sigma}}$.

The matrix $\underline{\underline{g}}^v$ is stationary with respect to variations in both $\underline{\underline{g}}^t$ and $\underline{\underline{g}}^\tau$ about the exact solution $\underline{\underline{g}}$. A very convenient set of trial functions for the problem may be generated by taking linear combinations of the terms arising in the iterative expansion of the Dyson equation, Eq. (B6):

$$\underline{\underline{g}}^t=\sum_{L=1}^{N}c_L\underline{\underline{T}}^{(L)},\quad \underline{\underline{g}}^\tau=\sum_{L=1}^{N}d_L\underline{\underline{T}}^{(L)} , \tag{B11}$$

where

$$\begin{aligned}&\underline{\underline{T}}^{(1)}=\underline{\underline{g}}_0 ,\\ &\underline{\underline{T}}^{(2)}=\underline{\underline{g}}_0\cdot\underline{\underline{\sigma}}\cdot\underline{\underline{g}}_0 ,\\ &\underline{\underline{T}}^{(3)}=\underline{\underline{g}}_0\cdot\underline{\underline{\sigma}}\cdot\underline{\underline{g}}_0\cdot\sigma\cdot\underline{\underline{g}}_0 ,\\ &\cdots .\end{aligned} \tag{B12}$$

As a first approximation we select one-parameter trial functions:

$$\underline{\underline{g}}^t=c_1\underline{\underline{g}}_0,\quad \underline{\underline{g}}^\tau=d_1\underline{\underline{g}}_0 . \tag{B13}$$

Inserting these trial functions into Eq. (B10), minimizing with respect to c_1 and d_1, and then solving the two linear equations for c_1 and d_1 we obtain the "best" matrix $\underline{\underline{g}}$. A typical element is

$$\underline{\underline{g}}^{(z)}_{jlmn}=\frac{\delta_{j,m}\delta_{l,n}}{z-i\hbar^{-1}\omega_{jl}-\sigma_{jlmn}(z)} . \tag{B14}$$

The function $\underline{\underline{\sigma}}$ is defined in Eq. (38) and requires an explicit form for $(\underline{G}\mid(z-i\hat{L}_1)^{-1}\mid\underline{G})$ and $\underline{\underline{\alpha}}$. These two are defined in Eqs. (43) and (41), respectively. Thus the explicit form of $\underline{\underline{\sigma}}$ can be obtained and from it the matrix $\underline{\underline{g}}$ via Eq. (B14).

APPENDIX C

In this appendix we present the necessary details to obtain the imaginary part of the Green's function $\underline{\underline{G}}(z)$ for real frequencies. For simplicity Eq. (48) can be symbolically rewritten as

$$2\pi G_{jlmn}(i\omega\pm\eta):=\left[\omega\mp i\eta-A_1+\frac{A_2}{\omega\mp i\eta+A_3}\right]^{-1}, \tag{C1}$$

where we have used $z=i\omega\pm\eta$. Since the quantity A_3 is real, we must use the standard equation to properly deal with singularities:

$$\frac{1}{x\pm i\eta}=\mathrm{P}\left[\frac{1}{x}\right]\mp i\pi\delta(x)\ . \tag{C2}$$

Then Eq. (C1) becomes

$$\tilde{G}_{jlmn}(\omega\mp i\eta):=\frac{1}{2\pi}\left[\omega\mp i\eta-A_1+A_2\mathrm{P}\left[\frac{1}{\omega+A_3}\right]\pm i\pi A_2\delta(\omega+A_3)\right]^{-1}, \tag{C3}$$

where we have used the definition $\tilde{G}(i\omega\pm\eta)=G(i(\omega\mp i\eta))\equiv\tilde{G}(\omega\mp i\eta)$. Since the equation contains a finite imaginary part in the form of the term $i\pi A_2\delta(\omega+A_3)$ we can now set $\eta=0$ without impunity as there is no danger of encountering singularities for real ω. We now have

$$\tilde{G}_{jlmn}(\omega):=\frac{1}{2\pi}[\omega-A_1+S(\omega)\pm i\Gamma(\omega)]^{-1}\ . \tag{C4}$$

Here, $S(\omega)=A_2\mathrm{P}((\omega+A_3)^{-1})$ becomes a frequency-dependent line shift and $\Gamma(\omega)=\pi A_2\delta(\omega+A_3)$ the frequency-dependent line broadening. The imaginary part of Eq. (C4) is readily taken to give

$$\mathrm{Im}\,\tilde{G}_{jlmn}(\omega):=\frac{1}{2\pi}\frac{\Gamma(\omega)}{[\omega-A_1+S(\omega)]^2+\Gamma^2(\omega)}\ . \tag{C5}$$

In all future development we will call $\tilde{G}(\omega)$ as simply $G(\omega)$.

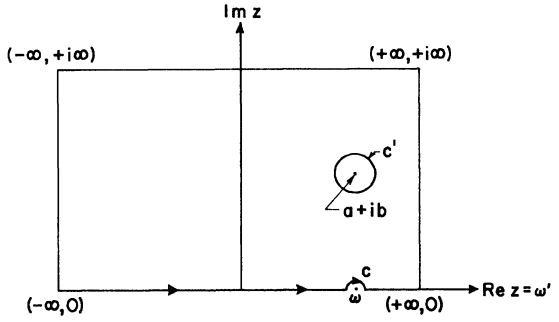

FIG. 1. Details of the contour used in Eq. (E6).

APPENDIX D

The calculation of the linewidth function consists, essentially, of computing the summations contained in the eight terms in the bracket of Eq. (48) for real values of the frequency. Since the calculations with the eight different terms are repetitive, it is sufficient to consider just one term, e.g., $\sigma^{(1)}$, for illustrating the technique.

We begin with

$$\sigma^{(1)}_{jlmn}(z)=\sum_{p,r}\frac{\rho_r(n_l-n_p)-\bar{n}_l n_p}{z+i\hbar^{-1}\omega_{p,l}-i\hbar^{-1}\Omega_r}\ . \tag{D1}$$

Employing the discussion of Appendix C we obtain for real frequencies

$$\sigma^{(1)}_{jlmn}(\omega)=\sum_{p,r}P\left[\frac{\rho_r(n_l-n_p)-\bar{n}_l n_p}{\omega+\hbar^{-1}\omega_{p,l}-\hbar^{-1}\Omega_r}\right]\pm i\pi\sum_{p,r}[\rho_r(n_l-n_p)-\bar{n}_l n_p]\delta(\omega+\hbar^{-1}\omega_{p,l}-\hbar^{-1}\Omega_r)$$
$$\equiv S^{(1)}_{jlmn}(\omega)\pm i\pi\Gamma_{jlmn}(\omega)\ . \tag{D2}$$

Here, $S^{(1)}(\omega)$ is the contribution to the line shift and $\Gamma^{(1)}(\omega)$ is the contribution to the linewidth from $\sigma^{(1)}$ and consequently $S(\omega)=\sum_{Q=1}^{8}S^{(Q)}(\omega)$ and $\Gamma(\omega)=\sum_{Q=1}^{8}\Gamma^{(Q)}(\omega)$. The line shift will be ignored in the present calculations as the resonance frequencies are not known *a priori* but are equated to the experimental values.

To evaluate the linewidth we convert the summation over r into an integral since the heat bath is much larger than the cell itself:

$$\Gamma^{(1)}_{jlmn}(\omega)=\hbar\delta_{j,m}\delta_{l,n}\sum_{p}\int dr\,w(r)[\rho(\Omega_r)(n_l-n_p)-\bar{n}_l n_p]\delta(\hbar\omega+\omega_p-\omega_l-\Omega_r)\ , \tag{D3}$$

where $w(r)$ is a density of phonon states for which we use the Debye model,

$$w(r)=\frac{V\hbar}{2\pi^2}r^2\ . \tag{D4}$$

The quantity Ω_r is the bath phonon frequency,

$$\Omega_r=vr\ , \tag{D5}$$

where v is the speed of sound in the bath. Inserting Eqs. (D4) and (D5) into Eq. (D3) gives

$$\Gamma^{(1)}_{jlmn}(\omega)=\frac{V\hbar}{2\pi^2 v^3}\sum_p(\hbar\omega+\omega_p-\omega_l)^2[\rho(\hbar\omega+\omega_p-\omega_l)(n_l-n_p)-\bar{n}_l n_p]\delta_{j,m}\delta_{l,n}\ . \tag{D6}$$

From the discussion given in Sec. V we can see that since $\sigma^{(1)}$ is a term of category (b), the final summation in Eq. (D6) is approximated by a single term $p=k$ and

$$\Gamma^{(1)}_{jlmn}(\omega)=\frac{V\hbar}{2\pi^2 v^3}(\hbar\omega+\omega_k-\omega_l)^2[\rho(\hbar\omega+\omega_k-\omega_l)(n_l-n_k)-\bar{n}_l n_k]\delta_{j,m}\delta_{l,n}\ . \tag{D7}$$

APPENDIX E

In this appendix we present some of the mathematical details required for the calculation of the principal-value integration appearing in Eq. (14). In the high-temperature limit ($\beta\to 0$) the ratio of the two exponential factors in Eq. (53) simplifies to

$$\epsilon''(\omega)=\frac{2\pi^2\omega}{VkT}\sum_{j,l}\frac{|\langle j|\hat{\vec{\mu}}|l\rangle|^2(|\chi|^2/\pi\hbar^2)\Gamma_{jl}(\hbar^{-1}\omega_{j,l})}{(\omega-\hbar^{-1}\omega_{j,l})^2+[|\chi|^4/\pi^2\hbar^4(n_l-n_j)^2]\Gamma^2_{jl}(\hbar^{-1}\omega_{j,l})}\ . \tag{E1}$$

Substituting Eq. (E1) into Eq. (14) we obtain

$$\epsilon'(\omega)=1+\frac{2|\chi|^2}{VkT\hbar^2}\sum_{j,l}|\langle j|\hat{\vec{\mu}}|l\rangle|^2\Gamma_{jl}(\hbar^{-1}\omega_{j,l})\mathrm{P}\int_{-\infty}^{\infty}d\nu\frac{\nu}{\{(\nu-\hbar^{-1}\omega_{j,l})^2+[|\chi|^4\Gamma^2_{jl}(\hbar^{-1}\omega_{j,l})/\pi^2\hbar^4(n_l-n_j)^2]\}(\nu-\omega)}\ . \tag{E2}$$

We define

$$a\equiv\hbar^{-1}\omega_{j,l}\ , \tag{E3}$$

$$b^2\equiv\frac{|\chi|^4}{\pi^2\hbar^4(n_l-n_j)^2}\Gamma^2_{jl}(\hbar^{-1}\omega_{j,l})\ . \tag{E4}$$

The principal-value integral can be given in a shorthand form by

$$I\equiv\mathrm{P}\int_{-\infty}^{\infty}d\nu\frac{\nu}{[(\nu-a)^2+b^2](\nu-\omega)}\ . \tag{E5}$$

Instead of I as defined by Eq. (E5) we consider another integral J,

$$J\equiv\int dz\frac{z}{(z-a+ib)(z-a-ib)(z-\omega)}\ . \tag{E6}$$

Here, the contour of integration over the variable z is selected according to Fig. 1. It is easy to show that the integrand vanishes along the contour except along the lines $-\infty<\chi\le\omega-i\eta$ and $\omega+i\eta\le\chi\le+\infty$ and the infinitesimally small semicircular contour C. Since the integrand is analytic over the entire upper half of the complex plane, with the exception of the point $z=a+ib$, the integral can be evaluated by shrinking the large, almost rectangular contour to an infinitesimally small circular contour around the simple pole at $(a+ib)$. Thus

$$\mathrm{P}\int_{-\infty}^{\infty}dx\frac{x}{(x-a+ib)(x-a-ib)(x-\omega)}+\int_C dz\frac{z}{(z-a+ib)(z-a-ib)(z-\omega)}=\oint_{C'}dz\frac{z}{(z-a+ib)(z-a-ib)(z-\omega)}\ . \tag{E7}$$

The right-hand side is evaluated by applying Cauchy's theorem as $\pi(a+ib)/b(a+ib-\omega)$. The second term in the left-hand side is calculated by changing to an angular variable θ, $z=\omega+\eta e^{i\theta}$, where θ extends from π to 0 and η is the radius of the semicircle C. Upon integration over θ we get for this term $-\pi\omega i/[(\omega-a+ib)(\omega-a-ib)]$. Collecting all the results yields

$$I=\frac{\pi(a^2+b^2-a\omega)}{b[(\omega-a)^2+b^2]}\ . \tag{E8}$$

Dielectric Measurement of Individual Microtubules Using the Electroorientation Method

Itsushi Minoura and Etsuko Muto
Brain Developmental Research Group, RIKEN Brain Science Institute, Wako, Japan

ABSTRACT Little is known about the electrostatic/dynamic properties of microtubules, which are considered to underlie their electrostatic interactions with various proteins such as motor proteins, microtubule-associated proteins, and microtubules themselves (lateral association of microtubules). To measure the dielectric properties of microtubules, we developed an experiment system in which the electroorientation of microtubules was observed under a dark-field microscope. Upon application of an alternating electric field (0.5–1.9 $\times$ 10^5 V/m, 10 kHz–3 MHz), the microtubules were oriented parallel to the field line in a few seconds because of the dipole moment induced along their long axes. The process of this orientation was analyzed based on a dielectric ellipsoid model, and the conductivity and dielectric constant of each microtubule were calculated. The analyses revealed that the microtubules were highly conductive, which is consistent with the counterion polarization model—counterions bound to highly negatively charged microtubules can move along the long axis, and this mobility might be the origin of the high conductivity. Our experiment system provides a useful tool to quantitatively evaluate the polyelectrolyte nature of microtubules, thus paving the way for future studies aiming to understand the physicochemical mechanism underlying the electrostatic interactions of microtubules with various proteins.

INTRODUCTION

Microtubules of eukaryotic cells play an important role in cellular organization, intracellular transport, and cell motility. In these cellular processes, microtubules serve as molecular tracks for motor proteins such as kinesin and dynein (1) and interact with a variety of microtubule-associated proteins (MAPs) (2).

Electrostatic interaction is thought to play an essential role in mediating these intermolecular interactions of the microtubules. For instance, the processive movement of the motor protein kinesin is modulated by its electrostatic interaction with the microtubule; the distance traveled by the kinesin along the microtubule is dramatically reduced by treatment with high salt concentration or by proteolytic removal of the acidic C-terminal tails of tubulin (3,4). This indicates that this part of the microtubule may serve as an electrostatic tether that keeps the kinesin molecule close to the microtubule surface. A similar decrease was observed in the distance traveled by cytoplasmic dynein by the proteolytic removal of the C-terminal region of tubulin (5). The electrostatic interaction is also implicated in the lateral association of microtubules, which leads to the formation of a variety of cellular architectures composed of microtubule bundles. In this context, the ability of microtubules to form bundles is affected by the presence of ions (6) or MAPs (7,8) in solution. The morphology of the bundle appears to depend on the species of ions (9) or the number of charges included in the microtubule-binding domain of the MAPs (10). These results indicate that both ions and MAPs may serve as cationic ligands that neutralize the negative charges of microtubules (9,10), although the formulation for these observations in terms of electrostatic interaction has not yet been presented.

Despite the potential significance of electrostatic interactions in mediating and regulating their intermolecular interactions, little is known about the electrostatic/dynamic properties of microtubules (11,12). This situation contrasts with the case of other biomolecular filaments such as DNA and actin; the polyelectrolyte nature of these polymers has been extensively characterized, and theoretical studies to explain the observed phenomena are underway (13–19).

To characterize the electrostatic/dynamic properties of microtubules, we performed dielectric measurements by using the electroorientation method (20,21). An alternating electric field was applied to microtubules, inducing dipoles and aligning them parallel to the direction of the applied field. By analysis of this electroorientation process, the microtubule conductivity was calculated to be 1.5 $\pm$ 0.1 mS/m, which is $>$15 times that of the surrounding medium. This high conductivity is probably due to counterion polarization (22–24). Since the microtubule has a large negative potential (12), counterions bind loosely and nonspecifically to it, whereas their diffusional motion along the long axis is unconstrained. Thus, the high conductivity is mainly attributed to the longitudinal movement of these counterions in response to the applied field. The polyelectrolyte nature of microtubules characterized in this study might define the physicochemical basis for nonspecific electrostatic interactions between microtubules and various proteins.

MATERIALS AND METHODS

Preparation of proteins

Tubulin was prepared from porcine brain by temperature-dependent cycles of polymerization and depolymerization (25). Tubulin depleted of MAPs was obtained by performing the second cycle of polymerization in a buffer containing 0.5 M piperazine-1,4-bis(2-ethanesulfonic acid) (PIPES) (pH 6.8) and 10% dimethylsulfoxide (DMSO) (26). Microtubules with lengths of 3–20 μm were polymerized using a short polymer segment as a seed for polymerization (27) in BRB80 buffer (80 mM 2-morpholinoethanesulfonic acid (MES) (pH 6.8), 2 mM $MgCl_2$, and 1 mM EGTA). The polymerized microtubules were stabilized by 0.2 mM taxol (T7402, Sigma, St. Louis, MO) and centrifuged at 250,000 $\times$ g for 12 min through glycerol cushions (40% v/v glycerol in the BRB80 buffer). The resulting pellet was resuspended in the BRB80 buffer containing 0.2 mM taxol at a final protein concentration of 15 mg/ml; it was stored on ice until use.

For the preparation of subtilisin-treated microtubules (s-MTs), taxol-stabilized microtubules in the BRB80 buffer (3 mg/ml) were incubated with subtilisin (P-5380, Sigma) at a molar ratio of 1:1 (tubulin dimer/subtilisin) at 37°C for 2 h (28). The reaction was stopped by 2 mM phenylmethylsulfonyl fluoride, and the mixture was centrifuged through a glycerol cushion to separate the microtubules from the enzyme and C-terminal fragments. The pellet was then resuspended in the BRB80 buffer containing 0.2 mM taxol. The digestion of both α- and β-tubulin was confirmed by SDS polyacrylamide gel electrophoresis.

To determine the site of subtilisin cleavage, amino acid sequencing with liquid chromatography/mass spectrometry (LC/MS; LCQ-DEACA XP, ThermoQuest, San Jose, CA) was carried out on subtilisin-treated tubulin. LC/MS analysis of the subtilisin-treated α-tubulin detected two cleavage sites—at positions Asp^{438} and Glu^{443}. The cleavage site in β-tubulin was not uniquely determined because of its multiple isoforms; the possible cleavage site is at position Ala^{430}, Asp^{431}, Glu^{432}, Gln^{433}, or Gly^{434}.

Buffer condition

A low-salt buffer (LS buffer) composed of 1 mM MES (pH 6.7), 10 μM $MgCl_2$, and 80 μM EGTA, supplemented with 10 μM taxol in DMSO, was used for electroorientation. The final concentration of DMSO was 1%. The LS buffer had a free Mg^{2+} concentration of 9.95 μM, as calculated by the method of Goldstein (29). The conductivity of this buffer solution was 9.7 mS/m, as measured with a conductivity meter (Horiba, Kyoto, Japan). The microtubules were stable in this solution for at least 3 h; all experiments were completed within 1 h of the microtubules being transferred to the LS buffer. EGTA was excluded from the LS buffer in electroorientation experiments for testing the effect of ion species.

Application of electric fields and observation of electroorientation

The orientation chamber with dimensions 6 mm $\times$ 6 mm $\times$ 0.15 mm was composed of a glass slide and a coverslip that were affixed to each other by means of double-sticky tape (Fig. 1 *A*). A pair of transparent electrodes was microfabricated on the upper surface of the glass slide; a 1500-Å-thick indium-tin-oxide (ITO)-precoated glass surface (Sanyo Shinku, Osaka, Japan) was etched by photolithography to form a pair of parallel electrodes with a spacing of 100 $\pm$ 1 μm. Each of these ITO electrodes was connected to a coaxial cable by means of a flexible phosphor bronze plate.

For the orientation experiment, a 7-μl microtubule solution, diluted to a final concentration of $\sim$1 μg/ml with the LS buffer, was first applied in the open orientation chamber; a coverslip was then placed on the top of the chamber to complete the ceiling. The motion of individual microtubules was observed under a dark-field microscope (Olympus, Tokyo, Japan) with a 50×, 0.5–0.9 NA oil-immersion objective lens (Olympus) and 100 W mercury-lamp illumination (OSRAM, Munich, Germany). Dark-field images were projected onto an electron-bombarded charge-coupled device camera (C7190 Hamamatsu Photonics, Hamamatsu, Japan) and stored using a videocassette recorder.

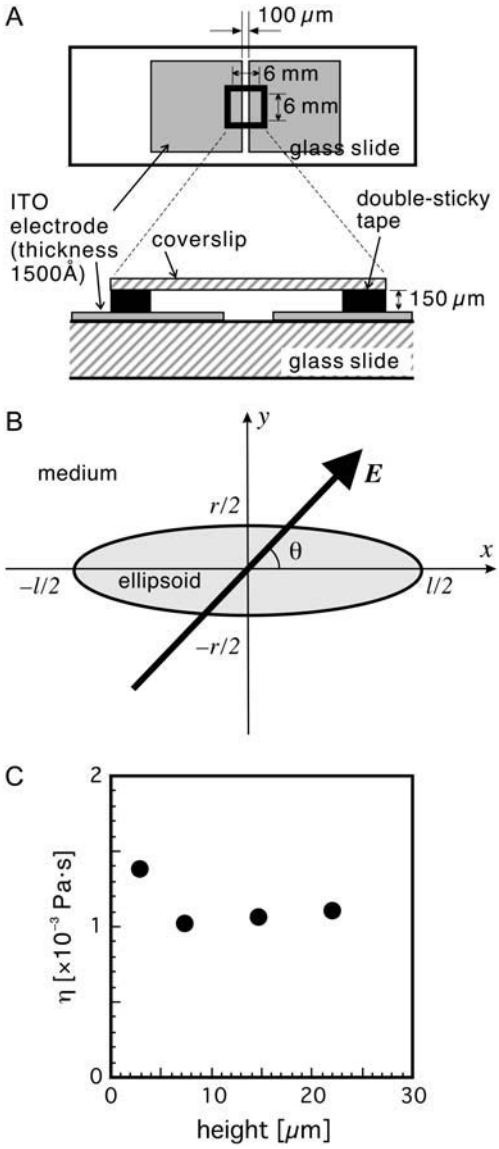

FIGURE 1 (*A*) Top and side views of the electroorientation chamber. Side view is vertically expanded to emphasize the structure. (*B*) Diagram illustrating a dielectric ellipsoid with its long axis x placed at angle θ to the external field E. The z axis is perpendicular to the page. (*C*) Viscosity in the chamber is plotted as a function of the distance from the bottom of the electroorientation chamber. The rotational diffusion constant of microtubule D_r was measured from the mean square rotation angle of the microtubule $\langle\theta^2\rangle$, and η was calculated from $D_r = kT/\pi\eta l^3 C_r = \langle\theta^2\rangle/2t$, where C_r is a form factor (Eq. 5) (55).

To apply the AC field to the microtubule solution, sinusoidal voltage in the frequency range of 1 kHz–10 MHz was generated by a function generator (WAVE Factory 1952, NF Co., Yokohama, Japan) and amplified up to 22 V rms (at 1 MHz) by a power amplifier (High Speed Power Amplifier 4055, NF Co.). The applied sinusoidal voltage was monitored using a digital oscilloscope.

The voltage applied to the electrode may get damped due to the resistance, capacitance, and polarization of the electrodes. Therefore, the voltage actually applied in the microtubule solution was estimated by the method of

Schwan (30), i.e., by using an electronic circuit simulation program (Circuit Maker, Altium, Sydney, Australia). In this simulation, the electrode resistance (1 Ω) was taken into account and coaxial cables were modeled as ideal transmission lines. The capacitance and resistance between the electrodes were measured using an impedance meter (Hioki E. E. Co., Ueda, Japan). The voltage drop caused by the impedance of the electrodes was thus estimated to be <1% at frequencies >10 kHz. The voltage drop increased at frequencies <10 kHz, and was estimated to be 6% at 1 kHz.

As the electric field was not uniformly generated near the edge of the ITO electrodes, dielectrophoresis of the microtubules was inevitable in that area (20). Thus, to avoid the effect of dielectrophoresis, the electroorientation of only the microtubules located in the central region of the chamber (>30 μm from the edges of both the electrodes) was analyzed. Experiments were performed at 25 ± 0.5°C.

Electroorientation model and calculation of microtubule polarization

Since the orientation is caused by an electric-field-induced torque acting on a microtubule filament, the orientation process was modeled as described below, following the equivalent dipole moment method (31,32).

The microtubule is considered as an ellipsoid with rotational symmetry of length l and radius r (Fig. 1 *B*). When the ellipsoid is placed with its long axis at angle θ to the electric field $\mathbf{E}^*$, the electrostatic torque exerted on the ellipsoid is calculated by

$$\mathbf{T}_e = 1/2\mathrm{Re}[\mathbf{p}^* \times \mathbf{E}^*], \tag{1}$$

where $\mathbf{p}^*$ is the dipole moment induced in the ellipsoid and Re[ ] denotes the real part. If we take the coordinate x in the direction of the longest axis of the ellipsoid and coordinate y perpendicular to it (both x and y are in the plane parallel to the direction of applied electric field), the orientation of the ellipsoid is caused by the torque about the z axis, which is perpendicular to the direction of electric field. This torque is thus expressed as

$$T_{ez} = 1/2\alpha E^2 \cos\theta \sin\theta, \tag{2}$$

where

$$\alpha = \mathrm{Re}[a_x^* - a_y^*] \tag{3}$$

is the effective polarization coefficient of the ellipsoid, $E = |\mathbf{E}^*|$, and a_x^* and a_y^* are the polarizability of the ellipsoid in the x and y directions, respectively.

On the other hand, the viscous countertorque T_v experienced by the ellipsoid is given by

$$T_v = \pi l^3 \eta C_r \frac{d\theta}{dt}, \tag{4}$$

where $\eta = 1.0 \times 10^{-3}$ Pa·s (see Fig. 1 *C*) is the viscosity of the medium, and C_r is a form factor. Assuming that $l \gg r$, C_r can be expressed as

$$C_r = \frac{1}{3(\ln(l/r) - 1/2)}, \tag{5}$$

where r is 12.5 nm for the microtubule.

The electrostatic torque should be balanced with the viscous countertorque by equating Eqs. 2 and 4, thus resulting in the following equation of motion:

$$\tau \frac{d\theta}{dt} = -\cos\theta \sin\theta, \tag{6}$$

where τ is the time constant of the orientation expressed as

$$\tau = \frac{2\pi l^2 \eta C_r}{(\alpha/l) E^2}. \tag{7}$$

Eq. 6 can be solved analytically for the case in which the field is applied stepwise with the initial condition $\theta = \theta_0$ at $t = 0$. The solution is

$$\ln(\tan\theta) = \ln(\tan\theta_0) - t/\tau. \tag{8}$$

Based on these equations, the time constant of the orientation, τ, was calculated from the orientation angle of the ellipsoid measured as a function of time (Eq. 8), and the effective polarization coefficient of the microtubule, α, was obtained (Eq. 7).

Calculation of microtubule conductivity

The effective polarization coefficient $\alpha = \mathrm{Re}[a_x^* - a_y^*]$ is actually a parameter related to both the conductivity and dielectric constant of an ellipsoid. For a high aspect ratio ellipsoid such as a microtubule, a_x^* and a_y^* can be approximated by the following equations (32,33):

$$\begin{aligned} \alpha_x^* &= \varepsilon_0 \varepsilon_1 V(\varepsilon_2^* - \varepsilon_1^*)/\varepsilon_1^* \\ \alpha_y^* &= \varepsilon_0 \varepsilon_1 V(\varepsilon_2^* - \varepsilon_1^*)/(\varepsilon_2^* + \varepsilon_1^*), \end{aligned} \tag{9}$$

where

$$\varepsilon_j^* = \varepsilon_j - i\sigma_j/2\pi f \varepsilon_0. \tag{10}$$

ε_j^* is the complex dielectric constant ($j = 1$ for the surrounding medium and 2 for the microtubule), ε_j is the dielectric constant, σ_j is the conductivity, ε_0 is the permittivity of free space, V is the volume of the ellipsoid, and f is the frequency of the applied field. The dielectric constant of water at 25°C, ε_1, is 78.5. According to these equations, σ_2 and ε_2 can be obtained by fitting the spectrum of α/l.

In the actual experiment, since the electroorientation was performed in a solution with low ionic strength, a cloud of counterions surrounding the microtubule may have significantly affected the orientation. Therefore, to calculate the conductivity, the entire microtubule including the surrounding counterion cloud was regarded as a polar entity of an ellipsoid, the radius of which was represented by the sum of the radius of the microtubule (12.5 nm) and the Debye length in the LS buffer ($\kappa^{-1} = (\sum_i \rho_i e^2 z_i^2/\varepsilon\varepsilon_0 kT)^{-1/2} = 9.1$ nm (34), where ρ_i is the concentration of ions in m^{-3}, z_i is the valence of ions, i represents each ion species, e is the elementary charge, k is the Boltzmann constant, and $T = 298$ K is the temperature).

Viscosity in the orientation chamber

The viscosity is assumed to be constant in the model. However, it is not homogeneous in the orientation chamber, but increases near the glass surface due to the wall effect (35). To analyze the electroorientation with our model, the orientation must be measured at positions sufficiently distant from the glass surface.

To determine the height appropriate for measurement, the viscous coefficient η was calculated from the rotational diffusion constant of the microtubules, D_r, at various heights above the glass surface (Fig. 1 *C*). The height of each microtubule from the bottom surface of the glass was determined by calibrating the focal plane of the microscope using the fine adjustment knob. The result revealed that the viscosity was constant at a height of 7–22 μm above the glass surface. Since the focal depth of the microscope was <6 μm, the electroorientation experiment was conducted on a focal plane 15 μm above the bottom of the chamber.

Temperature control

To accurately calculate the viscosity, a constant temperature should be maintained during electroorientation. However, the temperature may increase with the application of the electric field because of excessive Joule heating.

Therefore, we monitored the temperature of the solution using particles of stearic acid butyl ester (S-5001, Sigma) as a temperature indicator. Stearic acid butyl ester is a colorless wax with a melting point of 26.8°C. To monitor the temperature, particles of this wax (10–20 μm in size) were placed between the electrodes in the LS buffer, and the temperature of the stage was initially set to 24.0 ± 0.2°C. Then, upon application of an alternating electric field of 1.9×10^5 V/m (1 MHz), the time required to melt the particles was measured. Continuous application of the electric field for a period of 4 s resulted in melting of the particles (i.e., the temperature increased by ~3°C), whereas the repetitive application of the electric field for a period of 3 s with an interval of 7 s left the particles intact.

Based on these results, for the electroorientation conducted at 25.0 ± 0.5°C, we applied an electric field of $<1.9 \times 10^5$ V/m for a period <3 s with an interval >15 s. Under this condition, the increase in temperature of the solution during measurement should be <3°C.

Calculation of net charge density

The net charges of each α- and β-tubulin subunit at various pH values were calculated by the method of Skoog and Wichman (36), where the number of dissociated charges is obtained by the sum of the charges dissociated from the amino acid side chains and the terminal amino acids. In the calculation, the amino acid sequences of porcine α- and β-tubulin subunits were used (37,38). One molecule each of Mg^{2+} and GTP was included in α-tubulin, whereas one molecule of GDP was included in β-tubulin (39). The net charge of the tubulin dimer was then obtained by summing the net charge of each subunit. The formation of intradimer salt bridges was not taken into consideration in this summation (40) because the dissociated charges that participate in the salt bridge should cancel each other and therefore would not significantly affect the net charge of the dimer. The net charge of the tubulin dimer thus calculated was comparable to the values obtained by molecular dynamics simulation based on the crystal structure of tubulin (41).

RESULTS AND DISCUSSION

Observation and quantitative analysis of electroorientation

It has been demonstrated that in response to the applied electric field, parallel arrays of microtubules are formed due to the dipole moment induced along the long axis of the microtubules ((42), K. Sakata, M. Kurachi, and H. Tashiro, RIKEN, personal communication, 1994). We first attempted a reproduction of their results.

When the microtubules in the LS buffer solution (ionic strength 1.11 mM) were initially observed using a dark-field microscope, they exhibited Brownian motion in the chamber, being random in orientation (Fig. 2 *A*, *left*). Upon application of an alternating electric field (9×10^4 V/m, 1 MHz), the microtubules were oriented parallel to the field line in a few seconds (Fig. 2 *A*, *right*, and *B*; see Supplementary Material for video). The electroorientation occurred at a field strength $>5 \times 10^4$ V/m and in the frequency range of 10 kHz–5 MHz. At frequencies <10 kHz, the electroorientation was accompanied by a rapid flow of microtubules due to the convection of the solution. This convection can be

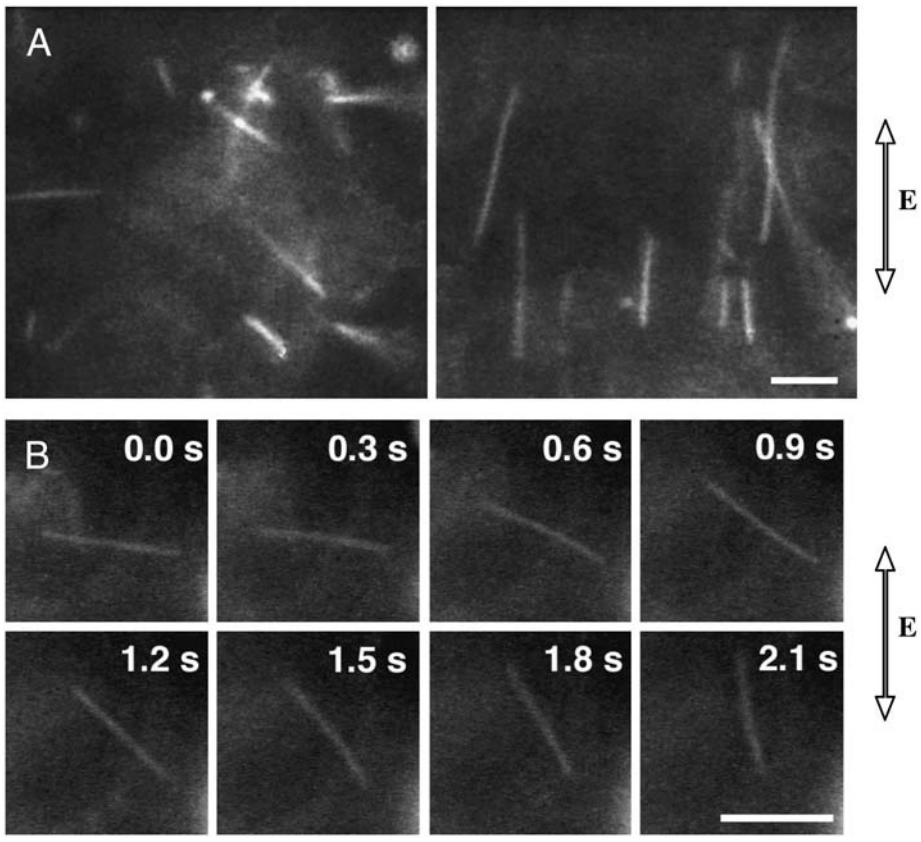

FIGURE 2 Orientation of microtubules at $E = 9 \times 10^4$ V/m, frequency 1 MHz. (*A*, *Left*) Orientation of microtubules is random in the absence of the electric field. (*Right*) Upon application of the electric field, the microtubules are oriented parallel to the direction of the field line. (*B*) Sequential images of a single microtubule after the onset of the electric field taken at intervals of 0.3 s. Arrows indicate the direction of the applied electric field. Scale bar, 10 μm.

attributed to the ionic current in the solution, as the flow became more obvious when the electroorientation was performed in a solution with higher ionic strength. To avoid convection, a frequency of 1 MHz and a field strength just sufficient to orient the microtubules was used in the following experiments, unless otherwise stated.

The process of electroorientation was analyzed by modeling the microtubule as a dielectric ellipsoid on which electrostatic and viscous countertorques were balanced (see Materials and Methods for details). From the video record of the electroorientation of a single microtubule, the angle of the microtubule long axis against the direction of the field line, θ, was measured frame by frame, and $\ln(\tan\theta)$ was plotted as a function of time (Fig. 3 *A*). As expected from Eq. 8 of the model, $\ln(\tan\theta)$ decreased linearly with time, and the slope gives the inverse of the orientation time constant, $1/\tau$.

When τ was calculated for microtubules with various lengths, it appeared to be proportional to the square of the microtubule lengths, l^2 (Fig. 3 *B*). This result is consistent with the model (Eq. 7), given that the dielectric property of microtubule is homogeneous along its length (α/l = constant). The model also predicts that τ normalized by l^2 should be proportional to E^{-2}, where E is the field strength (Eq. 7). This relationship was confirmed with data measured at various field strengths (0.53–1.9 $\times 10^5$ V/m) (Fig. 3 *C*). Together, these results were consistent with the dielectric ellipsoid model; therefore, the effective polarization coefficient of the microtubule, α, could be reliably deduced from our measurement. The effective polarization coefficient normalized for the microtubule length, α/l, was calculated to be $6.3 \pm 0.3 \times 10^{-24}$ Cm/V at 1 MHz.

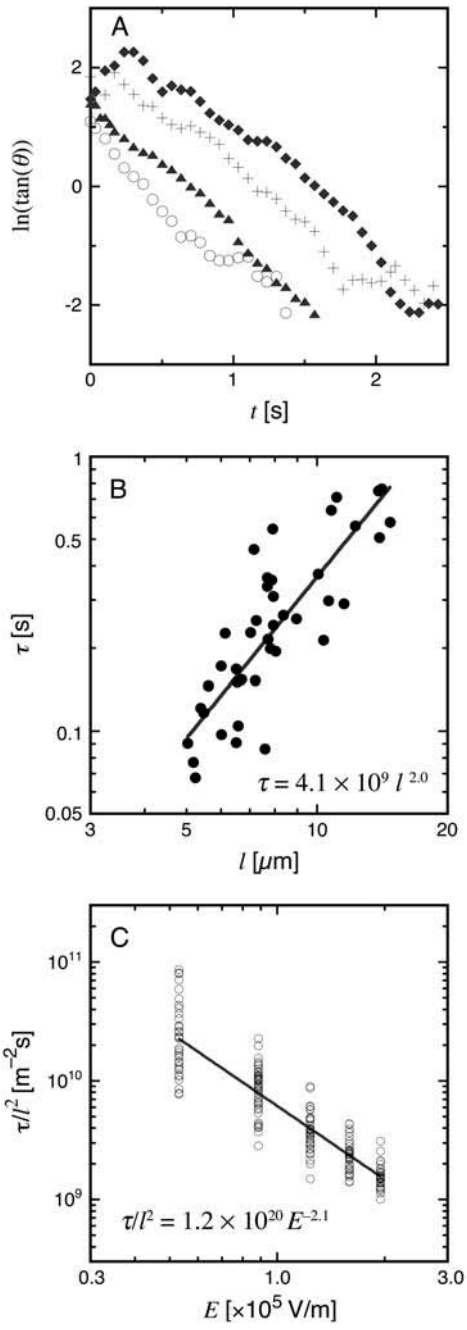

FIGURE 3 Quantitative analysis of microtubule electroorientation. (*A*) $\ln(\tan(\theta))$ plotted against time. Since the taxol-stabilized microtubule is rigid enough, θ can be uniquely determined at each time instant (see Gittes et al. (56)). Four representative examples for microtubules with lengths of 8–12 μm are shown. $E = 1.2 \times 10^5$ V/m, frequency 1 MHz. (*B*) Electroorientation time constant τ plotted as a function of the microtubule length l. τ is proportional to the square of the filament length (line represents the best fit: $\tau = 4.1 \times 10^9\ l^{2.0}$). (*C*) Time constant normalized for the square of microtubule length, τ/l^2, plotted as a function of the field strength E. Line represents the best fit: $\tau/l^2 = 1.2 \times 10^{20}\ E^{-2.1}$.

Dielectric properties of microtubules

The effective polarization coefficient $\alpha = \mathrm{Re}[a_x^* - a_y^*]$ is actually a parameter related to both the conductivity σ_2 and dielectric constant ε_2 of a microtubule. It is possible to approximate σ_2 and ε_2 if the frequency dependence of α is known (see Materials and Methods for details).

Fig. 4 *A* shows the spectrum of α/l measured in the frequency range of 10 kHz–7 MHz. Since the dielectric property of the microtubule was homogeneous along its length, the effective polarization constant was normalized by the microtubule length for the purpose of comparison between the frequencies. The magnitude of α/l was almost constant in the frequency range of 30–700 kHz. In the higher frequency range, α/l gradually declined with an increase in the frequency, and the orientation of the microtubule was not observed at frequencies >7 MHz. The gradual decline of α/l is not an artifact due to the voltage drop at high frequencies (see Materials and Methods for details). In contrast, at frequencies <30 kHz, the electroorientation was accompanied by fluid convection, and α/l measured at 10 kHz showed a large deviation.

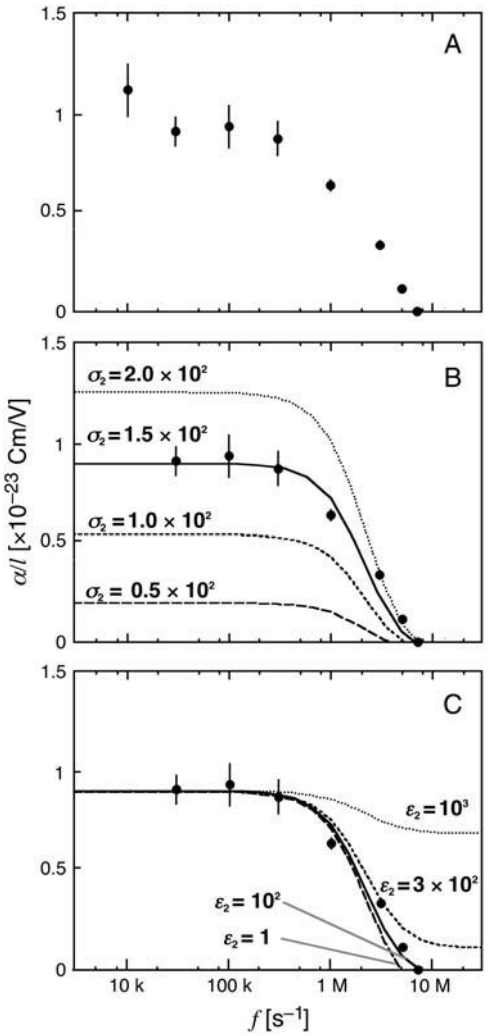

FIGURE 4 Spectrum of the effective polarization coefficient. (*A*) The effective polarization coefficient normalized for the microtubule length, α/l, was measured as a function of the frequency of the electric field, f. The field strength is just sufficient to orient the microtubules; $E = 0.71$ (<700 kHz), 0.88 (700 kHz), 1.2 (1 MHz), and 1.7 (>1 MHz) $\times$ 10^5 V/m. Scale bar represents the standard error for 15–20 measurements. (*B*) α/l simulated by Eqs. 3, 9, and 10, assuming $\varepsilon_2 = 10$ and $\sigma_2 = 0.5$, 1.0, 1.5, and 2.0 $\times$ 10^2 mS/m, respectively. The data obtained at 10 kHz was excluded in this simulation. (*C*) α/l simulated by the same equations, assuming $\sigma_2 = 1.5 \times 10^2$ mS/m and $\varepsilon_2 = 1$, 100, 300, and 1000. In both *B* and *C*, dots represent the measured values.

Fitting the spectrum by Eqs. 3, 9, and 10 using the nonlinear least-squares Marquardt-Levenberg method (with Maxima and GNUPLOT), σ_2 was estimated to be $1.5 \pm 0.1 \times 10^2$ mS/m (mean $\pm$ SD of the fit) (Fig. 4 *B*). ε_2 was estimated to be <100, but the exact value was not determined. As shown in the simulations, the spectrum is insensitive to the variation of ε_2 when ε_2 is <100 (Fig. 4 *C*).

The microtubule conductivity of 1.5×10^2 mS/m is ~15 times that of the surrounding medium. Such a high conductivity can be attributed to counterion polarization (22,24,43). A microtubule is a highly negatively charged polymer and is therefore expected to attract counterions from the solution. These counterions are loosely bound to the microtubule, yet they are mobile along its length. In response to the applied electric field, these counterions may move along the long axis of microtubule, resulting in a high microtubule conductivity.

If this interpretation is correct, according to the counterion condensation theory, the conductivity of microtubules should be affected by both their charge density and the counterion species (44,45). To validate this, the following experiments were conducted. Since the spectrum analysis showed that measurement at one frequency is enough to calculate the microtubule conductivity (Fig. 4), the measurements were performed at 1 MHz.

Effect of ion valence on polarization

The counterion polarization hypothesis predicts that the conductivity of polyelectrolytes might depend on the ion species in the solution. On the other hand, if the electro-orientation is caused by the electronic polarization of the tubulin molecule itself, the conductivity might not depend on the ion species in the solution.

To examine the influence of ion species on the conductivity of microtubules, the electroorientation was examined using various species of monovalent/multivalent ions (Fig. 5). Electroorientation of the microtubules was measured in a solution containing 0.90–1.00 mM MES (pH 6.8), 10 μM taxol, and 10 μM of one of the following salts: KCl, NaCl, $ZnCl_2$, $MgCl_2$, $[Co(NH_3)_6]Cl_3$, or $AlCl_3$. Although the microtubules become unstable in the absence of EGTA and Mg^{2+} (46), the filaments remained intact for several hours provided 10 μM taxol was included in the solution. The result showed that in the presence of monovalent ions such as K^+ or Na^+, the microtubule conductivity was ~20% higher than that measured with divalent cations. In contrast, in the presence of trivalent cations, the conductivity was ~75% of that measured with divalent cations.

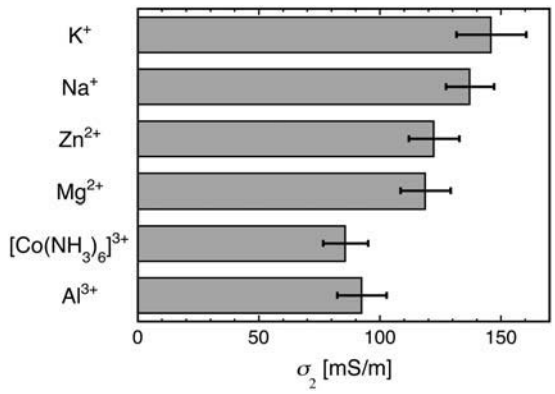

FIGURE 5 Effect of ion species on microtubule conductivity. Conductivity of the solution was adjusted to 9.5 $\pm$ 0.2 mS/m by controlling the concentration of the MES buffer. $E = 1.2 \times 10^5$ V/m. Error bar represents the standard error for 17–26 measurements.

The dependence of microtubule conductivity on ion species might be consistent with the counterion polarization hypothesis. In comparison with cations with lower valences, cations with higher valences are expected to be more strongly bound to the negatively charged surface of the microtubules due to Coulomb interaction (23,24). With an increase in the number of valences, the fraction of counterions being trapped in the so-called Stern layer would increase (34,47), and these trapped counterions should have less mobility compared to the counterions in the diffuse electric double layer (48). Consequently, the conductivity of microtubules in a solution containing ions with higher valences is expected to be lower than that in a solution containing ions with lower valences.

Effect of charge density on polarization

According to the counterion condensation theory, the formation of counterion clouds depends on the linear charge density of the polyelectrolyte. If the linear charge density of the polyelectrolyte is greater than the critical value ($q_{\text{crit}} = 1/z\lambda_B = 4\pi\varepsilon_0\varepsilon kT/e^2$, where ε is the relative dielectric constant of the polyelectrolyte, ε_0 is the permittivity of vacuum, kT is the thermal energy, e is the elementary charge, z is the valence of the counterion, and λ_B is the so-called ''Bjerrum length''), the counterions will condense around it (24,43). In such a situation, the number of mobile counterions on the polyelectrolyte is expected to be a linear function of its charge density.

To examine the actual relationship between the conductivity and charge density of microtubules, we analyzed the effect of pH on microtubule polarization. By changing the pH of the solution, we varied the degree of dissociation of the charges in tubulin and accordingly modulated the charge density of the microtubules. The result showed that the microtubule conductivity increased as the pH of the solution became farther from the isoelectric point of the microtubules (p$I \approx 4.2$ (49)) (Fig. 6 *A*). We were unable to measure the electroorientation below pH 5.5 because of microtubule depolymerization.

The microtubule conductivities were replotted as a function of the number of net charges per tubulin dimer under each pH condition, which was calculated based on the amino acid composition of tubulin (Fig. 6 *B*). The conductivity appeared to increase linearly with the number of net negative charges, with the x-intercept at 20 e per tubulin dimer. This result is consistent with the counterion condensation theory, and the threshold of net negative charges required for electroorientation (20 e per tubulin dimer) may correspond to the critical charge density for counterion condensation.

Baker et al. (12) recently calculated the electrostatic potential for a microtubule structure based on the Poisson-Boltzmann equation. Their result demonstrated that the ribs of a strong negative potential field are formed along the ridges of protofilaments, each intervened by small patches of a positive potential field. This suggests that counterion condensation occurs along the ridges of individual protofilaments rather than occurring homogeneously along the entire surface of the microtubule filament. In keeping with this idea, the threshold of net negative charges derived from our measurement—20 e per tubulin dimer—corresponds to a linear charge density of 2.5 e/nm along a protofilament, which is of the same order as the critical charge density theoretically predicted for a linear polyelectrolyte ($q_{\text{crit}} = 1.4$

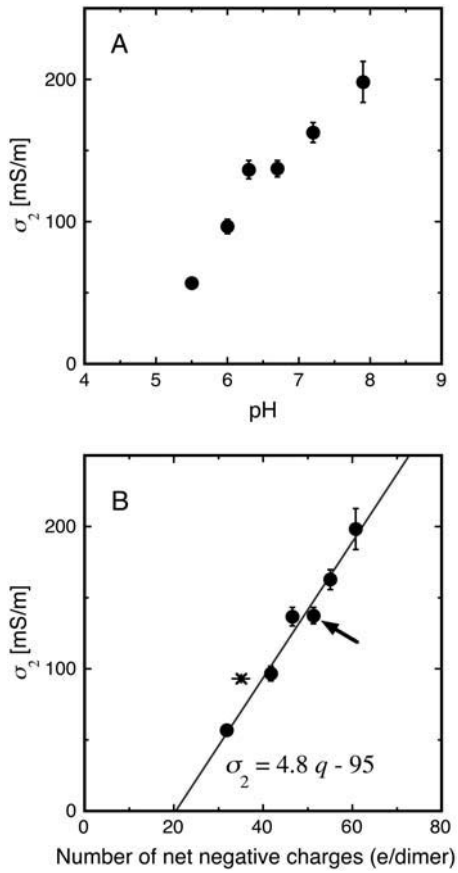

FIGURE 6 Effect of charge density on microtubule conductivity. (*A*) Conductivity of microtubules (σ_2) measured as a function of pH. Either MES (pH 5–7) or HEPES (pH 7–8) was used to adjust the pH of the medium, whereas the conductivity of the medium was kept constant by controlling the concentration of the buffer solution (9.7 ± 0.3 mS/m). $E = 1.2–1.7 \times 10^5$ V/m. Scale bar represents the standard error for 30–40 measurements. (*B*) Conductivity of microtubules replotted as a function of the number of net charges per tubulin dimer. The arrow indicates the data point measured for intact microtubules at a pH of 6.7, whereas the cross represents the conductivity of the s-MTs measured at the same pH. Since the subtilisin cleavage site was not unique, a range of all plausible charge densities is represented by a horizontal bar (see Materials and Methods for details). The line represents the best fit ($\sigma_2 = 4.8q–95$). It should be noted that our calculation of the net charges (*abscissa*) includes all the dissociated charges in the tubulin dimer and could thus overestimate the surface charges involved in the counterion condensation. Among the dissociated charges included in our calculation, those of some amino acids that are not directly exposed on the microtubule surface may or may not contribute to the counterion condensation.

e/nm for monovalent counterions and 0.7 *e*/nm for divalent counterions (see 24,43)).

Contribution of the C-terminus of tubulin to counterion polarization

In both tubulin α- and β-subunits, negative charges are highly concentrated in the C-terminal region. In each subunit, the disordered C-terminal region of a tubulin emerging from $\alpha-$helix 12, composed of only ~20 amino acid residues (a.a.), contains ~50% of the net negative charges (Table 1) (11). To assess the contribution of this highly acidic region to the conductivity of the microtubule, we examined the electroorientation of s-MTs, in which most of the C-terminal region, <1.5 kDa in size, was deleted from each subunit (50). The result showed that the conductivity of these s-MTs was ~60% that of the intact microtubules; this is consistent with the number of net negative charges expected for s-MTs (Table 2).

It has been observed that the decrease in the number of negative charges in microtubules—whether caused by the protease digestion or a change in the pH—resulted in a reduced microtubule conductivity. As shown in Fig. 6 *B*, the data points fall on the same regression line, represents a linear relationship between the charge density and conductivity of microtubules. These results indicate that all the charges in microtubules equally contribute to the microtubule conductivity.

Implication of nonspecific electrostatic interactions based on the polyelectrolyte nature of microtubules

Our analyses revealed that the microtubules had a high conductivity, which is probably due to counterion polarization. Counterions are trapped loosely and nonspecifically in the electrostatic field surrounding the microtubules, and they exhibited a behavior typical of counterions in polyelectrolyte solutions. The result was obtained under a low ionic strength condition (~1 mM); therefore, it is not immediately applicable to the physiological ionic condition (>0.1 M).

Nevertheless, under the physiological ionic condition, the fraction of the microtubule surface charges associated with the counterions would be same as that measured under a low ionic strength condition because the number of condensed counterions is determined solely by the charge density of the microtubule. Our result showed a linear relationship between the microtubule conductivity and the charge density with the *x*-intercept at 20 *e* per tubulin dimer (Fig. 6). The result indicates that each protofilament can be approximately considered as a linear polyelectrolyte with the *x*-intercept corresponding to the critical charge density for counterion condensation (24). Thus, based on the counterion condensation theory (23), the fraction of microtubule surface charge compensated by the condensed counterions can be determined by the equation $\theta = 1 - b/z\lambda_B$, where λ_B is the Bjerrum length, z is the valence of the counterion, and b is the average charge spacing of the protofilament. At pH 6.8, b is calculated to be 0.15 nm (which is the size of the tubulin dimer, 8 nm, divided by its charge density, 52.2 *e*); hence, θ is expected to be 79% in a solution of monovalent cations. It may reach 89% in the presence of sufficient divalent cations. The counterion condensation described by this equation is insensitive to the salt concentration in the solution (24,51). In short, at physiological pH and ionic strength, the majority of the microtubule surface charges are expected to be associated with the counterions.

The polyelectrolyte nature of microtubules may underlie the physicochemical mechanism by which microtubules interact with various microtubule-binding proteins. Analogous to the behavior of counterions, some of these binding interactions might be mediated by weak, nonspecific interactions in which the proteins behave simply as polyvalent cations attracted to the negatively charged surface of the microtubules. The interaction does not require the complementary surface of each protein (lock and key mechanism). The stability of the interaction is determined by the charge density of the microtubules and the net positive charges included at the binding site of the proteins. Such nonspecific electrostatic interaction might be involved, for example, in the processive movement of motor proteins such as kinesin and dynein along the microtubule filament (3–5). The weak electrostatic interaction may be advantageous because it may

allow the motors some freedom of motion along the longitudinal axes of microtubules during the weak binding state of the motors.

The stability of the nonspecific protein-microtubule interaction might be affected not only by the electrostatic attraction between the binding pair, but also by the entropy gained by the release of monovalent or divalent cations condensed on the microtubule surface (52,53). As described above, the majority of the microtubule surface charges are associated with counterions; therefore, the binding of cationic proteins would involve the release of counterions into solution, which is accompanied by an entropic gain. Accordingly, the thermal fluctuations of the condensed counterion density along the microtubules may affect/modulate the interaction of cationic proteins with the microtubule.

Regarding protein-protein interaction, we have largely focused on the short-range interaction, which is dependent on the specific, complementary structure of each protein. However, the importance of the weak electrostatic binding interaction, which is probably effective over a long range, has not been recognized until recently (18,34). A better understanding of the latter type of interaction may ultimately lend a new perspective to the function of intermolecular interactions mediated by cytoskeletal filaments. The experiment system developed in this study provides a useful tool to evaluate the polyelectrolyte nature of microtubules. Since the method requires only a small amount of sample ($\sim$1 μg), it is applicable to isotypically pure microtubules obtained by genetic engineering (Katsuki et al., unpublished). A combination of dielectric measurements and mutational analyses may facilitate future studies aiming to understand the fundamental physicochemical mechanisms underlying the intermolecular interactions of microtubules.

We thank Drs. H. Kondo and H. Tashiro for their help during the microfabrication and the Research Resources Center of RIKEN BSI for the LC/MS analysis. We also thank Drs. M. Suzuki, F. Oosawa, and T. Yamada for their critical comments upon reading this manuscript and Dr. M. Washizu for informative discussions.

Dielectric polarization, electrical conduction, information processing and quantum computation in microtubules. Are they plausible?

By J. A. Tuszyński[1], J. A. Brown[1] and P. Hawrylak[2]

The multitude and diversity of functions performed by the cytoskeleton of eukaryotic cells poses a major scientific puzzle. Microtubules, which are the main components of the cytoskeleton, are engaged in such important activities as material transport, cell motility, cell division, signal transduction and possibly information processing within axons of nerve cells. The latter aspect has been recently brought to the forefront of consciousness studies by R. Penrose and S. Hameroff. In this paper we discuss the potential of microtubules as information processing units from a physical standpoint. In particular, since electric dipoles are a characteristic property of protein molecules, and as such may undergo various ordering phase transitions, it can be expected that microtubules support the existence of various ferroelectrically ordered states. It is also argued that the piezoelectric effect may link electric and elastic properties of a dielectric polymer system and hence explain a number of experimental observations both *in vitro* and *in vivo*. Furthermore, preliminary results are shown of recent quantum mechanical calculations for the electrical conduction properties of microtubule protofilaments which support the assertion that the latter may function under certain conditions very much like semiconducting devices. Indirect evidence links the cytoskeleton with information processing and cognitive function. We discuss some plausible ways in which axonal microtubules can be involved in the functioning of the brain. Finally, we present a hierarchy of energy values for a number of physical and chemical interactions of interest and discuss their relative importance.

Keywords: microtubules; quantum computing; electrical conduction; neurotransmitter release; signal propagation; dielectric polarization

1. What are microtubules and what do they do in the cell?

The physical and chemical design underlying the complex multifunctional behaviour of the cell's cytoskeleton is one of the most intriguing unsolved problems of molecular biophysics. The cytoskeleton comprises actin, intermediate filaments, microtubules and centrioles (which, in turn, also contain bundles of microtubules). Microtubules (MTs) are ubiquitous in eukaryotic cell biology and they perform an astounding array of functions in addition to sustaining the structural architecture of the cytoplasm (Dustin 1984). These are (a) material transport of organelles via motor proteins; (b)

cell motility through cilia and flagella; (c) chromosome separation during mitosis; (d) signal transduction within axonal MTs; and most recently discovered (e) a role in the communication between the exterior of the cell and the nucleus (Glanz 1997; Maniotis *et al*. 1997).

Microtubules are hollow cylinders with a 25 nm outer and 15 nm inner diameter (see figure 1) which are formed in the process of polymerization of tubulin protein. Each tubulin molecule is a dimer composed of two highly homologous monomers called α-tubulin and β-tubulin, respectively. The length of each dimer is approximately 8 nm, the width 5 nm and the thickness also 5 nm. These dimers assemble themselves into protofilaments which number 13 almost without exception *in vivo*, although *in vitro* experiments indicate various deviations from the rule to be quite common.

In non-dividing cells, almost all MTs emanate from a centrosome but their individual length constantly varies in a process referred to as *dynamic instability*. In a dividing cell, the above phenomenon is used to form mitotic spindles, which grow at first randomly from the two oppositely positioned centrosomes to eventually anchor themselves to chromosomes and pull the latter apart in the final mitotic phase. During the stable state of a cell, MTs serve as tracks for the transport of vesicles and organelles mediated by various types of motor proteins. In neurons, vesicles are moved along MTs towards synapses by motor proteins.

Two distinct crystal lattices have been seen to form the MT structure and have become known as the A-lattice and the B-lattice (Chrétien & Wade 1991; Amos 1995). The A-lattice with 13 protofilaments is the only lattice without a seam where protofilaments run parallel to the MT axis (figure 2). The assembly and disassembly processes of MTs have been extensively studied over the past two decades both *in vivo* and *in vitro* (Mitchison & Kirshner 1984; Horio & Hotani 1986; Bayley *et al*. 1990; Mandelkow & Mandelkow 1995). The development of a single microtubule passes

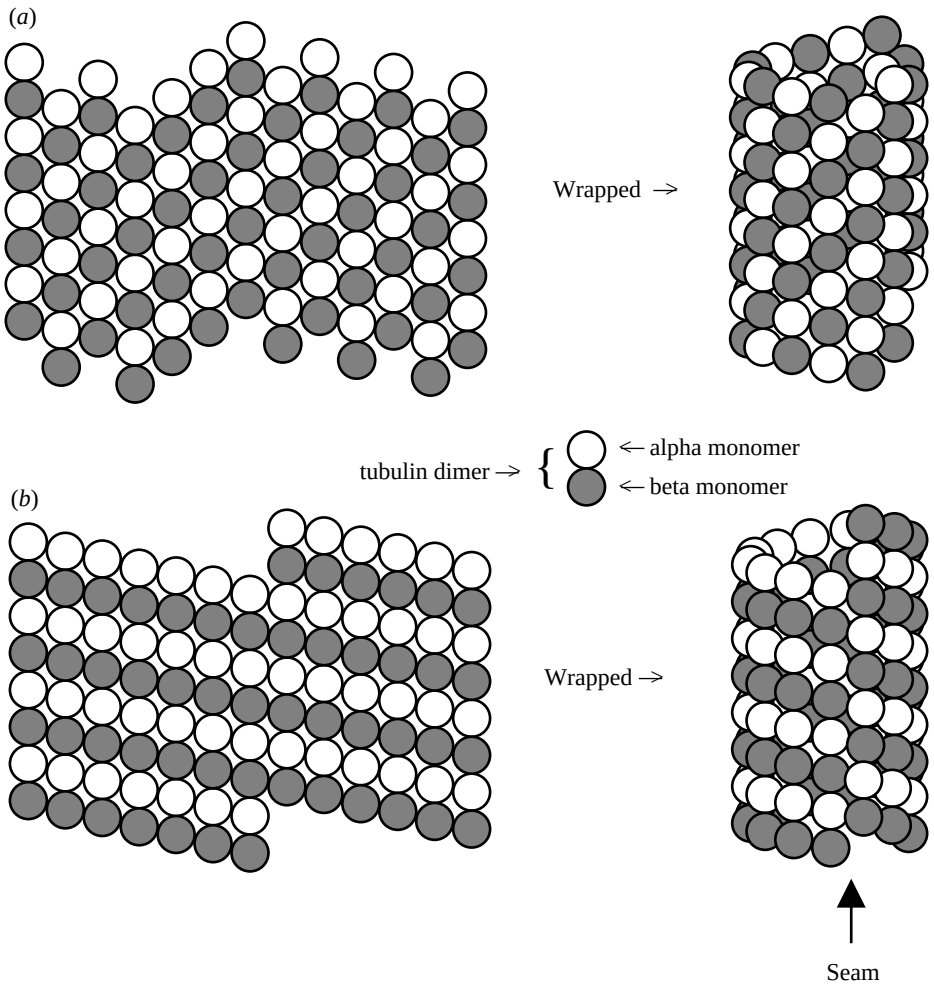

Figure 2. The A and B microtubule lattices: (*a*) the A-lattice exhibits perfect helical symmetry; (*b*) the B-lattice has a structural discontinuity known as a seam.

through several stages starting with a nucleation phase from seed oligomers or microtubule organizing centres (MTOCs) and requiring the presence of γ-tubulin (Sunkel *et al*. 1995). This slow, gradual process eventually reaches an asymptotic density of MT ends and is followed by an almost continuous growth stage which is randomly interrupted by a sudden and catastrophic disassembly followed by another regrowth stage. The ratio of guanosine 5′-triphosphate (GTP) to guanosine 5′-diphosphate (GDP) concentrations in solution determines whether or not and at what rate MTs elongate from a steady-state condition (Engelborghs & Van Houtte 1981). The modelling of MT assembly and disassembly processes *in vitro* as well as *in vivo* through the use of the sophisticated master-equation formalism based on the known chemical reactions and their rates has provided a very accurate and reliable analysis (Flyvbjerg *et al*. 1994). It should be emphasized in this context that MT assembly is a non-equilibrium phenomenon driven by the supply of energy-giving GTP molecules

since only the GTP-tubulin complex is capable of binding to a microtubule. Furthermore, Raman spectroscopy studies revealed that following binding to an MT, GTP attached to the exchangeable site on a tubulin dimer rapidly hydrolyses to GDP, imparting its energy to an unknown destination on the MT lattice. This picture is believed to apply to all but the top layer (or two) of tubulin dimers which have been speculated to form a so-called lateral cap that is required to prevent disassembly.

It is also noteworthy that 'the geometry' of growing MTs (straight protofilaments) differs from that of shrinking ones (curved protofilament ends). This is a direct result of the conformational change that tubulin undergoes upon GTP hydrolysis (Howard & Timasheff 1986). The breaking of lateral bonds first is also consistent with close to a two order of magnitude difference between the elasticity moduli along the axis versus about the circumference in a stable MT; the former being greater.

Finally, it should be mentioned that various types of defects are not uncommon, especially *in vitro*. The number of protofilaments may vary between 12 and as many as 17. MTs often exhibit internal vacancies, breakage points and line defects (Mandelkow & Mandelkow 1994). *In vitro* assembly initially involves a two-dimensional sheet which ultimately closes to form a cylinder and may continue growing as a sheet with the seam closing up behind the growth front. Some researchers claim that the closing of the sheet acts as a trigger for disassembly (Chrétien *et al*. 1995). These problems are almost non-existent *in vivo* where MTOCs provide a template for growth of MTs and MAPs provide additional stabilizing agents (Amos 1995).

We should also add that MTs are highly sensitive to the ionic environment, temperature, pH levels and a number of specific chemicals which bind to their surfaces. For example, Ca^{2+} ions promote disassembly of MTs by enhancing the catastrophe rates (O'Brien *et al*. 1997). The dynamics of MT polymerization are dramatically altered through the use of the drugs: vinblastine (Dhamodharan *et al*. 1995), taxol (Klauber *et al*. 1997) and colchicine (Skoutias & Wilson 1992). An increase in the value of pH of the solution causes an increase in the critical concentration of tubulin for MT formation (Audenaert *et al*. 1989). It has been demonstrated recently that high osmotic pressure in the order of MPa reduces the rate of MT assembly (Barthou *et al*. 1997). All of the above findings are of potential importance in devising new cancer therapies due to the crucial involvement of MTs in the cell division process.

Finally, in this introductory section we should comment on the structure of the constituent protein, tubulin, which has just been resolved at an atomic level (Downing 1998). The development of tubulin appears to be an early evolutionary achievement and a relatively small diversity in the structural isotypes in various species has been found. In a given organism, isotypes of α- and β-tubulin have been found to correlate to some degree with the function performed by the corresponding microtubule, although in some cases isotypes may be interchangeable (Joshi & Cleveland 1990). There are known to be six isotypes of α- and seven of β-tubulin in humans. What complicates the issue of linking structure with function is the plethora of post-translational modifications of tubulin which include phosphorylation, acetylation, detyrosination and glutamylation. It is interesting to note that the greatest divergence among tubulin isotypes is localized to a variable domain called the C-terminus, which is a quasi-linear protrusion from the protein surface containing at least 16 residues (Downing 1998) and possessing a net charge which depends on the solution's pH (Sackett 1997). We believe that this is closely linked to the dipolar properties of microtubules and their role in MTs as carriers of signals. In the next

section we take a closer look at the possibility of ordered dipole phases decorating the surface of a microtubule.

2. Can microtubules be ferroelastic?

Since MTs are protein polymers, there is reason to believe that they are dipolar in character and consequently should be sensitive to electric fields and their gradients. Calculations of electric multipole contributions for a number of proteins have been performed, and the dipole moments found for globular proteins similar in size to tubulin would appear to indicate the existence of a dipole moment in the order of 10^{-27} Cm (Nakamura & Wada 1985; Schlecht 1969). The dipole moment is directly related to each of the peptide groups. Residues of the peptide groups may be either protonated or deprotonated giving rise to a possible net charge on the helix.

According to Sackett (1997) the net charge on a tubulin dimer is pH dependent, being positive at low pH values and highly negative at high pH values. At physiological pH, eight negative charges are expected to exist, which reside mainly in the C-terminus region. Of course, in solution these charges are surrounded by counterions forming a dipolar zone whose thickness corresponds to the Bjerrum length and is of the order of 1 nm at room temperature. If this picture is even approximately correct, it would offer some very attractive possibilities, such as: dipolar orientation predominantly along the protofilament axis, relatively easy to create dipole oscillations, sensitivity to the pH and contents of the solution, cooperative effects, sensitivity to electric fields and their gradients, coupling between elastic deformation and the dipole moment (the piezoelectric effect), etc. Many of the above effects have been experimentally observed and we briefly list them below.

It was suggested a long time ago that bioelectric fields may act to orientate various growth-guiding filaments in the cell (Jaffe & Nuccitelli 1977). Indeed, rearrangement of the cytoskeleton and nuclear transfer was seen in *Tetrahymena thermophila* cells fused by electric fields in the range 300–900 V cm^{-1}. Pronounced effects of electric fields in the 10^3 V m^{-1} range on MTs and actin stress fibres in the fibroblast were observed where filament elongation took place perpendicular to the field gradient and a weakening parallel to it (Harris *et al*. 1990). A possible explanation involves Ca^{2+} influx charges which have been known to be sensitive to low-frequency (3–75 Hz) and low-amplitude electric fields ($E > 10^{-2}$ V m^{-1}) (Berg 1995). Unfortunately, there is only scant evidence indicating direct response of MTs to both electric and magnetic fields. Vassilev *et al*. (1982) observed alignment of MTs in parallel arrays due to the application of both electric and magnetic fields. Electric field intensities used were relatively low, in the range of 20–50 V m^{-1} and were of a pulsed shape. The magnetic field intensity applied was 0.02 T. Similarly, DC electric fields of magnitude 20 V m^{-1} applied in regenerating *Mongeotia* protoplasts resulted in the ordering of MTs (White *et al*. 1990).

If MTs are capable of ordering their dipoles into a ferroelectric state, as we try to argue in this section, this would not be an unusual situation among biopolymers. Indeed, the electret state of most hydrated biopolymers has been found to be a general property of these systems (Fukada 1974). Moreover, bound water was found to strongly contribute to dielectric polarization of biomolecules in solution. Nonlinear effects in transport and polarization storage were discovered which depend on hydration. The nonlinear bioelectret may stimulate ferroelectric hysteresis curves which

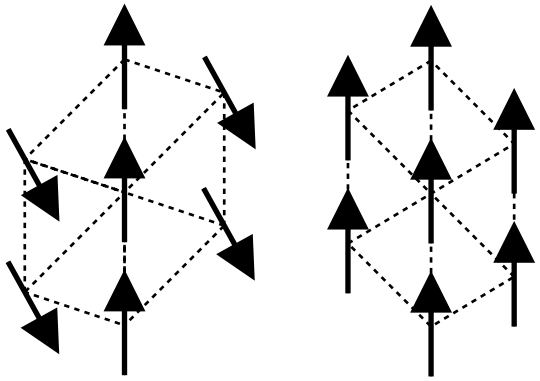

Figure 3. The nearest neighbours of each dimer are arranged as shown in the following diagram. Along the protofilament, parallel alignment is preferred so that the negative heads are close to the positive tails. Between protofilaments, the preferred orientation is determined by the vertical offset between the neighbouring protofilaments.

introduce both memory and irreversibility to the behaviour of these systems (Mascarenhas 1974). Fukada (1974) reported that DNA and RNA are bioelectrets in their hydrated state with a polarization storage as high as $10^{-4}\ \mathrm{C\,m^{-2}}$ at fields as low as $100\ \mathrm{V\,m^{-1}}$. Polarization storage varies drastically with the hydration level, indicating the role of bound water in creating an ordered dielectric state of the complex.

The dielectric constant has a nonlinear dependence upon the protein concentration; this has been linked to the existence of local order in protein molecular assemblies. This is indicative of positional ordering of elongated molecules with permanent dipole moments and it could lead to liquid crystalline properties as well as to molecular electric fields of the order of 10^4–$10^5\ \mathrm{V\,m^{-1}}$ in solutions with protein concentrations of the order of $100\ \mathrm{mg\,mL^{-1}}$ (Post 1995).

In our modelling of dipolar properties of MTs our working assumption was that each tubulin dimer possesses a dipole moment $\boldsymbol{p} = Q \cdot \boldsymbol{d}$, where Q is the net charge capable of transfer over distance d. We have also assumed that the projection of the dipole moment on the protofilament axis can only be $+p$ or $-p$ due to strong anisotropy which constrains the mobile charge to only two locations in the dimer. We chose these locations to correspond to the central region in an α- and β-monomer, respectively (Tuszyński *et al*. 1995). The interaction energy between the neighbouring tubulin dimers, labelled i and j, was taken to be of the standard dipole–dipole form:

$$E_{ij} = \frac{1}{4\pi\epsilon\epsilon_0}\frac{3\cos^2\theta - 1}{r_{ij}^3}p^2, \tag{2.1}$$

where ϵ_0 is the permittivity of the vacuum, ϵ is the dielectric constant of the medium, r_{ij} is the distance between sites i and j and θ is the angle between the dipole axis and the direction joining the two neighbouring dipoles (see figure 3).

As stated earlier, we assume that the electric dipole of the tubulin dimer has two possible orientations depending on the conformational state of the molecule. One orientation of the dipole points along the protofilament axis; this is the *up* state. We have some freedom to choose the direction of the dipole in the *down* state since the electric dipole has not been measured in each of tubulin's conformational states. We

have chosen a direction which is roughly opposite to the direction of the *up* state but which is 29° from the vertical and points out away from the MT. This choice is based on the geometry of MT ends which are splaying apart and of tubulin oligomer rings. Our simulations have been carried out with both the tilted and non-tilted down states for comparison. Note that some degree of tilting is necessary for axonal MTs if action potentials are to influence the dipole dynamics.

However, from the dipole interaction point of view, the lattice type is crucial. In the B-lattice, dimers are aligned in nearly horizontal rows. As a result, there is a strong interaction between neighbouring dimers which favours opposite dipole orientations. In the A-lattice, the neighbouring dipole is shifted vertically such that identical orientation of the dipoles is favoured. In either case, there is a strong interaction along individual protofilaments which favours similarly orientated dipoles. The effect of the dipole interactions is that the lattice of *up* and *down* dipoles will self-organize into an energetically favourable configuration. It can be easily predicted that at high temperatures, the lattice has a random state—each individual dimer can be found in the *up* or the *down* state in a rather arbitrary fashion. At lower temperatures, the interaction energy dictates the dipole arrangement and the lattice becomes ordered. The key question is in what temperature range is the the resultant phase transition from dipolar order to disorder to be expected? The answer crucially depends on the choice of as yet largely unknown physical parameter values.

There are two numbers which are put into the model by hand. One is the relative permittivity of tubulin, or more precisely that of tubulin in cytosol, ϵ. As an approximation, we are using the value 10. The dynamics of the model are unaffected by the choice of ϵ but it scales with temperature. Larger values of ϵ reduce interaction strengths and thereby act like a temperature increase. The other number which is put in by hand is the dipole strength of the conformational states of tubulin. We have chosen the dipole magnitude, p, by considering the corresponding dipole charge to be an elementary charge in magnitude and the charge separation to be 4 nm which is the monomer spacing. This gives a value of $p = 192$ Debye which is comparable to the measured dipole moments of some other protein molecules.

The simulations show that a highly ordered phase exists for both the A- and B-lattices at low temperatures. Whether the MT is ordered at physiological temperature depends critically upon p and ϵ since these parameters determine the transition temperature from disorder to order. In the MT A-lattice with 13 protofilaments, we have found a transition temperature of 105 K and in the MT 13B-lattice, the corresponding transition temperature is 218 K. In the case where the *down* state is directly opposite to the *up* state (the non-tilted case), the corresponding transition temperatures are somewhat higher: 160 K for 13A and 248 K for 13B. This shows that the existence of a transition to order is quite robust but that the transition temperature is sensitive to the specific choice of the *down* dipole. All of these temperatures are below human physiological temperature (310 K, 37 °C) but all have been derived based upon our estimates of the dipole moment, p, and the electric permittivity, ϵ:

$$T_{\mathrm{c}} = T_{\mathrm{c}}^{0}\left(\frac{p}{p_0}\right)^{2}\left(\frac{\epsilon_0}{\epsilon}\right). \tag{2.2}$$

This equation demonstrates the scaling of the transition temperature, T_{c}, in a MT which is not subject to electric fields. The values p_0 and ϵ_0 are the values which we have estimated, while p and ϵ are the actual values of the dipole moment and

permittivity of tubulin. The scaling is more complicated in the presence of electric fields. The transition temperature scales directly with the square of p, and inversely with ϵ. Hence, if the dipoles are twice as large as our estimate then the transition temperature would be raised by a factor of four. Should the permittivity be half as large as estimated, the transition temperature would double. The main result is that the MT could easily exist in an ordered state at physiological temperatures without the application of external fields provided $p^2/\epsilon_{\mathrm{r}} > 10\,800\,\mathrm{Debye}^2$. Our original estimate of $p^2/\epsilon_{\mathrm{r}}$ was about $3600\,\mathrm{Debye}^2$ which comes within a factor of three of what the model requires. We are hopeful that an experimental value for the dipole moment of tubulin will soon be available or a better estimate arrived at using the latest atomic resolution map of tubulin (Downing 1998).

For modelling purposes, in both lattice types the effective Hamiltonian has been represented as a two-dimensional Ising model (Yeomans 1992) on an appropriate triangular lattice whose interaction constants have been calculated based on the geometry of the lattice chosen:

$$H = -\sum_{\langle nn \rangle} J_{ij} S_i^z S_j^z, \tag{2.3}$$

where S_i^z are dipole projection values on the z-axis which can be either $+1$ or -1. The application of an axial electric field, E, along the length of the MT may serve to order the MT at higher temperatures than without an external field and the effective Hamiltonian becomes

$$H = -\sum_{\langle nn \rangle} J_{ij} S_i^z S_j^z - p \sum_i E S_i^z, \tag{2.4}$$

where p is the magnitude of the dipole moment.

Our simulations suggest that for the 13A-lattice, the electric field starts to be effective at the range 10^4–$10^5\ \mathrm{V\ m^{-1}}$. This is because at these fields the potential energy $-pE$ becomes of the order of magnitude of the dipole–dipole interaction energies. These values of the electric fields are at least three orders of magnitude larger than those reported by Vassilev *et al.* (1982) as being used in their experiments on aligning MT assemblies. On the other hand, such strong electric fields may be supported across cell membranes. While the effect of the electric field is quite dramatic in the MT 13A-lattice, for the 13B-lattice the effect is greatly reduced because the orientation of the ground state is not ferroelectric. The dipolar ordering is also affected by the binding of microtubule-associated proteins (MAPs). The influence of MAPs was studied for three different superhelical patterns that attached MAPs formed on a MT. An assumption was made that MAPs prevent the dipoles on the tubulin dimers to which they bind from flipping. MAPs enhance the number of dipoles that point in the same direction as the dipole on the MAP tubulin.

Of the three types of cytoskeletal polymers (actin filaments, intermediate filaments and microtubules), it is the two polar structures which participate in material transport (including axonal transport) and cell motility through the use of their respective motor proteins. It is tantalizing to speculate that it might be this polarization which is responsible for guiding the motor proteins, kinesin and dynein, which travel along the MT in opposite directions (Audenaert *et al.* 1989; Barthou *et al.* 1997). It would immediately explain why the transport would be so efficient because collisions would not occur. The motor proteins would simply have to bind preferentially to a particular conformational state of tubulin. The kinesin and dynein protein motors may

be sensitive to the dipole moments of the tubulin molecules on which they step. An ordered lattice would allow for the efficient transport of material along the lattice. For example, if the lattice were ordered in the same way as the MT 13B-lattice, where alternating protofilaments have opposite dipole orientations, one motor might follow the first, third, fifth, etc., protofilaments while the other would follow the second, fourth, sixth, etc., protofilaments.

3. Can axonal MTs propagate secondary signals?

Neurons have a specialized structure and function. Many of the resources of the cell are spread out in the axons which may project for distances greater than 1 m from the cell body. The cytoplasm within the axon is distinct from that in the cell body. It is generally free of organelles, and filled with microtubules and neurofilaments. These filamentous proteins are arranged parallel to the axon, each neuronal MT being typically about 100 μm long, thus spanning more than 10^5 tubulin subunits. The network of cytoskeletal tubes is interconnected by high molecular weight proteins known as MAPs. Their precise function is not understood but tubulin dimers coassembled with MAPs *in vitro* are polymerized more easily and are more stable than MTs assembled from tubulin in the absence of MAPs (Mandelkow & Mandelkow 1995). The MTs of the axon have uniform polarity and lie with their positive ends distal to the cell body (Baas *et al*. 1988; Baas & Black 1990). Once the axonal MTs have been assembled, they are post-translationally modified and their properties are changed. These changes to the MTs cause them to become more stable (Li & Black 1996; Pryer *et al*. 1992). The post-translational post-MT assembly change has also been frequently studied in the last decade. The transition from newly synthesized tubulin to detyrosinated tubulin within a MT can be used to estimate the age of an individual MT.

Greater stability allows the neuronal MTs to participate in other cell activities. Information processing (Hameroff 1987; Tuszyński *et al*. 1995) and energy transport (Satarić *et al*. 1993) have been proposed as secondary MT functions. Consider the central theme of biology in which DNA codes for functional proteins. Now, not only is the tubulin which makes up neuronal MTs specific to humans, but it is also specific to nerve cells and is known to be post-translationally modified. The highly specialized nature of the functional proteins suggests that it has been selected to perform a very specific function which we conjecture may be signal transduction.

Hameroff *et al*. (1988) have introduced a cellular automaton model where a discrete charge is associated with each tubulin dimer and can either be localized in the top monomer (α state) or bottom monomer (β state). The MT lattice of dimers in their α or β states has then been considered as a binary biological computer. The Hameroff model (Hameroff *et al*. 1988) found that signals introduced onto the MT 13A-lattice would propagate along protofilaments. The propagation was either bidirectional or unidirectional depending upon the choice of flipping force thresholds and whether they were symmetric or not. The model also admitted the possibility of signals which periodically flipped back and forth between α and β states but did not move along the protofilaments. The moving patterns of defects were named gliders and the non-propagating defects were called blinkers. The other feature of the Hameroff model was its ability to filter input signals. Some would propagate, others would be modified and would subsequently propagate, and still others would be annihilated. Thus, the

cellular automaton model accepted certain patterns and rejected others. The first modification introduced in our work (Brown & Tuszyński 1997) was simply to replace the discrete charges with dipoles as motivated by our earlier discussion in this paper. Some arbitrary torque threshold was required akin to the force threshold of the original model. Despite the relative weakness of dipole interactions, most of the original features of signal transduction were still present in the modified model. The one difference was a shift in the direction of signal propagation from the N–S direction (along the protofilament) to the NW–SE direction (around the helix).

The lattice dynamics were simulated using a standard Monte Carlo technique (Binder 1988). For a given time-step, the energy of the present state and of the opposite state were calculated. Whether a change of state occurs is a random event whose probability is determined by the availability of stored lattice energy, the temperature, and the threshold to reaction. An important additional feature of the model is the removal of the unphysical flip-flop of states which plagued our early attempts at modelling this system. This is removed by forbidding nearest neighbours from both changing states in the same time-step. Thus, when the dipole interaction favours paired dipoles and the current state of the neighbouring dipoles is *up–down*, in the next time-step they may be *up–down* (unchanged), *up–up* or *down–down* but not *down–up*. When a dipole flips, the change in conformational energy is either removed from or added to the lattice at that location. After the evolution step, energy diffuses to neighbouring sites. Our simulations have been carried out with a diffusion constant which is isotropic and small enough that several time-steps are required for localized energy to dissipate. Energy is conserved by the lattice in our current model; none of the energy is returned to the surrounding medium. It is important to note in this context, that the conformational state of tubulin is not coupled to GTP hydrolysis. These two events are separate but GTP hydrolysis can easily induce the conformational change. Some authors have directly linked these two events and on occasion have proposed the opposite causality, that the conformational change of tubulin induces GTP hydrolysis (Chrétien *et al*. 1995).

Consider the interaction of a MT lattice with an action potential, in which a signal can be identified as a particular sequence of antialigned dipoles on an otherwise well-ordered lattice. Associated with this signal or defect is some additional energy which is recovered when the antialigned dipole falls back to its original configuration (see figure 4). The energy may diffuse in all directions so with six nearest neighbours a single defect is not likely to cause neighbouring dipoles to flip since they receive only about a sixth of the required energy. However, a larger defect such as a group of three or more dimers might successfully maintain its integrity. This has been observed in our model; larger defects have larger lifetimes.

The interesting question is: how does the MT respond to the presence of defects on the ordered lattice? A defect could arise by GTP hydrolysis to GDP at the exchangeable site upon addition of an additional tubulin subunit or by the less frequent hydrolysis of GTP at the non-exchangeable site (Semenov 1996). In either case, the energy released might go into changing the conformation of the molecule and its electric dipole. We no longer observe the smooth propagation of signals along the MT unless some additional mechanism is added to the model. There is nothing to direct the propagation of the defect so it takes a random walk about the MT and dissipates its energy. The efficient propagation of signals could be restored by several mechanisms. Such mechanisms include (i) the application of an external

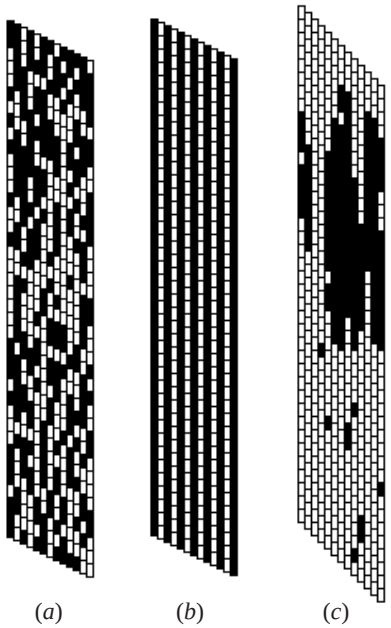

Figure 4. Portions of three MTs are shown. Light boxes represent the 'up' state and dark boxes the 'down' state: (*a*) above the critical temperature of the B-lattice there is disorder; (*b*) below the critical temperature there is spontaneous ordering; (*c*) below the critical temperature of the A-lattice, a large defect (signal) has been introduced. Smaller thermal defects also dot the structure.

field which would bias signal propagation; (ii) an asymmetry in the dipole structure which simply makes it more favourable to propagate in a particular direction; or (iii) mechanical stress if dipoles are coupled to a lattice distortion. The second mechanism could be the result of the bonding between tubulin dimers. If the energy deposited by a dipole flip is comparable with the vibrational energy of a particular bond, it is most likely that this energy would be propagated in that direction. The third mechanism would be the result of a piezoelectric effect, which will be discussed in the next section. There could also be some sort of refractory period which prevents the retrograde propagation of this signal. Since external fields are known to act upon MTs in neurons, the study of these fields and their interaction garners our attention.

As expected, application of a large electric field along the MT causes nearly all dipoles to orientate themselves in the direction which most closely follows that of the field. Thus, a wave of dipole flips is induced along the MT as the field is translated along the MT. This is similar to what happens as an action potential moves along an axon (figure 5). The field is felt by MTs in the vicinity of the cell membrane. Suppose the field is orientated in a direction which favours an alternate ordering for the lattice, such as is the case in MTs, these dipoles will reorientate themselves. The field acts like a pump and stores energy in the dimers. Once the field has passed, these dimers may return to their original configuration and release their stored energy. A weaker field does not actually create defects by changing the orientation of dipoles in the ground state, but may act as a bias and direct the movement of existing defects.

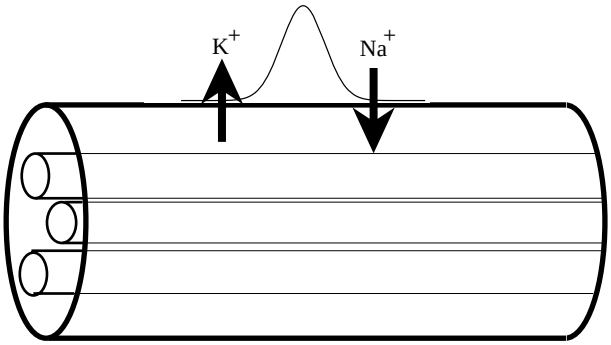

Figure 5. An action potential moving along an axon. There is an electric field caused by the potential difference and a magnetic field caused by the moving charges.

Our simulations have shown this exact behaviour. When the strength of the interacting action potential is large, such as for those MTs in close proximity to the cell membrane, a wave of structural deformation travels parallel to the action potential along the MT. As the wave reaches the MT end, its effects are unclear. Once the MT relaxes to its ground-state structure, energy should once again be available for cellular use if the structural change at the MT terminus is coupled to another cellular structure via a MAP. It might also simply serve as a cellular signal indicating when motor proteins should be activated, MT assembly instructions or any other host of functions associated with the MT terminal which could involve signalling another MT or some part of the axon terminal depending on the location of the individual MAP coupled to an MT.

Once dipole defects have been induced upon the MT lattice, they may propagate along the length of the MT. While some nonlinear effect or external guidance seems to be required, processing of these signals cannot be ruled out. In particular, signal transduction from the distal end of the axon towards the cell body is at least theoretically possible—although unlikely in our opinion. Transduction along the length of the MT is simpler to explain from the proximal end to the distal end though because of the existence of action potentials and the need to explain how a signal may be passed from one MT to another.

Our simulations place a firm limit on the minimum strength of the dipoles required for self-organization. The required dipole strength of about 320 Debye is slightly larger than the value which we estimated for tubulin (as discussed in § 2). In addition, if the angle of the dipole directions of each of tubulin's conformational states is smaller than predicted, an even larger dipole strength would be required. Should the value for tubulin be smaller than this figure, information processing must be ruled out. Energy might still be passed along due to the passage of an action potential, but it would be marked by the highly ordered configuration of the signal upon the random background. The quantity of energy associated with such an entropic change is much smaller than other values mentioned, about $0.06\,\mathrm{kcal\,mol^{-1}}$.

On the topic of information storage in MTs, the simple introduction of thermal energy has removed the possibility of information storage in MT. The energy involved in flipping the conformation of the dimer would have to be significantly larger for

such a form of storage to be possible; not to mention the need for some kind of mechanism which would preserve the integrity of the information.

It is clear that electromagnetic properties are important in cell biology. In addition, the intrinsic polarity of MTs seems to be very important. If it were not so, one would expect the MTs within the axon to be randomly orientated. The question which might be asked is: what is the specific usefulness of a signal which is coupled to the axonal action potential and which travels along MT protofilaments inside the axon? We shall return to provide a plausible answer in the next section.

There has been additional speculation about the role of MAPs in this discussion. Certain MAPs are specific to neuronal MTs (Hirokawa 1991) and their periodic patterns of attachment are somewhat of a paradox (Dustin 1984; Hameroff 1987). Models have attempted to confirm their organizing effect; it seems that due to the interconnections and intraconnections which MAPs make between neuronal MTs, the possibility of parallel information processing is facilitated. In particular, it has been ascertained that the content of an especially important MAP, τ, increases progressively with distance to the soma (Black *et al*. 1996), indicating that its function may not only be a greater stability and assembly but perhaps enhancement of signal transfer properties. We have not pursued this sort of examination to this point; however, if even the most elementary features of MT cellular automata are experimentally corroborated, the importance of electric properties within cells will be clearly demonstrated.

4. Can signal transduction be piezoelectric?

A piezoelectric solid is usually defined as one which generates a voltage proportional to an applied mechanical force, either due to mechanical distortion or displacement of electric dipoles in its crystal lattice. Biological piezoelectricity has been observed directly in bone, DNA, RNA, myosin and collagen (Cope 1975). Piezoelectric materials are usually also pyroelectric, which means that an electric potential is generated by the application of a temperature gradient. Pyroelectricity has been directly observed and measured in tendon, bone and nerve cells. Athenstaedt (1974) was the first to describe microtubules as piezoelectric biopolymers. Piezoelectric properties of biological polymers have been reviewed by Fukada (1983), indicating that almost all biologically relevant macromolecules exhibit piezoelectricity. Included as an example of piezoelectricity was the mechanism of flagellar beating. The pyroelectric effect has also been listed as common among proteins.

Trying to link piezoelectricity with the properties of MTs, the natural starting point is to recall changes taking place in the tubulin dimer upon assembly. GTP bound to tubulin hydrolyses rapidly into GDP, imparting energy to the MT lattice. Furthermore, comparison studies of GTP and its non-hydrolysable analogue, guanylyl-(a,b)-methylene-diphosphonate (GMPCPP), by Hyman *et al*. (1995) indicate that hydrolysis results in an anisotropic deformation of the protein affected such that the non-hydrolysed monomer length is increased by approximately 1.5 Å with the opposite effect taking place in the perpendicular direction.

At neutral pH, the hydrolysis of GTP in solution proceeds according to the chemical reaction

$$\mathrm{GTP}^{4-} + \mathrm{H_20} \rightarrow \mathrm{GDP}^{3-} + \mathrm{HPO}_4^{2-} + \mathrm{H}^{+} + \Delta E, \tag{4.1}$$

where $\Delta E = 8.7\,\mathrm{kcal\,mol^{-1}}$. It is also worth pointing out that the release of a proton in this reaction may play an important role in both dielectric and conductive properties of the cytoplasm.

It appears that the amount of hydrolysis energy changes drastically when GTP is bound to either a single tubulin or a whole microtubule. This was studied by Caplow *et al.* (1994) using GMPCPP, which stabilizes microtubules. In solution, the hydrolysis of GMPCPP releases $5.18\,\mathrm{kcal\,mol^{-1}}$, which is reduced to $3.79\,\mathrm{kcal\,mol^{-1}}$ for GMPCPP attached to a tubulin dimer and to only $0.90\,\mathrm{kcal\,mol^{-1}}$ when GMPCPP is embedded in a microtubule structure. The difference in these numbers is believed to indicate the amount of energy stored in the microtubule structure. However, the last figure also indicates that upon assembly an excess of energy is imparted to the tubulin subunits without an apparent designation. It has been suggested that this excess amount of energy could be used to change protein bond strengths, or cause conformational changes of tubulin, or even be stored as fault energy of the lattice which may be released later through a collapse catastrophe. This energy can conceivably be harnessed in the form of mechanical work, for example, by coupling disassembly to the vesicle or chromosome movement or even providing the coordinated behaviour of the ciliary motor proteins.

Several groups of researchers have developed nonlinear models of energy propagation along a microtubular protofilament. Chou *et al.* (1994) showed that kinks and pulses excited by the energy freed in the GTP hydrolysis can propagate along MTs due to elastic coupling between tubulin dimers. Another model of solitary wave formation was proposed by Sataric *et al.* (1993) and further developed by Trpišova & Tuszyński (1997). The working assumption here is that tubulin dimers possess dipole moments which are spontaneously ordered at physiological temperature. Consequently, solitary waves carrying the free portion of the hydrolysis energy correspond to kink-type domain walls connecting two regions of the protofilament with opposite electric polarizations.

The physical model is based on the lattice Hamiltonian

$$H = \sum_{n=1}^{N}\left[\tfrac{1}{2}M\left(\frac{\mathrm{d}u_n}{\mathrm{d}t}\right)^2 + \tfrac{1}{2}K(u_{n+1}-u_n)^2 - (\tfrac{1}{2}\alpha_2 u_n^2 - \tfrac{1}{4}\alpha_4 u_n^4) - cu_n\right], \qquad (4.2)$$

where u_n represents the projection on the protofilament axis of the dimer's conformational change (coupled to the dipole moment) and the various other terms represent the kinetic energy, the elastic restoring energy and the effective nonlinear potential, while the last term is responsible for the effect of external (electric or pressure) fields on the system of coupled dipoles placed on tubulin molecules, each of mass M.

Furthermore, cellular MTs are embedded in cytosol, which is a liquid ion-filled solution which interacts with the MTs both via electric forces and by providing a viscous medium which damps the motion of tubulin dimers. This latter effect can be modelled by including a frictional force $F_{\mathrm{v}} = -\gamma\partial u_n/\partial t$ in the equation of motion. Taking the continuum limit such that $u_n(t) \to u(x,t)$ yields the following equation of motion for the displacement variable:

$$M\frac{\partial^2 u(x,t)}{\partial t^2} - KR_0^2\frac{\partial^2 u}{\partial x^2} - \alpha_2 u + \alpha_4 u^3 + \gamma\frac{\partial u}{\partial t} - q_{\mathrm{eff}}E = 0. \qquad (4.3)$$

Somewhat surprisingly, an analytic kink-type solution has been found in the form

$$u(\xi) = u_2 + \frac{u_1 - u_2}{1 + \exp[(u_1 - u_2)\xi/\sqrt{2}]}, \tag{4.4}$$

where u_1 and u_2 are the real roots of the cubic polynomial in equation (4.3) and ξ is the moving coordinate $\xi = x - vt$. The sound velocity of MTs was estimated elsewhere as $v = 610\,\mathrm{m\,s^{-1}}$ (Sirenko *et al.* 1996). The damping coefficient γ was estimated to be $\gamma = 5.2 \times 10^{-11}\,\mathrm{kg\,s^{-1}}$ (Trpišova & Tuszyński 1997). Consequently, it was determined that for sufficiently small electric fields E, the velocity of kink propagation, v, is proportional to the electric field strength E and it ranges from $10^{-2}\,\mathrm{m\,s^{-1}}$ for $E \sim 2 \times 10^5\,\mathrm{V\,m^{-1}}$ to $10^{-4}\,\mathrm{m\,s^{-1}}$ for $E \sim 10^2\,\mathrm{V\,m^{-1}}$. These numbers appear to be on the high side of the known MT-associated processes (assembly, disassembly speeds or motor protein velocities) but one should also be aware of the great sensitivity of v to the dielectric constant of the medium and to the presence of impurity potentials along the path of a moving kink which was studied numerically. In fact, for large enough potential wells or bumps, kink motion can be stopped altogether (Trpišova & Tuszyński 1997). The question arises as to what happens to the energy transported by a kink excitation. We may speculate that it is transferred to another MT via an attached MAP or that it could play an important role in the movement of a motor protein. Another possibility is that it creates a domain wall between two portions of a MT protofilament in which tubulin dimers are in different dipolar and conformational states. This could be an important factor in developing microscopic models of dynamic instability.

Models have also been developed which explicitly account for the coupling between tubulin dipoles and the conformational (elastic) degrees of freedom (Trpišova & Tuszyński 1997). A phenomenological Landau–Ginzburg free-energy expansion has been formulated for the entire stable MT in terms of the total dielectric polarization P and the mechanical stress σ which is coupled to P via the piezoelectric effect. The free energy then takes the form

$$F = F_0 + \tfrac{1}{2}AP^2 - \tfrac{1}{4}BP^4 + \tfrac{1}{6}CP^6 - \tfrac{1}{2}e\sigma P^2 + \tfrac{1}{2}D(\partial P/\partial x)^2 - \tfrac{1}{2}s_0\sigma^2. \tag{4.5}$$

The time-evolution of the order parameter (net polarization P) is given by the time-dependent Landau–Ginzburg equation

$$\frac{\partial P}{\partial t} = -\Gamma\frac{\delta F}{\delta P}, \tag{4.6}$$

where Γ is the phenomenological Landau–Khalatnikov damping coefficient providing a time-scale for relaxation processes. In our case this equation takes the form

$$\frac{\partial P}{\partial t} = \Gamma(AP - BP^3 + CP^5 - e\sigma P) + \Gamma D\frac{\partial^2 P}{\partial x^2}, \tag{4.7}$$

and it is coupled to the stress–stain relationship

$$\epsilon = \frac{\partial u}{\partial x} = -\frac{\partial F}{\partial \sigma} = \tfrac{1}{2}eP^2 + s_0\sigma. \tag{4.8}$$

These two equations can be effectively decoupled by taking note of the fact that ϵ also satisfies the wave equation

$$\rho\frac{\partial^2 \epsilon}{\partial t^2} = \frac{\partial^2 \sigma}{\partial x^2}, \tag{4.9}$$

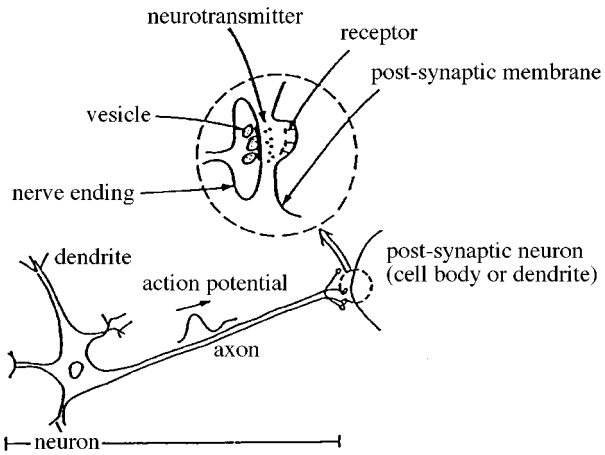

Figure 6. Schematic diagram of a neuron. Inset shows a neuron–neuron synapse.

which results in an effective equation for travelling polarization waves:

$$\Gamma D\frac{\mathrm{d}^2P}{\mathrm{d}\xi^2} + v\frac{\mathrm{d}P}{\mathrm{d}\xi} - \Gamma(AP - \tilde{B}P^3 + CP^5) = 0, \tag{4.10}$$

where $\xi = x - vt$ and $\tilde{B}$ is a 'dressed' expansion coefficient. This model was also studied numerically (Trpišova & Tuszyński 1997). The polarization wave describes a localized nucleation which moves with a constant velocity along a protofilament. Above the transition temperature for the paraelectric phase to the ferroelectric phase transition, which could be in the physiological range for most of electric field values, collisions of coupled $P - \sigma$ waves with an impurity potential result in the formation of a constant stress along the MT. This could lead to a build-up of fault energy and a subsequent disassembly. This model has also been analysed in the presence of an external pressure applied to a MT. Several effects have been seen in these latter simulations: (a) a decrease in the kink's propagation velocity down to the $\mu\mathrm{m\ s}^{-1}$ range when hydrostatic pressures are applied; (b) a dielectric phase transition which may be induced by applying pressure to the microtubule. Some numerical estimates were made and compared to the observed values of Young's modulus, Y, in the protofilament direction where $Y = 0.5 \times 10^9\ \mathrm{N\ m}^{-2}$ has been reported (Mickey & Howard 1995). Our estimate of the longitudinal stresses which accompany the propagation of a kink along the protofilament is $\sigma = 10^6\ \mathrm{N\ m}^{-2}$.

We conclude that nonlinear models of energy transfer along microtubules provide a conceptual link between the excess energy released in GTP hydrolysis directly after tubulin assembly and the various processes associated with the functions of MTs, especially motor protein motion, chromosome segregation forces and disassembly velocities.

In the context of neuronal MT functioning, the piezoelectric properties of MTs may offer a very attractive connection between the internal structure of the axon and its function, namely synaptic communication (see figure 6). The first link that may be established has to do with the control mechanism of exocytosis of neurotransmitters. Segel & Parnas (1991) argued convincingly that the Ca^{2+} wave in the extracellular medium is insufficient to explain quantitatively the sensitivity of the neurotransmitter release mechanism to depolarization at the release site. They pro-

posed the existence of an additional polarization mechanism which, in our opinion, may well be the coupled polarization–stress wave propagating along the MT that accompanies the action potential motion.

The other possible link involves the architecture of neurons which number 10^{10} in the brain and, through sensory stimulation, each of them develops an extensive dendrite tree with a signal target made up of 10^3–10^5 other neurons. These nearest-neighbour neurons are connected via synapses mentioned above. In some neurons over 99% of their surface area is accounted for in the dendritic tree. The functioning of the dendritic trees consumes up to 60% of the brain's energy (Mel 1994). How can individual synaptic connections within such a tree be maintained or abandoned depending on their usefulness or lack thereof, respectively? As argued earlier, when the action potential travels along the axon it affects the MTs dipoles such that the GTP energy that MTs constantly receive from the cell is smoothly transferred from one MT end to the other. We found that the propagation of dipole kinks is feasible even at velocities in the 1–20 $\mathrm{m\,s^{-1}}$ range, roughly corresponding to the action potential velocity of propagation. We also stressed here that there is electroconformational coupling in MTs. That means that stable MTs have straight protofilaments (tense). However, unstable MTs have protofilaments which curve away from the axis (relaxed). Instability comes about when too much energy is delivered to MTs and it is stored in them without an outlet. For example, it can get stored in the form of mechanical fault energy, causing crystal lattice defects. Therefore, when action potential signals are very infrequent, MTs may have difficulty getting rid of excess energy, so they become curved or full of defects. This would eventually lead to several possible modes of MT degeneration: (a) falling apart of the middle part if, for example, MAPs are also weakened. This could be the case with Alzheimer's disease where τ protein does not clamp onto the scaffold structure of MT bundles. The consequence would be that axons themselves would be affected and synaptic connections destroyed. (b) If they don't fall apart, they may still experience negative effects due to piezoelectricity. The MTs would, for example, build unidirectional stress that could curve their axis away from the straight line of the synaptic connection. The result could be the two ends on the opposite sides of the synapse moving away from each other. They may eventually find other new partners with which to pair up within the dendritic tree. The latter possibility would explain why synaptic connections are eliminated if they are not used sufficiently.

5. Can MTs conduct electrical currents?

Conjectures regarding the possibility of electrical conduction in biological polymers were originated by Szent-Györgyi in the 1940s and elaborated on later by Pullman & Pullman (1962) who pointed to the role of delocalized π-electrons in biochemical compounds. They predicted the existence of both extrinsic and intrinsic semiconducting properties of protein polymers. Pethig (1982) performed band-structure calculations for some simple protein polymers and found the band gap to be of the order of 6.0 eV with a band width of approximately 1.5 eV, indicating that they would most likely be insulators unless disorder in the structure was introduced to drastically reduce the energy gap.

Table 1. *Potential functions of molecular complexes as bioelectronic materials*

function	molecular complexes

Table 2. *Abundance of n-type and p-type amino acids in α- and β-tubulin*

amino acid	electronic type	% in α-tu	% in β-tu
Asp	*n*	10.3	11.1
Lys	*p*	3.9	3.8

A general discussion regarding the potential for bioelectronic devices based on molecular complexes predicts a range of fascinating possibilities, as shown in table 1 following Tsong (1989) and Wangermann (1980).

Based on table 1, one might expect MTs under suitable conditions to provide wiring for the transmission of electrical pulses (e.g. inside axons or as mitotic spindle apparatus) or perform input/output functions using electromagnetic signals if they can be photosensitive under special circumstances (as is believed to be the case in centrioles and in the phototaxis mechanism of cilia). A recent paper (Insinna *et al*. 1996) has given an exhaustive account of the accumulated evidence for the participation of MTs in electrical conduction within the cell via electron or proton transfer mechanisms which can be coupled with GTP hydrolysis. In fact, Koruga & Simić-Krstic (1990) pointed out that semiconducting properties of MTs are to be expected simply on the basis of the tubulin's constitution from the linear *n*-type (Asp) or *p*-type (Lys) amino acids. This is shown in table 2 and would indicate that there is approximately three times more *n*-type than *p*-type amino acids based on the number of amino acid residues and, hence, one expects an excess of mobile electrons to exist.

Using the above premise we have undertaken to examine the issue of conductivity in a theoretical detail. For comparison purposes, we assumed the presence of just

two conduction electrons for each tubulin dimer, leading to the conduction electron density of $n_0 = 10^{19}$ cm^{-3}. This may be an overestimation, since in comparison with other materials, this value is higher than typical semiconductor concentrations, usually 10^{13}–10^{17} cm^{-3}, but is much less than typical metals which have a conduction electron density of 10^{22}–10^{23} cm^{-3}. However, the electrons are expected to have relatively low mobilities unless they are excited from the ground-state configuration. The excitation energy is a function of both the number of electrons within the protofilament and its size. Suppose that the mobility of excited electrons is at least similar to the mobility of electrons within semiconductors such as Si, where the electron mobility, μ_e, is about 1300 cm^2 V^{-1} s^{-1}. The conductivity, σ, is given in a semiclassical model by

$$\sigma = ne\mu_e, \tag{5.1}$$

where n is the conduction electron density and e is the electron charge. The electron density is given as

$$n = n_0 e^{-\Delta/kT}, \tag{5.2}$$

where n_0 represents the total number of electrons per cm^3. If we assume that the gap between valence and conduction bands, Δ, is about eV, which is the small barrier height in our model, then at physiological temperature, some of the carriers will be thermally excited and should be available to conduct. Applying equation (5.1), a conductivity of about 10^{-2} is expected for the protofilament:

$$\sigma \sim (10^{25} e^{-0.40/0.026})(1.6 \times 10^{-19})(0.13) \sim 0.04\,\Omega^{-1}\,\mathrm{m}^{-1}. \tag{5.3}$$

However, if the hybridization of electronic orbitals lowers the gap to a value closer to zero, the expected conductivity would be significantly higher:

$$\sigma \sim (10^{25})(1.6 \times 10^{-19})(0.13) \sim 2 \times 10^5\,\Omega^{-1}\,\mathrm{m}^{-1}. \tag{5.4}$$

This is an upper limit on conduction in MTs due to the optimistic choice of electron mobility. This value should be compared to values in excess of 10^8 for copper and other good conductors, 10^7 for lesser conductors and semimetals. Typical semiconductors such as Si and Ge have intrinsic conductivities of 10^{-3} to 10^{+1} at room temperature, but when heavily doped the conductivity may rise to between 10^4 and 10^5.

In subsequent quantum-mechanical calculations each protofilament is pictured as a chain of periodically distributed potential double wells whose two sites represent two binding sites, one each on each monomer between which the electron may hop (figure 7). We can estimate the relevant parameters of the well depth and the well width from kinetic studies and with a knowledge of the molecule's overall geometry. Once the bound states and their energies are known for this system, this knowledge may be applied to a second-quantization scheme. Hopping along the protofilament by electrons presumably has an energy comparable to the binding energy. We have estimated 0.4 eV for intradimer hopping. Thus, a single hydrolysis event is not expected to cause disassembly.

The results for the single-electron eigenstates of a double quantum well may be found in a rather straightforward manner using a transfer matrix method for the eigenfunctions of the time-independent one-dimensional Schrödinger equation:

$$\hat{H}\psi = \frac{\hat{p}^2}{2m}\psi + \hat{V}\psi = E\psi. \tag{5.5}$$

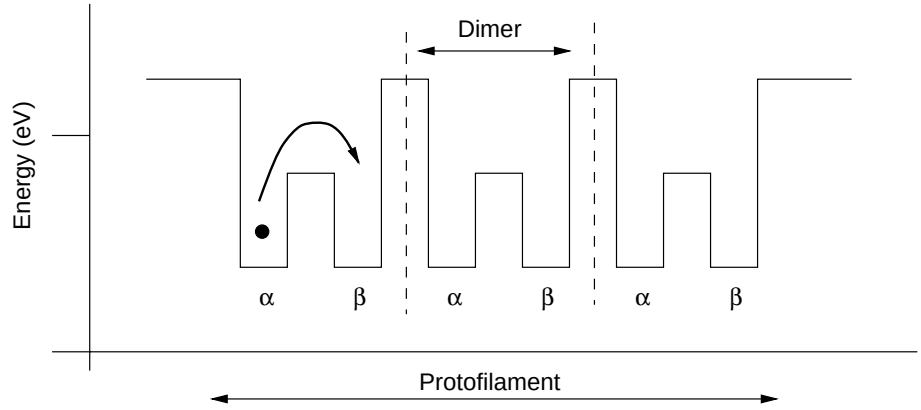

Figure 7. Model of the MT protofilament with a binding site located on each α-monomer and β-monomer.

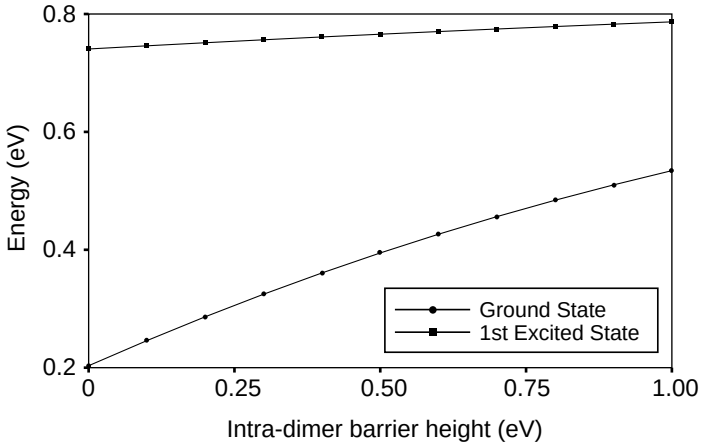

Figure 8. Variation of the bound-state energies of a dimer with the central barrier height.

In figure 8 we show the results of our numerical solutions for the two bound states of a single dimer (ground and excited) as a function of the energy of the central potential barrier. One may then calculate the energy of such states for a sequence of n such dimers. This leads to the development of bands as hybrid orbitals stretch across the polymer. Roughly speaking, one band is of hybridized symmetric orbitals and the high-lying band of hybridized antisymmetric orbitals (figure 9). The separation of the two bands and the spread of each individual band is important. They determine the values of the parameters which shall be used in the tight-binding Hubbard model which shall be used to model the polymer. The Hubbard model is the simplest second-quantized model to capture all of the essential features of a real system of interacting particles (Lieb 1995). In this model, the particles, i.e. electrons, are fundamental excitations described by the Hamiltonian

$$\hat{H} = \sum_{i,\sigma} \epsilon_i \hat{C}^{\dagger}_{i\sigma} \hat{C}_{i\sigma} + \sum_{i \neq j,\sigma} t_{ij} \hat{C}^{\dagger}_{i\sigma} \hat{C}_{j\sigma} + \sum_{i} U_i \hat{C}^{\dagger}_{i\uparrow} \hat{C}_{i\uparrow} \hat{C}^{\dagger}_{i\downarrow} \hat{C}_{i\downarrow}, \tag{5.6}$$

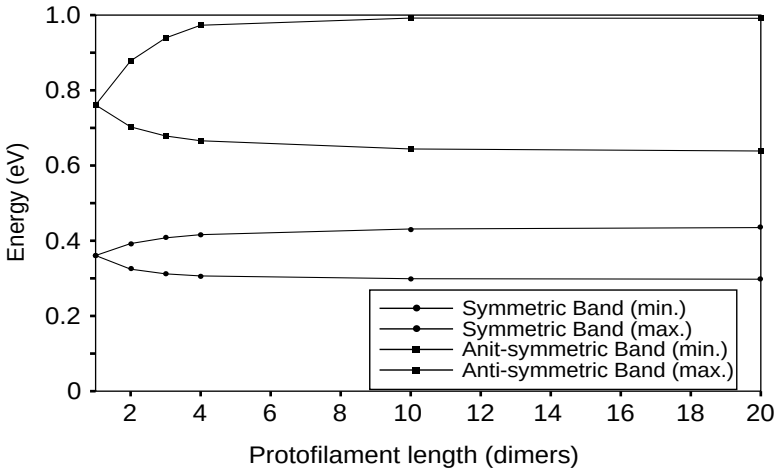

Figure 9. Band formation as the protofilament is lengthened.

where the operators $\hat{C}^{\dagger}_{i\sigma}$ and $\hat{C}_{i\sigma}$ are the usual fermion creation and annihilation operators, and where $i = 1, \ldots, 2n$ represent the two sites on each of the n dimers. The ϵ_i represent the potential energy at each site and the kinetic terms t_{ij} account for hopping from one site to another. We are accounting for nearest-neighbour interactions in the model, but there are two different kinds of interactions depending on whether an electron hops within a dimer, or between dimers. Hence, this kinetic parameter has two different values along the chain: t_{d} or t_{l}, respectively. The final term accounts for electron–electron repulsion now that we have gone to a many-electron system. In our simple model, this is limited to an on-site interaction. To this point, we have made each of the site energies equivalent ($\epsilon_i = \epsilon$); since the Hamiltonian conserves the particle number, this term may be ignored as a trivial constant. We have also made the electron repulsion the same at all sites ($U_i = U$). We expect $U = 2.0\,\mathrm{eV}$, which is the energy associated with two bare electrons lying about 0.7 nm apart. This choice seems reasonable within a well of width 2.0 nm.

On comparison with figure 9, which shows the band formation in the quantum well formulation, we can assign values to t_{d} and t_{l}. The two bands are separated by about 0.40 eV, so $t_{\mathrm{d}} \approx 0.20\,\mathrm{eV}$ and using the bottom band to estimate t_{l}, it widens until it is about 0.10 eV thick, so $t_{\mathrm{l}} \approx 0.05\,\mathrm{eV}$.

Suppose an external field is applied; we want the conductivity that is the response to the total electric field in the solid. This conductivity takes into account all of the currents induced by the external fields which create their own fields. In other words, we are looking for the self-consistent conductivity:

$$J_\alpha(r,t) = \sum_\beta \sigma_{\alpha\beta}(q,\omega) E_\beta \mathrm{e}^{\mathrm{i}qr - \mathrm{i}\omega t}. \tag{5.7}$$

This tensor, $\sigma_{\alpha\beta}$, is the conductivity we are looking for which relates the macroscopic electric field to the currents of the system which may be measured.

In terms of the Hamiltonian's eigenstates $|n\rangle$ and frequency dependence, conduc-

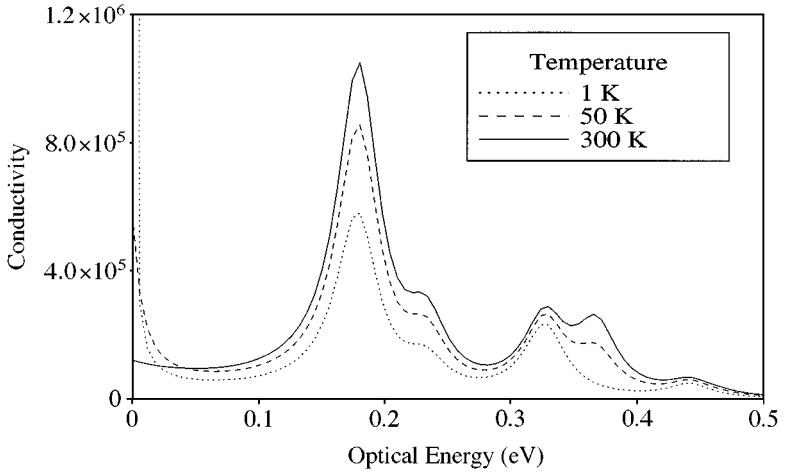

Figure 10. Conductivity is plotted as a function of the optical energy for a short protofilament. The spectrum changes as the temperature is raised. Note the single peak which becomes a double peak close to 0.35 eV.

tivity is expressed as (Mahan 1981)

$$\sigma(\omega) = \frac{\pi}{Z}\frac{1}{\omega}\sum_{m,n}(\mathrm{e}^{-\beta E_m} - \mathrm{e}^{-\beta E_n})|\langle n|j_\alpha|m\rangle|^2\delta(\omega - (E_n - E_m)). \tag{5.8}$$

Modelling the protofilament as a Hubbard chain, the eigenstates are found by exact diagonalization techniques and these are then used as input for the Kubo model of electrical conduction. The δ-functions of the last expression are replaced with Lorentzians of finite width as follows:

$$\delta(\omega - a) \to \frac{1}{\pi}\frac{\epsilon}{(\omega - a)^2 + \epsilon^2}. \tag{5.9}$$

This approximates relaxation processes and the degree of experimental precision. In addition, the temperature which we have chosen, 300 K, is approximately physiological temperature since conductivity is temperature dependent. In the Hubbard chain model of the MT protofilament at 0 K, there is conduction only at the frequencies which are equal to jumps between the ground state and each of the excited states. As the temperature is raised, the excited states may themselves be populated. Consequently, more peaks are observed as transitions between excited states may also contribute to the overall conduction (figure 10). Now, we are interested not only in the peak values of conductivity and how it may vary with the protofilament length, but particularly also in how the conductivity varies with the number of charge carriers. The tubulin which forms protofilaments is composed of two dimers, α and β. Each of these monomers has several isotypes. MTs localized in different places within the body differ in their isotypic composition. The isotypic composition may also change in a given location as a function of the cell cycle (Moskowitz & Oblinger 1995). These isotypes of α- and β-tubulin have different regulatory roles and differ almost superficially along certain side chains. That is, these changes do not seem to affect the MT structure, or cause the assembly properties to change much, but may be of utmost importance to the conducting properties of MTs by introducing electron or hole doping into this picture. For example, distinguishable β-tubulin

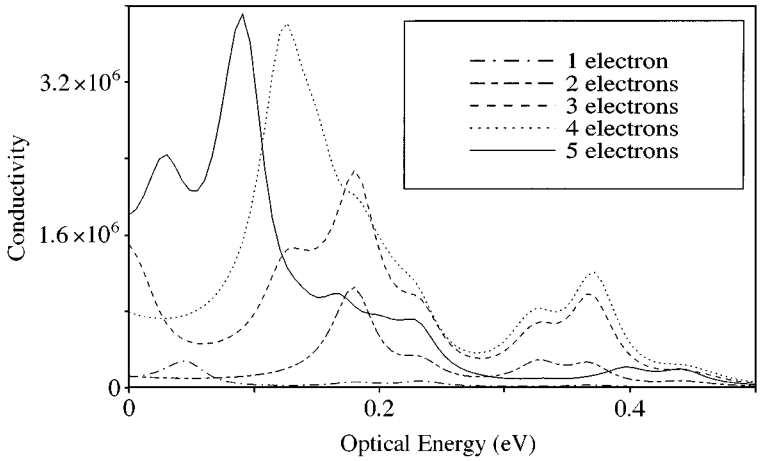

Figure 11. Conductivity is plotted as a function of the carrier concentration.

isotypes have been found to be differentially distributed among the peripheral and central axoplasm. In addition to the interactions these specific isotypes may have with MAPs, certain amino acid residues on these side chains may be hydrolysed or glutamylated to varying extents and this modification may provide additional (or fewer) charge carriers. Consequently, we hope to find the best carrier concentration for conduction which might dictate a specific ratio between the levels of the various tubulin isotypes which should be incorporated into MTs.

Typical MTs in which we are interested span 1000 or more subunits. Such objects which are of the order of a few microns long could be experimentally studied. However, these cannot be tackled theoretically using the present techniques because of computational limitations related to the diagonalization and multiplication of large matrices. As a result, the work is being carried out on short filaments of a few dimers length.

Figure 11 displays a sample of conductivity curves in a protofilament of three dimers with various numbers of electrons. The single-electron case is expected to differ from the others since there is obviously no Coulomb repulsion in such a system and it turns out to have the lowest conductivity. Conductivity seems to increase as electrons are added to the system until it is precisely half full. The situation at half-filling is somewhat of a puzzle but we surmise that the low conduction is the result of more localized electrons at that specific fractional filling. One electron may be confined to each monomer and Coulomb repulsion avoided. However, the movement of any electron ruins this energetically stable state. At other fractional fillings, electron movement is possible without disturbing the energy of the system similarly.

Now, while our results are preliminary to this point, it is interesting to attempt to make predictions for the entire MT. This involves extending the Hubbard model to a second dimension. Hopping is allowed in a second direction about the helix in addition to along the protofilament. This adds several complications; first, there are many more states in a model of this system. Consequently, the matrix which must be diagonalized is much larger. As the density of states is much greater in the MT, one may expect that the conductivity will also be higher—that is in an MT of the

same length as a protofilament. Physically, one might rationalize this simply. There are a larger number of paths available for the electron to move from one end to the other; consequently, one would expect the resistivity to be lower—conductivity, which is the inverse of the resistivity would therefore be larger. In addition, the close spacing of energy levels implies that there should be more peaks at lower energies corresponding to the level spacing. Consequently, conduction along the MT should be greatly improved over protofilament conduction, especially at lower frequencies. The added complication is that conductivity becomes a tensor with the introduction of the additional protofilaments in the MT. In axonal MTs the field is expected to be radial while it would be conduction along the MT which is of interest.

There are also questions of conductivity if the charge carriers are not electrons but hydrogen ions (H^+). Proton hopping may be modelled in a similar way but protons have a much larger mass than do electrons. The higher mass means that energy levels are more closely spaced; again this probably means higher conduction at lower frequencies, but for our choice of parameters for the double quantum well, no bound states exist. Thus, binding of the protons must be somewhat larger. This would therefore have a negative effect on the conductivity. No meaningful statement can be made on protonic versus electronic conduction without further investigation.

6. Can MTs function as quantum computers?

It is a very attractive proposition to consider protein assemblies performing the task of a computer. Protein-based computers could operate 10^3 times faster than semiconductor-based computers. Furthermore, they could be designed one atom at a time, offer parallel processing architecture, three-dimensional data storage and a number of other features. In fact, a case has recently been made (Bray 1995) to view the already existing intracellular assemblies of proteins as computational elements which in essence constitute the cell's equivalent of a nervous system. Many aspects of cell behaviour display capacity for information processing independent of the genome and are controlled by proteins, e.g. motility. Bray (1995) maintains that GTP supply is the key element as it activates proteins while GDP deactivates them, which is consistent with our earlier discussions. Protein circuits in cells include hundreds of different channels, receptors and kinases which together monitor and respond to internal and external environmental stimuli. Can MTs be viewed as part of such circuitry? If so, how can their functioning as information processors be accomplished?

Some evidence links the cytoskeleton with information processing and cognitive function. Production of tubulin, the MT subunit and MT activities is correlated with peak learning, memory and experience in baby chick brains. When baby rats begin their critical learning phase for the visual system (when they first open their eyes), neurons in the visual cortex begin producing vast quantities of tubulin (Cronly-Dillon 1974). Tubulin production is drastically reduced when the critical learning phase is over (when the rats are 35 days old). Bensimon & Chernat (1991) found that selective destruction of brain MTs by the drug colchicine caused cognitive defects in learning and memory which mimic the clinical symptoms of Alzheimer's disease, in which the cytoskeleton becomes entangled. Further suggestion for cytoskeleton computation and/or information storage stems from the spatial distribution of discrete sites (or states) in the cytoskeleton. For example, tubulin subunits in closely arrayed MTs have a density of about $10^{17}\,\mathrm{cm}^{-3}$, which is very close to the theoretical limit for

Table 3. *Characteristic physical quantities describing MTs and their environment.*

tubulin dimer mass	110 kDa $\simeq 10^{-21}$ kg
dielectric constant	5–10
mobile charge	1–2e^- $\simeq 10^{-19}$ C
electric field strengths

charge in axon	1–2 m s^{-1}
motor protein	0.5–2 μm s^{-1}
light wavelength (λ)	400–700 nm

charge separation (Gutmann 1986). Thus the cytoskeleton polymers have maximal density for information representation by charge, and the capacity for dynamically coupling that information to mechanical energy and chemical events via cooperative dipole states.

Recently, Hameroff & Penrose (1996) advanced the hypothesis which in a nutshell states that MTs are biological quantum computers providing a molecular substrate for the emergence of consciousness. In their model, called orchestrated objective reduction, or Orch OR for short, MTs' tubulin dimers are viewed as existing in a quantum superposition state which may self-collapse (hence the term objective reduction) upon reaching a quantum gravity threshold. The resultant wavefunction collapse event was linked by these authors (Hameroff & Penrose 1996) with numerous synaptic/neural functions and, in particular, with the formation of a thought process. While the Orch OR hypothesis cannot be proved or disproved at present, we will try to assess its validity within the context of the physical properties of MTs presented earlier in the paper.

In this connection, it is worthwhile recalling several thoughts on the topic of physics, computation and biology verbalized not too long ago by Hopfield (1991). First, he stated that: 'the human brain is the most mysterious and complex of these biological computational systems'—which would perhaps give legitimacy to searches for very exotic explanations of its functioning. However, he also said that 'contrary to the expectations of a long history of ill-prepared physicists approaching biology, there is absolutely no indication that quantum mechanics plays a significant role in biology'. He emphasized the role of complexity in biological systems where a change in a meaningful bit of information will have an effect on macroscopic behaviour of a living system. This is not so in physical systems.

Returning now to the issue of MTs, we wish to summarize the key physical parameters describing these protein polymers and their cellular environment (cytosol). These are shown in table 3. Based on these numbers and our earlier discussions throughout this paper we can put together a summary of energy-scale estimates for the processes that have been either observed or postulated to play a role in the functioning of MTs. This is summarized in table 4. For better clarity, this information is illustrated graphically in figure 12. What are the general conclusions we can draw regarding these processes? First of all, for all intents and puposes, gravitational effects

Table 4. *Estimates of energy scales*

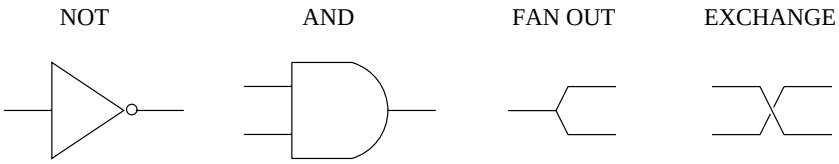

Figure 13. Basic function elements for a quantum computer.

should be entirely overshadowed by the remaining processes. Secondly, it is likely that electrons and motor proteins are guided by electric fields in order to overcome thermal noise. There is also substantial scope for cross-effects between different types of interactions, e.g. (a) photoconduction; (b) mechano-chemical coupling; (c) chemically triggered dipole reversals; (d) electromechanical; and (e) a possible induction of magnetic fields by electric currents. Turning now specifically to the Orch OR model of Hameroff & Penrose (1996), the chief difficulties of reconciling their proposal with our analysis can be listed as follows.

(i) The size of the tubulin protein is probably too large to make quantum effects easily sustainable.

(ii) Conformational effects are expected to involve distances *ca.* 10Å, which, again, are larger than those called for in the Orch OR model.

(iii) Physiological (room) temperature requirements make it extremely difficult to defend the use of the quantum regime due to the persistence of thermal noise.

(iv) A possible effect mediating against thermal fluctuations might be some form of screening of tubulin from the cell's 'noisy' environment. As discussed earlier, MTs are extremely sensitive to their environment, especially ionic and microelement concentrations. Hence, we doubt that MTs can be shielded from their environment.

(v) It appears that the two (or possibly more) conformational states of tubulin are separated by a sizeable potential barrier which again requires an external stimulus (such as GTP hydrolysis) to overcome it.

(vi) The calculations of the 500 ms preconscious processing time may be directly related to the action potential's travel time along the axon plus the refractory lag time in synaptic transmission, rather than to the quantum collapse time.

We, therefore, believe that the Orch OR model is not tenable for MT functioning. Is there still another possibility, that MTs are quantum computational devices? Feynmann (1986) presented a very lucid analysis of a quantum-mechanical computer which basically deals with a physical system composed of two-state units. The four key operations are shown in figure 13. Feynmann translated the action of these logical elements into the language of second quantization and found corresponding Hamiltonian terms. Recently, an application of these concepts to a system of quantum dots was made (Brum & Hawrylak 1997) and it was demonstrated that a quantum exclusive-OR gate can be made. The Hamiltonian relevant in this case was of the Hubbard type and it represents the same class of problems as the electronic conduction model in a MT presented in § 5. The full set of quantum functions shown in figure 13 can be realized through the coupling provided by MAPs with the proviso that there exists a mechanism maintaining the two-level structure of mobile electronic states.

Discussion

P. Marcer (*BCS Cybernetic Machine Group, Keynsham, UK*). I believe that no one, with the exception of Professor Zoller, has touched on the fact that computations must concern UNIT WIRE and EXCHANGE primitives as well as ANDs and ORs (as was pointed out by Feynman), or their quantum equivalents. Perhaps, therefore, this is a basic function of the microtubule, particularly as it has been shown that such tubules have two fundamental phases, one conductive and one semiconductive. This would support the Penrose–Hameroff consciousness postulate, which states that this phase transition is pertinent to allowing the transmitted signals to rise to a higher 'quantum' level of awareness via conduction rather than semiconduction until the brain becomes consciously rather than unconsciously aware. The ubiquitous nature of microtubules would also be consonant with this function as a unit wire, as is the case with current technology.

J. A. Tuszyński. I agree with the first part of the statement. We do indeed maintain that microtubules can be suitable semiconducting devices. As much as we have tried to open-mindedly examine, however, we have not found any empirical basis for viewing microtubules quantum mechanically. They certainly play a significant role in the functioning of the brain, but linking them with the emergence of consciousness is in our view somewhat premature.

Institute of Radio Engineering and Electronics, Academy of Sciences of Czech Republic, Chaberská 57, 18251 Prague 8, Czech Republic

Received 15 November 1997; revised 4 March 1998; accepted 9 March 1998

Abstract

Living cells are organized by the cytoskeleton with a fundamental role of microtubules. The mechanisms of organization are largely unknown. We analyze the vibrations in the microtubules which are polar and are accompanied by polarization waves. Oscillating electric field generated around microtubules can be as high as 10^5 Vm^{-1} and may have an important role in information system and mass transport in living cells. Energy from hydrolysis of guanosine triphosphate (GTP) stored in microtubules can excite the vibrations above thermodynamic equilibrium level. © 1998 Elsevier Science S.A. All rights reserved.

Keywords: Molecular biophysics; Vibration states in microtubules; Bioelectric phenomena; Electric field of microtubules; Hydrolysis of GTP; Condensation of energy

1. Introduction

Living cells are structurally and dynamically organized by protein polymer network which is called cytoskeleton. The cytoskeleton is a highly dynamic structure which reorganizes continually as the cell changes its shape, divides, and responds to its environment. The essential data and description of the cytoskeleton, its components, and function are given in the book by Alberts et al. [1]. The cytoskeleton is composed of intermediate filaments, of actin filaments (which are also called microfilaments), and of microtubules. The filaments and the microtubules are connected to a large variety of accessory proteins and form a three dimensional network in the cell. The cytoskeleton is connected to transmembrane proteins. The cytoskeleton enables transport of molecules, structures, and organelles (by means of motor proteins), receives signals from cellular environment through the membrane proteins, and has an important role in the mitotic spindle.

The microtubules are the main organizers of the cytoskeleton. They are formed by cylindrical structures (hollow tubes with the outer and the inner diameters of about 25 nm and 17 nm, respectively) composed of 13 (or 14) protofilaments which are one dimensional chains of heterodimer tubulin molecules. The structure of the microtubules was disclosed by Amos and Klug [2]—Fig. 1a. A tubulin molecule is formed by two globular proteins—α- and β-tubulins; each of them has the relative molecular mass of about 55,000 ('molecular weight' in daltons) but the masses are not equal. Conformation of the heterodimer molecule can be changed from the α state (non tilted) to the β state (tilted by 29° from the microtubule axis)—Fig. 1b. The heterodimer molecule is an electric dipole [3–5] (18 Ca^{2+} ions are bound in the β-monomer). Therefore, the microtubules are polar structures with the plus end (fast growing) and the minus end (slow growing) embedded in the centrosome—a centre of the cytoskeleton. Polarity of the microtubules are closely connected with their function [6,7]. The function of the microtubules can be regulated by phosphorylation and dephosphorylation of microtubule-associated tau protein [8].

The dynamics of the microtubules is one of the most prominent features. The microtubules are capable of rapid polymerization and depolymerization [9] which enables exchange of the subunits between soluble and polymer pools. The microtubules grow toward the cell periphery and then shrink back toward the centrosome. They may shrink partially and grow again or they may disappear to be replaced by new microtubules. This process is called the dynamic instability. The treadmilling (i.e. addition of the tubulin subunits at the plus end and removal of the tubulin subunits at the minus end at an identical rate)

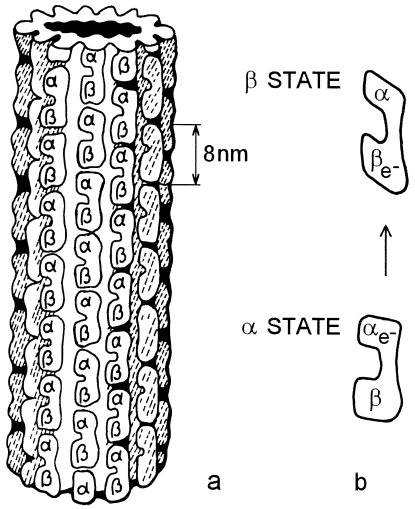

Fig. 1. A schematic picture of a microtubule (a), and of conformation change of a tubulin heterodimer from the α to the β state (b). After Refs. [2,4].

appears if both the ends of a microtubule are exposed [1]. Newly polymerized subunits (heterodimer molecules) contain energy rich nucleotide guanosine triphosphate (GTP). After polymerization the guanosine triphospate molecules bound to the β-tubulins are hydrolyzed to the guanosine diphosphate (GDP). The significance of the GTP in microtubule dynamics is analysed in Refs. [10–12]. The growth of a microtubule can continue if an energy rich cap at its plus end is maintained, i.e. if the GTP's in the cap subunits are not hydrolyzed to the GDP's. The microtubule dynamics may depend on kinetochores too [13].

The microtubules depolymerize and repolymerize continually in animal cells. The majority of the microtubules can incorporate new subunits within 20–30 min although complete exchange of the subunits in a cell can be achieved within 1 h [14]. The half-life of an individual microtubule is of about 10 min [1]. Depolymerization removes the subunits with the GDP and repolymerization adds the energy rich subunits with the GTP to a microtubule. The hydrolysis energy is not used for polymerization. The majority of the hydrolysis energy is stored in the microtubule [15]. The mechanism of depolymerization and repolymerization provides continual supply of energy into the microtubule structures in a cell and signifies that the total energy storage is renewed within one hour.

The mechanisms of the cytoskeleton activity are still not well understood. The cytoskeleton exerts forces and generates movements without any major chemical changes [1]. A physical mechanism is probably responsible for the cytoskeleton function. Vibrations in the microtubules can be one of possible mechanisms as follows from the analysis given in Ref. [16]. As the tubulin heterodimers are polar the vibrations generate an oscillating electric field. The vibrations can be excited by the energy released from the hydrolysis of the GTP. The excited vibrations may be far from thermodynamic equilibrium and need not be of random nature. We will analyze the properties of the electric field generated by the microtubules and its possible effects on ordering and on the mass transport in living cells.

2. Vibrations in the microtubules

A part of the microtubule composed of protofilaments is shown in Fig. 1a. Fig. 1b shows the tubulin heterodimer molecule in the α and in the β states. The globular tubulins in a protofilament may be considered as mass units in a chain with translation symmetry. These units have internal vibrations (exerted by atoms and by parts of the tubulins) and external vibrations in the chain (i.e. the vibrations exerted by each tubulin as a whole). On account of translation symmetry the external vibrations may be analysed using a method which is similar to that employed in the solid state physics [17]. Nevertheless, we have to point out certain differences between crystalline solids with translation symmetry and the microtubules. The 'diameters' of atoms in solids are of about 0.1 nm and the distances between their centres are about twice or three times greater. The 'diameters' of the tubulins are of about 4 nm; they are only slightly smaller than the distances between their centres of mass. Atoms in a lattice are not rigid but in comparison with them the tubulin globules are highly elastic particles. The external vibrations will be analyzed without including dynamic deformations of tubulin globules.

Fig. 2 shows a scheme of the one-dimensional chain of particles. The circles denote the centres of mass of tubulins in equilibrium positions, the black spots show the theoretical equidistant control points (the distance between them is a), Δ_1, Δ_2 are distances of tubulins from the corresponding control points, m_1, m_2 are masses of tubulins, and f_1, f_2 are the elastic force constants which need not be equal.

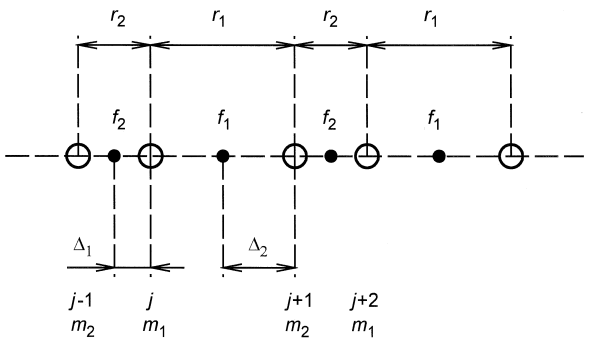

Fig. 2. Translation symmetry in a protofilament.

The interactions between the closest neighbours will be assumed. The dispersion relation is given by [16]

$$\omega_{\pm}^2 = \frac{(f_1+f_2)(m_1+m_2)}{2m_1m_2} \pm \sqrt{\left[\frac{(f_1+f_2)(m_1+m_2)}{2m_1m_2}\right]^2 - 4\frac{f_1f_2}{m_1m_2}\sin^2 ka} \quad (1)$$

where k is the absolute value of the wave vector and ω_+ and ω_- denote the frequencies of the optical and of the acoustical branches of vibrations, respectively. In the acoustical branch the neighbouring particles (tubulins) move in the same direction and in the optical branch the particles move in opposite directions under condition that the centre of gravity remains at rest [17]. The term vibration mode is used for the waves propagating in both directions along the chain with the same absolute value k of the wave vector.

The protofilaments in a microtubule are bound and build up a wall of a cylinder. The vibrations in particular protofilaments are not independent and form a common vibration system in a microtubule. As a microtubule is composed of 13 protofilaments we assume, that a microtubule 'particle' has 13 times greater mass than a protofilament 'particle' (this assumption may be considered as a zero order approximation). The elastic force constants in isolated parts of the protofilaments (oligomers) and in the microtubules may be different. Frequency vs. absolute value of the wave vector evaluated from Eq. (1) is shown in Fig. 3a for $f_1 = f_2$ and in Fig. 3b for $f_1 = 10f_2$ [16]. The elastic force constants are parameters of the curves. We used several values for the elastic force constants as they can vary in a wide range of values. We will not discuss here the dependence of the elastic force constants on the viscoelastic properties of the cytoskeleton including the entanglements, cross-linkings, and lengths of microtubule sections and filaments as it is beyond the scope of this paper. The reader may find it e.g. in Ref. [16]. We only note that they may be determined from the elastic shear moduli and Young's moduli. Fig. 3a,b shows strong dependence of the frequency of the vibrations on the elastic force constants [16].

The microtubule chain is composed of discrete mass units which we denote microtubule 'particles' and, therefore, the frequency spectrum of the vibrations is discrete. The boundary conditions enable us to determine the absolute values of the wave vector k. If we assume that the tubulins at the end of the microtubule are at rest we get [17]

$$k = \frac{\pi}{Na}g \quad (2)$$

where $N+1$ is the number of microtubule 'particles' in the chain, g is an integer $(1 \le g \le N-1)$, and the length

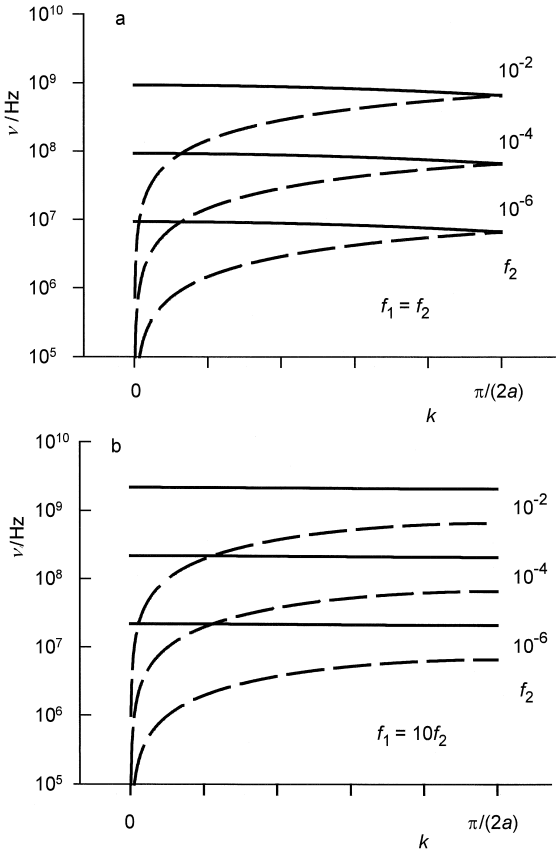

Fig. 3. Dispersion relation for a microtubule (frequency vs. wave vector). The full lines and the dashed lines denote the optical and the acoustical branches, respectively. Elastic force constants are assessed $f_1 = f_2$ (a), $f_1 = 10f_2$ (b). After Ref. [16].

of the microtubule is $L_m = Na$. The number of modes in one branch of vibrations is equal to the number of mobile particles (in the Brillouin zone). We will assess the lowest frequency of the acoustical branch. For a microtubule the lowest frequency for $\nu \neq 0$ of the acoustical branch is in the band of 5–50 MHz if the length of a microtubule is 10 μm $(= \lambda/2)$ and velocity of the acoustical waves is in the range from 10^2–10^3 ms^{-1}.

If the elastic force constants in a heterodimer and between two heterodimers are not equal (i.e. $f_1 \neq f_2$) the potential of 'the tubulin particle' as a function of distance is asymmetric with respect to the equilibrium position. Therefore, the system is non-linear and higher harmonic components (i.e. $\omega = n\omega_j$) and components with combination frequencies (i.e. $\omega = n\omega_j + m\omega_k + \ldots$) are generated ($n$, m, ... are integers). The dispersion relation (1) does not contain these harmonic and combination terms.

The biological reality can certainly yield more complicated patterns of vibrations in the microtubules than those derived in this paper as a number of simplifications was used. For example the internal vibrations were neglected and simple rigid structures of the tubulins were assumed. The internal vibrations are combined with the external

vibrations giving rise to complicated spectral patterns. On account of small mass and great values of the elastic force constants the frequencies of the internal vibrations are much higher than those of the external vibrations. The frequency spectrum can contain frequency lines in the millimeter and in the far infrared regions too.

3. Energy supply to the microtubules

When a microtubule grows tubulin heterodimers add to the free plus end and the GTP's attached to the β-tubulins are hydrolyzed to the GDP's [1,10–12,15]. The rate of polymerization may be greater than the rate of hydrolysis and an energy rich cap can be formed at the end of the microtubule. This energy rich cap is hydrolyzed later. The measurements of hydrolysis of the GTP analogue guanylyl-(a,b)-methylene-diphosphonate (GMPCPP) in solution, in tubulin heterodimers, and in tubulin subunits in the microtubules led to a conclusion that the free energy was -5.18, -3.79, and -0.9 kcal mole^{-1} (-21.7, -15.9, and -3.8 kJ mole^{-1}), i.e. 0.22, 0.16, and 0.04 eV per one entity, respectively [15]. Therefore, energy of about 4 kcal mole^{-1} (17 kJ mole^{-1}) was assumed to be potentially available from the hydrolysis of the GTP. A part of the energy is expended on dissociation of the inorganic phosphate P_i but the majority of it is stored in the microtubule lattice [15]. A remeasurement of the dissociation rate constant allowed better estimation of the free energy for hydrolysis and release of P_i which is $+0.7$ kcal mole^{-1} ($+2.9$ kJ mole^{-1}) [18] rather than -0.9 kcal mole^{-1} as was reported in Ref. [15]. The energy stored in the microtubule lattice is assessed to be 1.7 kcal mole^{-1} (7.1 kJ mole^{-1}). We have to emphasize that the measurements of the energy available from hydrolysis were carried out on the GTP analogue GMPCPP.

The experimental findings given e.g. in Refs. [15,18] show that energy from hydrolysis is stored in the microtubules. The form in which the energy is stored in the microtubule lattice is a special issue. Mandelkow et al. [11] assume that the tubulin–GDP subunit prefers a conformation which leads to coiling of the protofilaments and as a consequence energy may be stored in the form of a tense state of the microtubule lattice. Caplow et al. [15] come to the conclusion that energy is stored in protein conformation and presumably as a repulsive force between subunits. A similar mechanism of energy storage in the microtubules is given in Ref. [4], i.e. that energy from the hydrolysis of the GTP to the GDP is imparted into the microtubule lattice via tubulin conformation changes. Real physical mechanisms of energy transformation are irreversible and a part of the energy is always transferred to the random heat vibrations. Even if the energy levels of two conformation states of a tubulin subunit are different (e.g. if the level of the β state is higher than that of the α state) after the transition to the higher energy level a part of the energy which is used to surmount the potential barrier between the conformation states can be transformed into vibration energy. The opposite relaxation process and restoration of the α conformation state should convert energy to the microtubule vibrations too. Creation of the tense state with altered forces between the subunits in the microtubule has to supply energy into the lattice. Therefore, we may assume that energy is stored in the microtubule lattice not only in the conformation changes and in the tense state of the lattice but also in the vibration states. Besides energy stored in the cytoskeleton during polymerization a part of the energy from the ATP hydrolysis supplied to motor proteins moving along a microtubule [1] can be transferred to the microtubule as random excitations of the vibrations.

The energy stored in the microtubule can do work in the cell [15] but a precise manner in which the energy is utilized is still not understood [19]. As the cytoskeleton is not subjected to any major chemical changes [1] the energy has to be used in some biophysical processes. The hydrolysis energy can change bond strength [19] and excite solitons or soliton like waves [3,19]. As it causes the conformation changes of the tubulin heterodimers kink wave reorientation of the heterodimer dipoles can be excited in the microtubule [3]. It can excite the lattice vibrations and polarization waves, which may be coherent on account of the Fröhlich mechanism [19] or the intrinsic non-linear mechanism. (The Fröhlich mechanism is described e.g. in Refs. [20–22]). Regardless of the primary mechanisms of the energy storage at a later stage at least a part of it is always supplied to the vibrations in the microtubules. Nevertheless, the majority of the energy stored in the microtubules may be converted into the vibrations. Therefore, the vibrations are excited and can be far from thermodynamic equilibrium. We suggest that the mechanism of the coherent polar vibrations in microtubules utilizing the stored energy is a tool for the microtubule organization function. The electric fields generated by the polar vibrations can do work in the surroundings of the microtubules. A mechanism of this type (large scale quantum coherent phenomena in microtubules) is suggested and supported by theoretical analysis e.g. in Refs. [23,24]. The mechanism discussed e.g. in Ref. [23] assumes interaction between coherent modes in the microtubule with water in its surroundings, especially in the microtubule cavity. Experimental data necessary for assessment of the energy transfer between the microtubule and its ambient medium and of damping of the vibrations are still missing.

We assess the amount of energy which might be supplied to the cytoskeleton vibrations from the hydrolysis of the GTP. If the energy supplied by the hydrolysis of the GTP is 4 kcal mole^{-1} (17 kJ mole^{-1}) then energy per one entity is about 7 times greater than energy in thermodynamic equilibrium in the frequency range from 10^7 to 10^{11} Hz. On account of non-linear mechanism the energy may be accumulated in certain vibration modes.

4. Oscillating electric field

The thermal vibrations are omnipresent and biological systems are no exception. The typical feature of the vibrations in thermodynamic equilibrium is their randomness. Using classical concepts we may state that the 'amplitude' and the 'phase' have no coherent components. The tubulin heterodimers are polar and the vibrations create oscillating dipoles or oscillating multipoles. The polar vibrations generate an electric field. We will adopt a linear model of a microtubule with a length of $L_m = 3$ μm where each heterodimer carries an oscillating electric dipole $p = bel_h$ (e is the elementary charge, $l_h = 8$ nm, and $b = b(x)$ where x is the distance along the microtubule axis). Except for b the dipole moments are identical. The frequency of vibrations $\nu = 100$ MHz and the relative permittivity of the ambient medium $\varepsilon' = 81$. We evaluate the intensity of the electric field along the lines parallel with the microtubule axis.

The intensity of the electric field for random orientations of the dipole moments is given in Fig. 4. (We note that this case may correspond to the thermal vibrations.) E_r and E_x shown in Fig. 4a,b are the absolute values of the intensity in the r and x directions (where r denotes the radial direction perpendicular to the microtubule axis),

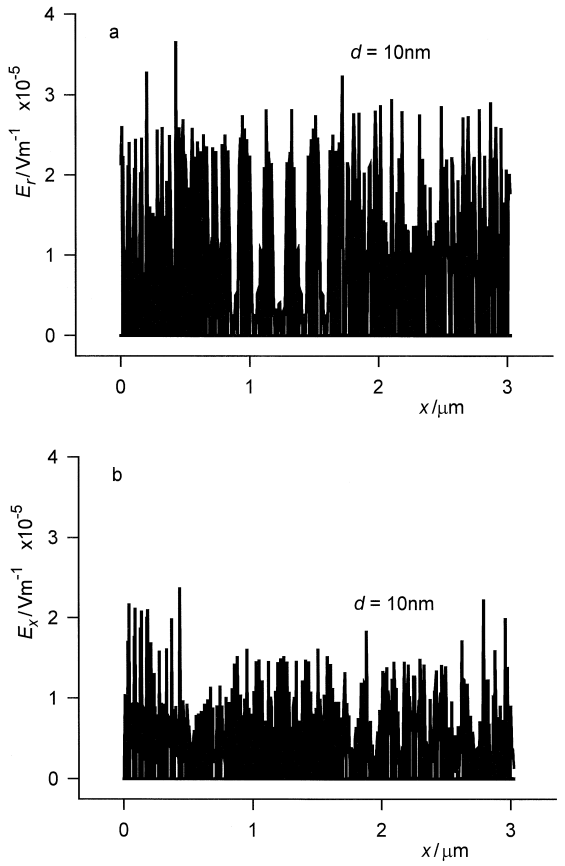

Fig. 4. The thermal vibrations: The absolute value of the intensity of the electric field E_r (a) and E_x (b) as a function of x.

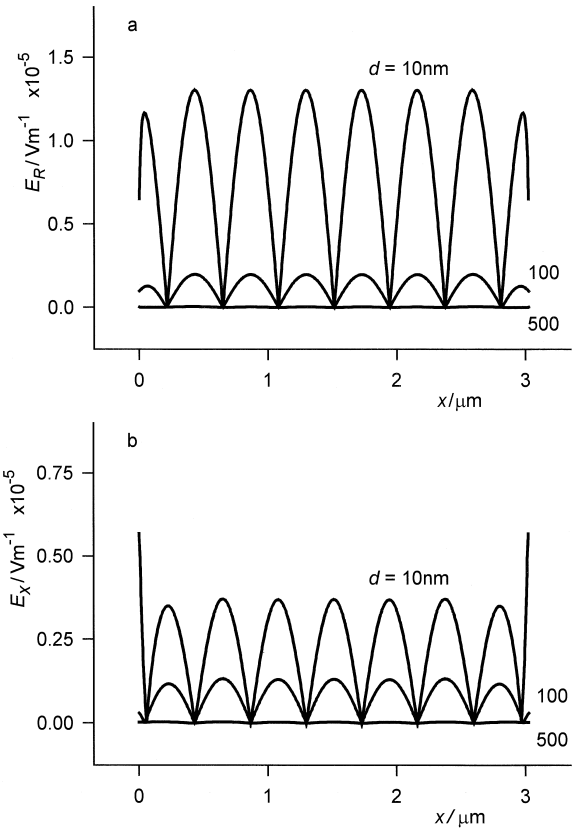

Fig. 5. The coherent vibrations of a vibration mode: E_r (a) and E_x (b) as a function of x.

respectively. The distance d from the 'surface' of the model microtubule is 10 nm. The greatest absolute value of the intensity is of the order of 10^5 Vm^{-1}. At a distance 0.1 and 0.5 μm the peak values are about 10^2 and 1 V m^{-1}, respectively. We used the generator of random numbers to determine the orientations of dipole moments in particular heterodimers ($b = \pm 1$). The intensity of the electric field has random fluctuations in space and time and can decrease to very small values. In the random case the space–time distribution of the dipole moments should correspond to the maximum value of entropy (on account of the Second Law of Thermodynamics).

In thermodynamic equilibrium the Planck's Law determines the distribution of energy in the normal modes. A vibration mode is equivalent to the harmonic oscillator which is subjected to random disturbances. The resulting vibrations are given by superposition of vibrations of all the modes. Nevertheless, under certain conditions the excited vibrations can be far from thermodynamic equilibrium with an important coherent component. In a coherent state certain mode (or modes) is (are) excited; its (their) energy is far from thermodynamic equilibrium value. An example is shown in Fig. 5. Fig. 5a,b shows E_r and E_x, respectively, of the vibration mode $k = 7\pi/L_m$ as a function of x. The distance d is 10 nm, 0.1, and 0.5 μm. The vibrations generate a dynamic periodic potential around

the microtubule. The k value may be considerably greater than that used in Fig. 5 and the period of the standing waves may be comparable in size to the heterodimers. The intensity of the electric field depends on the excitation of vibrations in the microtubule.

5. Discussion

The potential energy U of a dipole in the external electric field E is given by

$$U = -p \cdot E \tag{3}$$

where p is the dipole moment. If $E = 10^6$ V m^{-1}, $p = 10^{-28}$ Cm then the absolute value of U is of the order of 10^{-22} J, i.e. about one order smaller than the energy kT.

The electric field exerts forces on charges, dipoles and multipoles, and even on neutral molecules and particles on account of dielectrophoretic effect. For instance the force exerted on a dipole by the generated field is equal to the gradient of the scalar product

$$F = \nabla(p \cdot E). \tag{4}$$

If the intensity of the electric field decreases from 10^6 to 10^5 V m^{-1} within a distance of 10 nm then for a dipole moment $p = 10^{-28}$ Cm parallel to the intensity of the electric field the force is of the order of 10^{-14} N. The force acts in the direction of the gradient if the dipole is free, i.e. if it is capable of the flip–flop reorientation of the dipole moment.

The inhomogeneous electric field can exert forces on and cause translation motion of neutral dielectric particles. The particle is polarized and the field acts on the induced dipole. The relation for the dielectrophoretic force can be written in the form [25,26]

$$F \propto V(\varepsilon_2' - \varepsilon_1')\varepsilon_0 \nabla(E^2) \tag{5}$$

where ε_2' (ε_1') is the relative permittivity of the particle (of the ambient medium), ε_0 is the permittivity of free space, and V is the volume of the particle. If $\varepsilon_2' > \varepsilon_1'$ the particle is attracted in the direction of the gradient of the intensity of the electric field. If $\varepsilon_2' < \varepsilon_1'$ the force acts in the opposite direction (i.e. the particle is expelled from the field). If the difference of $\varepsilon_2' - \varepsilon_1' \approx 70$, $V = 10^{-27}$ m^3 we can derive for the same electric field as in the case of the dipole that F is of the order 10^{-16} N.

If the vibrations in particular parts of the source structure are random then the generated electric field has the same random properties. If the vibrations are coherent the generated electric field is coherent too. The oscillating electric field in biological systems may have an important role in cell signaling system. Motion of matter and its transport may be caused or organized by the electric oscillating field generated by the cytoskeleton (especially the long distance transport). The endogenous electric field generated by the microtubules can be an organizing factor in living cells.

6. Conclusions

The thermal vibrations are an omnipresent phenomenon existing in inorganic as well as in organic and biological matter. A method similar to that employed in the solid state physics can be used to analyse vibrations in the microtubules. The optical and the acoustical branches of vibrations can exist in microtubules. As the tubulin heterodimer molecules are polar the vibrations generate an oscillating electric field. Generation of the electric field by the microtubules was not analysed yet.

The energy supplied from the hydrolysis of the GTP's to the GDP's can cause excitations of the vibrations to a state far from thermodynamic equilibrium. The generated electric field can have a strong effect on the long distance mass transport and on the organization of chemical reactions in living cells.

Self-organization

ABSTRACT

Microtubules are electrically polar structures fulfilling prerequisites for generation of oscillatory electric field in the kHz to GHz region. Energy supply for excitation of elasto-electrical vibrations in microtubules may be provided from GTP-hydrolysis; motor protein–microtubule interactions; and energy efflux from mitochondria. We calculated electric field generated by axial longitudinal vibration modes of microtubules for random, and coherent excitation. In case of coherent excitation of vibrations, the electric field intensity is highest at the end of microtubule. The dielectrophoretic force exerted by electric field on the surrounding molecules will influence the kinetics of microtubule polymerization via change in the probability of the transport of charge and mass particles. The electric field generated by vibrations of electrically polar cellular structures is expected to play an important role in biological self-organization.

1. Introduction

Cytoskeleton, which consists of microtubules, actin filaments, and intermediate filaments, is considered to be an organizing structure of the eukaryotic cell (Alberts et al., 2008). Microtubules (MTs) are of special interest since they manifest several features that distinguish them from other subcomponents of the cytoskeleton. MTs, which consist usually of 13 protofilaments (PT), resemble hollow tubes with inner and outer diameter of 17 nm and 25 nm, respectively (Fig. 1a). The building subunits of MT are the tubulin heterodimers composed of α- and β-tubulin (Fig. 2). The heterodimers have high electric dipole moment of over 1000 Debye (10^{-26} C m) (Tuszyński et al., 2002; Mershin et al., 2004); they are responsible for the high electrical polarity of MTs. In the interphase of the cell cycle, microtubules are radially organized with their chemical minus ends embedded in a centrosome (organizing center), which is located in the center of the cell near the cell nucleus. There are several hundreds of MTs in a cell, depending on the organism and the cell type. In the interphase microtubules undergo dynamic growth (polymerization) and shrinkage (depolymerization), so-called "dynamic instability" (Fig. 1b). During the existence of mitotic spindle, MTs are subject to treadmilling, i.e. they polymerize at the plus end and depolymerize at the minus end (chemical plus and minus).

1.1. Microtubule Vibrations

Elastic and vibrational properties of MTs have been studied by several authors. Sirenko et al. (1996) analyzed vibrations of microtubules in a fluid modeled as elastic cylindrical shell with isotropic mechanical properties. Maximum frequency of tens of GHz corresponded to nonradiative elastic waves localized at the MT wall.

Pokorný et al. (1997) analyzed the vibrations of MTs modeled as one dimensional chain of mass particles with translation symmetry. Vibrations of cellular structures have been considered to be viscously overdamped in cytosol and thus not realistic (Foster and Baish, 2000; Adair, 2002). However, most of the water in the cell has different properties than bulk water (Preparata, 1995; Del Giudice et al., 2000, 2005; Zhadin and Giuliani, 2006; Zhadin et al., 2007) due to the molecular crowding and consequent large hydration surfaces. If the slip layer condition for MT longitudinal vibrations is taken into account, vibrations may be excited (Pokorný, 2004, 2003, 2005).

Portet et al. (2005) describe the microscopic dynamical properties of MTs using a discrete model based on a lattice of dimers. It was pointed out that various experimental methods yielded wide range of values of Young's and shear modulus between 1 Pa (Janmey et al., 1991; Sato et al., 1988) up to 1 GPa (Portet et al., 2005). This would be explainable by the fact that mechanical properties of microtubules are anisotropic and orthotropic.[1] This was showed by Kis et al. (2002) who obtained the most accurate values for both the Young's ($E > 100$ MPa) and shear modulus ($G = 1.4 \pm 0.4$ MPa).

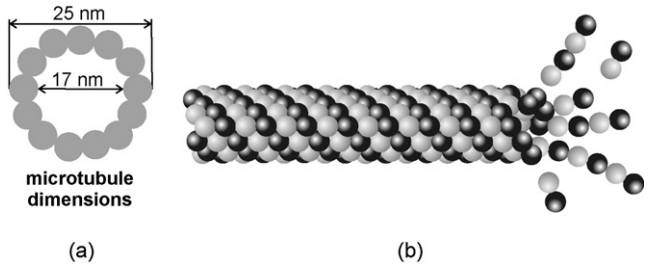

Fig. 1. (a) Cross section of microtubule. (b) Detail of chemical plus end of a microtubule undergoing dynamic instability.

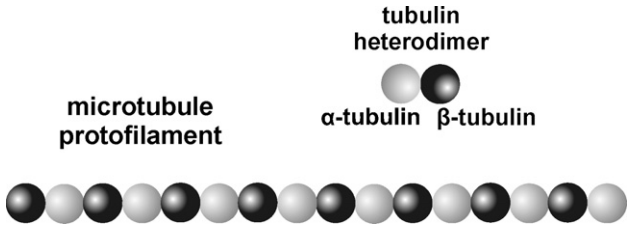

Fig. 2. Structural subunits of microtubules: protofilament composed of tubulin heterodimers.

The oscillation modes involving a change in the diameter of the MTs strongly depend on the shear modulus (Kasas et al., 2004).

Tuszyński et al. (2005) reviewed characteristic elastic properties of microtubules. Wang et al. (2006) and Wang and Zhang (2008) developed orthotropic elastic shell model to study microtubule vibrations and determined more realistic frequencies of radial and circumferential modes than that provided by Sirenko et al. (1996) which was confirmed by Qian et al. (2007).

It can be seen from above given references that frequencies of MT vibration modes may span over broad spectral range from kHz to GHz. Due to non-linearities and to mechanical anisotropy of MTs, frequency mixing and energy transfer between the modes, one may expect various frequencies of oscillations.

1.2. Energy Supply to Microtubules

Excitation of mechanical vibrations in MTs, which are electrically polar, would give rise to electrical oscillations. To excite and sustain vibrations the energy needs to be supplied. In the case when at least a part of energy supplied to MTs excites elastic vibrations of electrically polar structures, generated oscillatory electric field has the same frequency as that of elastic MT vibrations. We analyzed three possible sources of energy supply to MTs (Jelínek et al., 2009):

- Energy released from hydrolysis of guanosine triphosphate (GTP) in processes of dynamic instability of MTs (Fig. 2) is the energy supply dependent on internal MT process. β-Tubulin bound GTP is hydrolyzed to guanosine diphosphate (GDP) after polymerization of tubulin heterodimer. In the interphase the half lifetime of individual unstable MTs (subject to dynamic instability) is about 5–10 min (Alberts et al., 2008). Energy from hydrolysis of GTP stored in MT lattice is estimated to be 1.7 kcal/mol[2] (Caplow et al., 1994; Caplow, 1995; Caplow and Shanks, 1996). The corresponding power input to MT lattice due to GTP hydrolysis is about 1.8×10^{-14} W/mm of MT (if we accept 5 min as a half life of a single MT) which range roughly corresponds to the previous estimate (Pokorný, 1999; Pokorný and Wu, 1998). Assuming 100 μm total length of MT structure in a cell (the length is assumed for yeast cell (King and Hyams, 1982; Winey et al., 1995; Sobel, 1997)), one obtains the power of about 3×10^{-18} W in whole microtubular network. In the M phase, the dynamics of polymerization and depolymerization is increased about 20-fold, for instance by treadmilling in the metaphase.
- Energy transferred from moving of motor proteins and their interaction with MTs may also contribute to excitation of vibrations in MTs (Fig. 3). Motor protein dynein moves towards the cell center (minus end of a MT) and kinesin moves towards the cell periphery (plus end of a MT). One ATP (adenosine triphosphate) molecule is hydrolyzed for each step of motor protein. One step of motor protein is ca. 8 nm long, corresponding to axial dimensions of tubulin heterodimer. Energy released during ATP hydrolysis under cellular ATP concentrations (1–10 mM) is ca. 14 kcal/mol[3] which corresponds to activation energy of motor proteins (Kawaguchi and Ishiwata, 2001, 2000; Pelling et al., 2004). Motor proteins move with a velocity ca. 0.1–2 μm/s (Alberts et al., 2008). Assuming four motor proteins on each of 100 MTs in the cell, each motor protein moving with average velocity of 800 nm/s, power exerted by all motor proteins in a cell is about 4×10^{-15} W. Assuming that 1–25% of this power excites vibrations in MTs, it corresponds to 4×10^{-17}–10^{-15} W, respectively.
- Energy released from mitochondria as "wasted" energy in the course of citric acid cycle may be the most significant energy source for excitations of MT vibrations.

  Whole metabolic turnover of *Saccharomyces cerevisiae* cell is 0.1 pW (10^{-13} W) (Lamprecht, 1980). Mitochondria are considered "power plants of the cell" generating ATP by means of energy from pyruvate and fatty acid. Less than 50% of energy is stored in ATP. The rest of the energy ("wasted" energy), i.e., more than 50%, is released to surroundings of mitochondria in the form of heat and emitted radiation (Fig. 4). Corresponding wasted power may be 0.05 pW. Since mitochondria are located near microtubules, part of the "wasted" power (we may assume 20%, i.e., 10^{-14} W) may be involved in excitation of the vibrations in MTs.

2. Method and Parameters Used for Calculation of Electric Field Around MT

First assessment of oscillating electric field around MTs has been done by Pokorný et al. (1997). Intensity of the electric field was evaluated along the lines parallel with the MT axis up to the distance of 500 nm. Their model included microtubules with heterodimers with random or coherent oscillating dipoles. Frequency of coherent excitations has been chosen as 100 MHz.

We made a preliminary assessment of MT electric field with different calculation method in Havelka and Cifra (2009a), Havelka (2008), Havelka and Cifra (2009b), but we used a higher value of dipole moment than corresponds to the real state. The complete

[2] 1.7 kcal/mol = 7.1 kJ/mol = 118×10^{-22} J = 0.074 eV.

[3] 58.2 kJ/mol = 0.97562×10^{-19} J = 0.609 eV.

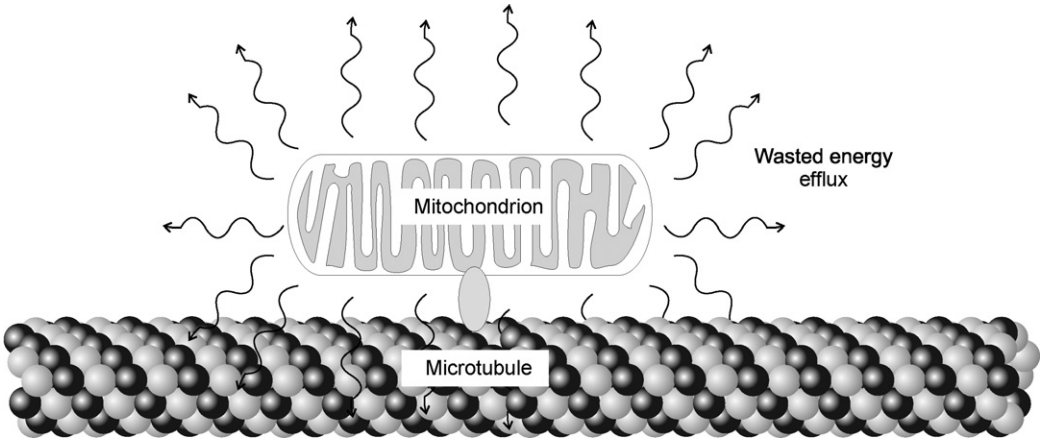

Fig. 4. Microtubule bathed in energy efflux from a mitochondrion. The mitochondrion not in scale to microtubule.

and more realistic results are presented in this paper. We analyze electric field generated by MT longitudinal axial vibration modes. We also study the spatial distribution of electric field of MT since this has not been performed before.

Due to axial longitudinal vibrations in the MT lattice an electric dipole moment will have an oscillating component in the direction parallel to MT axis. Oscillating dipole with the dimensions much smaller than wavelength of generated electric field can be represented by elementary oscillating electric dipole (Hertz dipole).

2.1. Components of the Electric and the Magnetic Fields of the Elementary Oscillating Electric Dipole

We use standard relations for the field of oscillating electric dipole in the form as provided in Novotný (1997):

$$\vec{H}_\phi = -\frac{Id}{4\pi}k^2 \sin\theta \left(\frac{1}{jkr} + \frac{1}{(jkr)^2}\right) e^{-jkr}\vec{\phi}_0 \quad (1)$$

$$\vec{E}_r = -\frac{Id}{4\pi}Zk^2 2\cos\theta \left(\frac{1}{(jkr)^2} + \frac{1}{(jkr)^3}\right) e^{-jkr}\vec{r}_0 \quad (2)$$

$$\vec{E}_\theta = -\frac{Id}{4\pi}Zk^2 \sin\theta \left(\frac{1}{jkr} + \frac{1}{(jkr)^2} + \frac{1}{(jkr)^3}\right) e^{-jkr}\vec{\theta}_0 \quad (3)$$

H is magnetic field intensity; E is electric field intensity; I is equivalent current; d is length of the dipole; k is propagation constant; Z is wave impedance; j is imaginary unit and coordinate symbols are according to Fig. 5. None of these equations is dependent on ϕ and all equations include:

$$Id = j\omega p \quad (4)$$

ω is angular frequency, and p is dipole moment ($Id = (\partial Q/\partial t)d = j\omega Qd$, $Qd = p$, Q is charge).

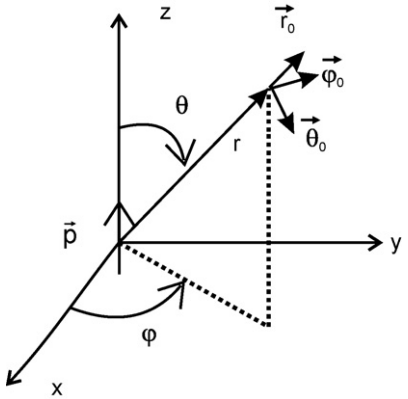

Fig. 5. A dipole in the Cartesian and spherical coordinate system.

2.2. Description of the Electric Field Around a Microtubule

Electric field around MT can be calculated as a vectorial sum of elementary electric components generated by individual tubulin heterodimer dipoles. Frequency of the oscillations of individual dipoles has been set to the 1 GHz which falls into the spectrum predicted by Sirenko et al. (1996), Wang et al. (2006) and Wang and Zhang (2008) and also fits almost exactly the frequency of optical branches of vibration modes of microtubule calculated by Pokorný and Wu (1998) and Pokorný et al. (1997).

The near field around electric dipole has the electric component much stronger that the magnetic one. We concentrated therefore on the electric field component.

We have rewritten the Eqs. (2) and (3) for electric field in Cartesian coordinates which can be used for arbitrarily placed and tilted dipole in lossy medium. The procedure is described thoroughly in Cifra (2009). All calculations and figures have been made in MatLab.

2.3. Shift of Protofilaments

Although the MTs are tube-like structures, their wall does not have cylindrical symmetry. This is due to longitudinal shift of protofilaments in MT lattice. Accordingly, lattice with longitudinal shift of PTs simulates more realistic organization of protofilaments in the MT. This gives us more accurate information about the spatial distribution of electric field intensity of the around MT. We have chosen the configuration in A-lattice (Song and Mandelkow, 1993, 1995; Kikkawa et al., 1994; Amos, 1995), which is a lattice with a longitudinal shift of protofilaments of 4.92 nm (Table 1 and Fig. 6).

2.4. Types of Excitation and Calculation Parameters

Geometry and orientation of tubulin dipole moments in MT is approximately known. However, the elasto-electrical waves in

Table 1
Longitudinal shift of PT in A-lattice.

Number of PT	2	3	4	5	6	7
Shift to 1st PT (nm)	−4.92	−1.84	−6.76	−3.68	−0.6	2.48
Number of PT	8	9	10	11	12	13
Shift to 1st PT (nm)	−2.44	0.64	−4.28	−1.2	−6.12	−3.04

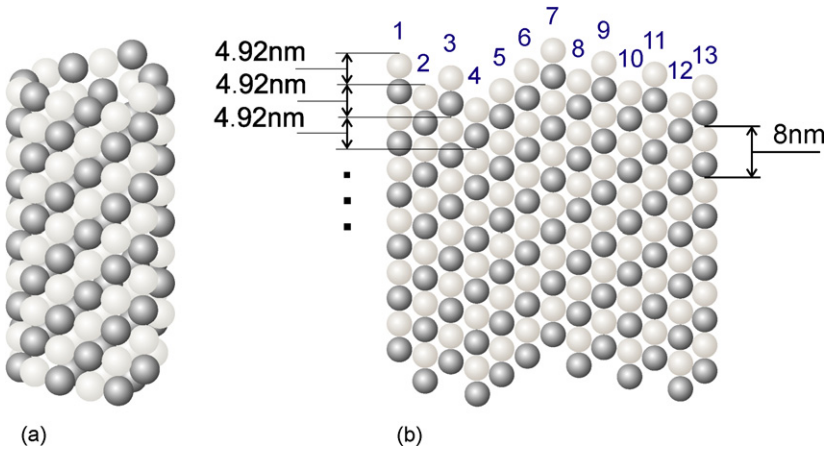

Fig. 6. (a) Microtubule with longitudinal shift of PT of 4.92 nm. (b) Shell of MT with longitudinal shift of protofilament.

microtubules also determine the efficiency, spatial distribution and dynamics of generated electric oscillations. There may be acoustical and optical modes of axial longitudinal oscillations. In optical modes, neighbor particles move in opposite direction. In acoustical modes, neighbor particles move in the same direction (except the end of Brillouin zone where the k-vector is large).

In the case of optical mode a component of dipole moment which is oriented along the axis would oscillate and generate electric oscillations.

Vibration modes which displace whole dipole along its axis would be significantly less efficient in generation of electric oscillations. This is due to the fact that opposite charges near each other and oscillating along the same axis with the same phase and frequency will behave as antiphase dipoles which effectively cancel each other field.

As shown in Tuszyński et al. (2002) and Mershin et al. (2004) a significant part of the tubulin dipole moment is oriented radially from MT axis. Certain kind of vibration modes involve radial oscillation of MT wall. Such kind of modes would involve displacement of rather large mass of surrounding cytosol, hence they would undergo stronger damping compared to the longitudinal optical oscillations in the direction along MT axis.

Circumferential elastic vibrations may be also connected with generation of oscillating electric field due to oscillatory changes of the distance between electric charges. Frequency of the modes depends on Young's and shear modulus. As the moduli exhibit large differences in magnitudes in different directions the frequencies of oscillations are corresponding.

Based on the discussion above, we have focused our analysis on the longitudinal optical oscillations of MT. Frequency of oscillations was chosen to be 1 GHz. It corresponds to calculations of MT vibrations of Pokorný and Wang. We estimate the oscillatory displacement of the charge in tubulin dipole moment along the MT axis to be around 0.1 nm for the vibrations in GHz region.[4] The static dipole moment (p_s) in the direction of the MT axis is accepted to be about 330 D (Tuszyński et al., 2002; Mershin et al., 2004). Length of the tubulin heterodimer is 8 nm, so the effective oscillatory component of the dipole p_a at the frequency of 1 GHz may be estimated as $p_a = (0.1/8)p_s = 4.125\,\mathrm{D} = 1.376 \times 10^{-29}\,\mathrm{C\,m}$.

Excitation of vibrations in our calculations was based on following models:

- Random excitation–random phase of oscillations was approximated by modulation of dipole moment of each of dipoles by function $\sin(2\pi n)$, n = random number from interval $\langle 0, 1\rangle$.
- Coherent excitation – modes with wavenumber k (k-modes) – longitudinal waves on the MT have been approximated by modulation of dipole moment of the individual heterodimers along the MT axis by function $a + b \times \sin(k_0 nz)$, z-axis corresponds to MT axis. Physically, these vibration modes belong to optical branch where neighbor particles (here α- and β-tubulin monomers in protofilaments) oscillate against each other. This corresponds to our approximation of heterodimer as an oscillating dipole. Number of mode n is provided instead of wavenumber k to indicate number of maxima. Note that direction of electric field vector is opposite in neighboring maxima as given by $\sin(k_0 nz)$ modulating function. In a special case all the dipoles may oscillate with the same phase (corresponds to $k = 0$ optical branch of longitudinal lattice vibration).

Dielectric parameters of the surrounding medium have been chosen based on experimentally obtained results from Asami et al. (1976) and Asami and Yonezawa (1996). Compared to the cited literature, we use slightly different value of the cytoplasm relative permittivity; instead 50 (Asami et al., 1976) we use 60. Slightly higher permittivity used corresponds physically to higher water content assumed (Table 2).

3. Results

Colormap figures depict MT electric field spatial distribution in the plane which contains the MT axis. White lines in the figures are contours of the MT wall. The arrows in the colormap figures denote the direction of the electric field vector. Note that neither arrow density nor arrow length is related to intensity. For greater dynamic range common logarithm of electric intensity is used for all

Table 2
Fixed parameters of calculations.

Frequency of vibrations	1 GHz
Number of protofilaments in MT	13
Number of heterodimers in each protofilament	50
Oscillatory component of dipole moment	$4.125\,\mathrm{D} = 1.376 \times 10^{-29}\,\mathrm{C\,m}$
Relative permittivity of the medium	60
Conductivity of the medium	1 S/m

[4] This estimate is based on measurements of Pelling et al. (2004) and Pelling et al. (2005) who found oscillations of yeast cell membrane (likely excited by cytoskeleton) in the frequency range about 1 kHz and amplitudes about 1–10 nm. Microtubules associated with motor proteins are also able to vibrate at frequencies of hundreds of kHz and amplitudes up to 10 nm in cilia and flagella (Kamimura and Kamiya, 1989, 1992; Sakakibara et al., 2004).

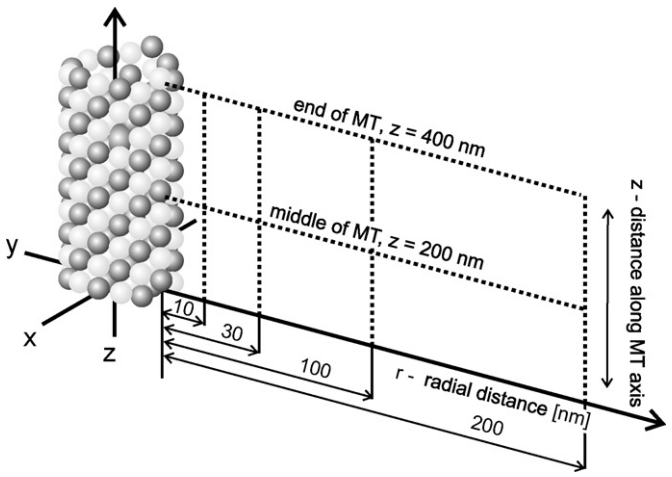

Fig. 7. The lines along which the electric field intensity has been plotted.

graphs and figures, e.g. color on the colorbar denoted 4 corresponds to intensity 10^4 V/m.

Electric field intensity dependence on distance radially from MT axis and along MT axis in selected distances from MT axis has been plotted in separate figures for simpler comparison. See Fig. 7 for the clarification of the plotting geometry.

3.1. Coherent Excitation

First we studied the simple model of the special case of coherent excitation. The spatial distribution of electric field around MT in this case is depicted in Fig. 8.

Coherently excited (at $k = 0$) MT behaves like a giant dipole having maxima of electric field intensity at its ends. This is of no wonder since it consists of chains of in phase oscillating dipoles with the same orientation of dipole moments.

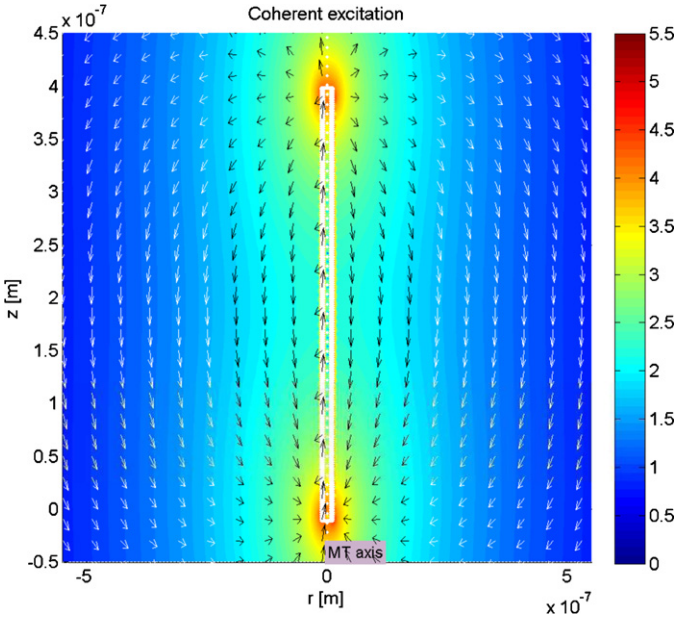

Fig. 8. Electric field around microtubule with coherent excitation ($k = 0$). Color coded electric field magnitude is in log scale (log(V/m)). Arrows represent electric field vector.

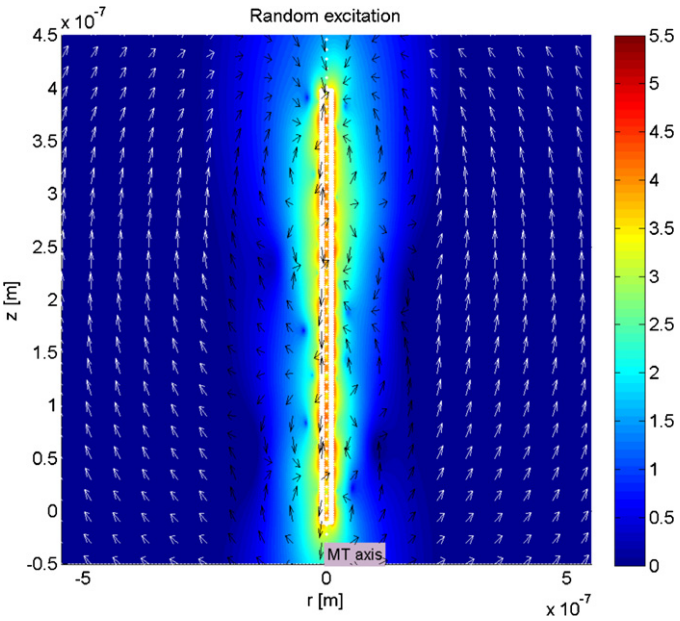

Fig. 9. Electric field around microtubule with random excitation. Color coded electric field magnitude is in log scale (log(V/m)). Arrows represent electric field vector.

3.2. Random Excitation

Spatial distribution of electric field generated by random (thermal) excitation of MT is given in Fig. 9.

The spatial distribution depicted in the Fig. 9 is just one example which results from the certain random number sequence. Naturally, the spatial distribution of random excitation can take various forms and often exhibits local minima.

3.3. Comparison of Coherent and Random Excitation

Comparison of coherent ($k = 0$) and random excitation of electric field is provided in Fig. 10.

We clearly see the difference between the field generated by random and in phase (coherent) oscillations. Although electric field intensity is higher in the middle of the MT axis ($z = 200$ nm) at the surface of MT for random excitation, it falls off faster with the dis-

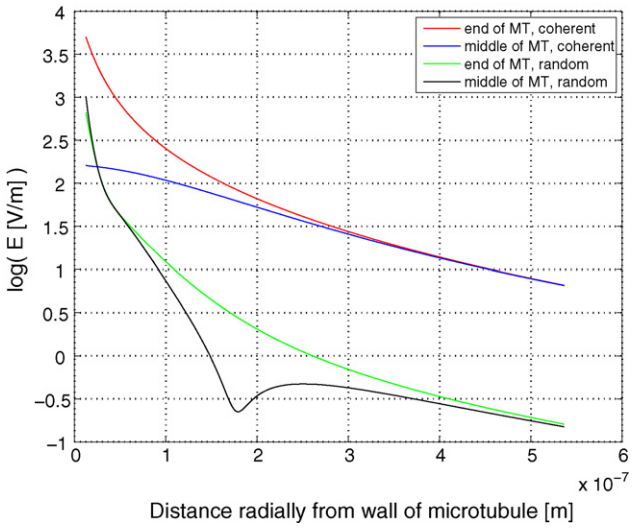

Fig. 10. Electric field intensity radial dependence from the wall of microtubule for the coherent and random excitation. From the end of MT ($z = 400$ nm) and from the middle of MT ($z = 200$ nm).

tance compared to the in phase (coherent) excitation (Fig. 10). The electric field intensity is higher at the ends of MT ($z = 400$ nm and 0 nm[5]) for the in phase excitation compared to the random one (Fig. 10). There is a difference by one and a half orders of magnitude between the electric field intensity of randomly and in phase excited vibrations in the distance larger than ca. 100 nm.

3.4. Coherent Excitation of Higher k-modes

Normal vibration modes (termed as *k*-modes) can be excited in microtubules. We primarily chose to study *k*-modes number $n = 2$, 5 and 50 as the representative ones. We depict the spatial distribution of the *k*-mode 2 in Fig. 11 and zoomed in spatial distribution in 12.

Two maxima in the MT lattice are clearly discernible in Fig. 12 whereas in Fig. 11 they are not. Therefore we chose to provide only zoomed in figures when displaying spatial distribution of electric field for higher ($n > 0$) modes. Note that abscissa and ordinate have different scales in zoomed in figures; the *r*-axis (ordinate) is 10-fold stretched to resolve the details of electric field in direction radially from MT axis.

The zoomed in spatial distribution of electric field around MT of *k*-modes 5 and 50 is depicted in Figs. 13 and 14, respectively. Electric field of higher modes is depicted in figures in supplementary material.

We observed that every half-wave of *k*-mode of longitudinal lattice vibration produces effectively a *k*-mode "dipole" field[6] the maxima of which are located on the poles of the "dipole". Moreover, *k*-mode "dipoles" are oriented to each other with the same pole. This can be seen also from the orientation of electric field vectors (see, e.g. Fig. 12 where two *k*-mode "dipolar" fields are discernible in each intersection of the MT wall; the plus poles are in the middle of the MT wall, i.e. the electric field vector is oriented radially from the plus poles of the "dipole"). The effective number of maxima in the field intensity up to the distance of 10 nm from the MT wall (or more, depending on the mode number) for the *k*-modes $n > 0$ is actually $n + 1$ since each pole of *k*-mode "dipole" contributes by one maximum. The number of maxima further changes in greater distance.

Higher the mode, the total dipole moment of whole MT is split into many small *k*-mode "dipoles" with opposite directions. The MT obtains multipolar *k*-mode character with rising mode number. Multipolar character of field source distribution explains the steeper decrease of intensity from the MT for higher mode numbers (e.g. see Fig. 15).

We provide figures depicting electric field intensity radial dependence from MT end and middle of MT for *k*-mode 2, 5, 10, 20 and 50 in Figs. 15 and 16.

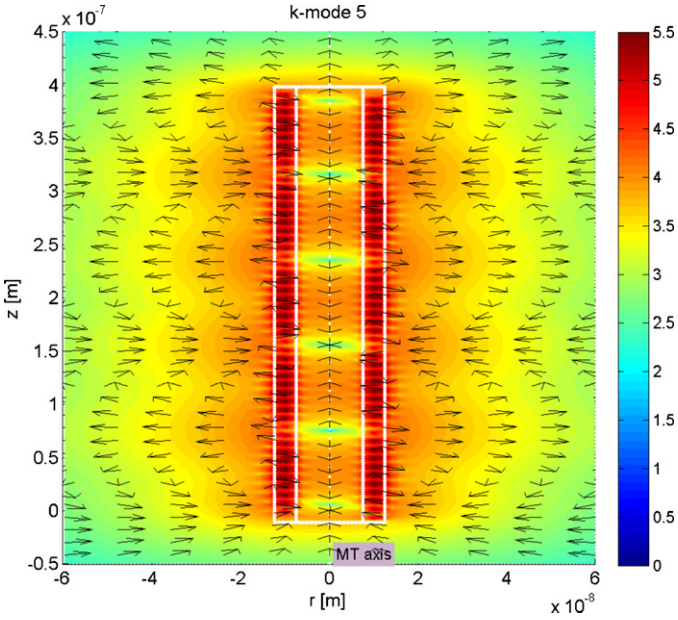

Fig. 13. Electric field distribution around MT of *k*-mode 5, zoomed in radial axis. Color coded electric field magnitude is in log scale (log(V/m)). Arrows represent electric field vector.

[5] Values are not depicted for $z = 0$ nm but they are essentially the same as for $z = 400$ nm due to the symmetry.

[6] We use term "*k*-mode 'dipole'" to describe an effective "dipole" field structure which appears in the MT wall due to every half wave of MT vibration. Number of mode indicates the number of *k*-mode "dipoles".

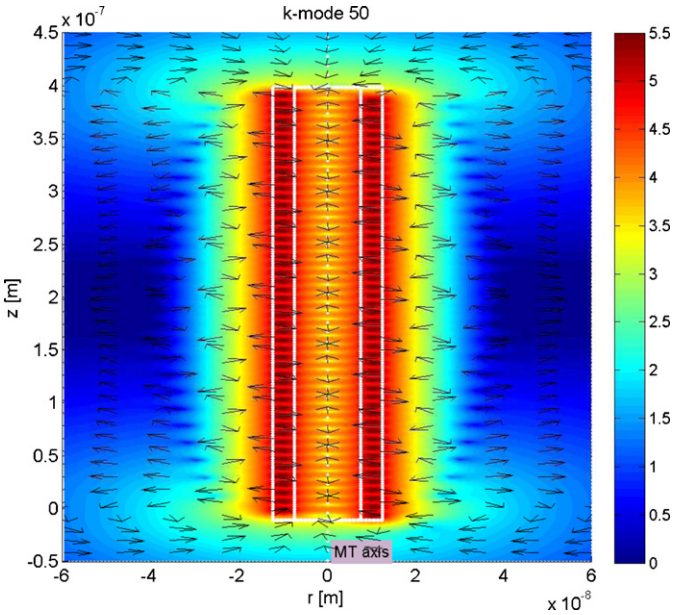

Fig. 14. Electric field distribution around MT of mode 50, zoomed in radial axis. Color coded electric field magnitude is in log scale (log(V/m)). Arrows represent electric field vector.

At the close distance from the MT, for certain regions, there is a specific k-mode which has highest intensity, see Figs. 15 and 16. We see that different k-modes manifest different rate of decrease of intensity with increasing distance radially from MT wall. This resembles multipolar behavior of intensity dependence on distance: higher the multipole degree (k-mode number of MT vibrations) steeper the decrease of intensity from the multipolar source.

Following this line of thought, it is interesting to observe the profile of the intensity for various distances r from the microtubule. In Figs. 17, 18 and 19 we provide the profiles of intensity parallel to MT axis for k-mode 2, 5 and 50, respectively.

4. Discussion

First the frequency dependence will be discussed. For the frequencies up to high THz region, we can work with the microtubule generated field as near field in the distances we treat here (up

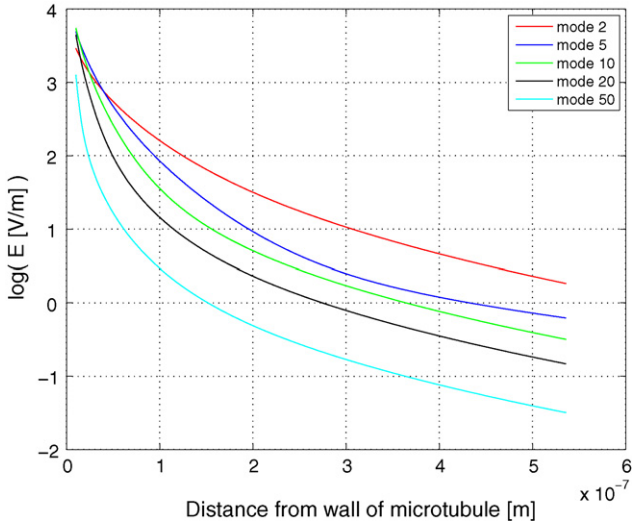

Fig. 15. Electric field intensity radial dependence from the wall of microtubule for the k-modes 2, 5, 10, 20 and 50. From the end of MT ($z = 400$ nm).

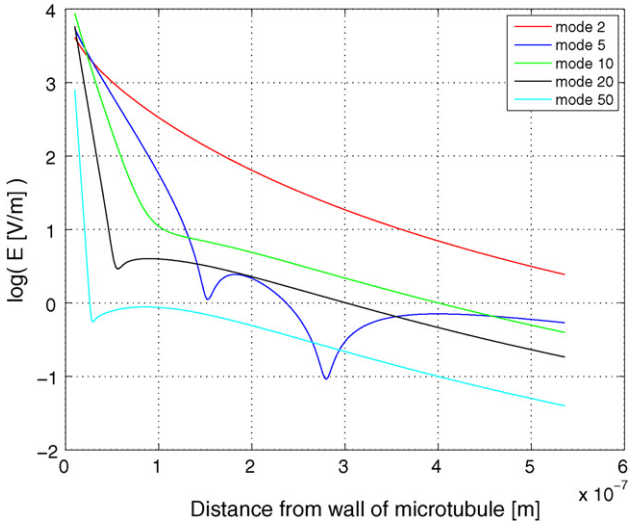

Fig. 16. Electric field intensity radial dependence from the wall of microtubule for the k-modes 2, 5, 10, 20 and 50. From the middle of MT ($z = 200$ nm).

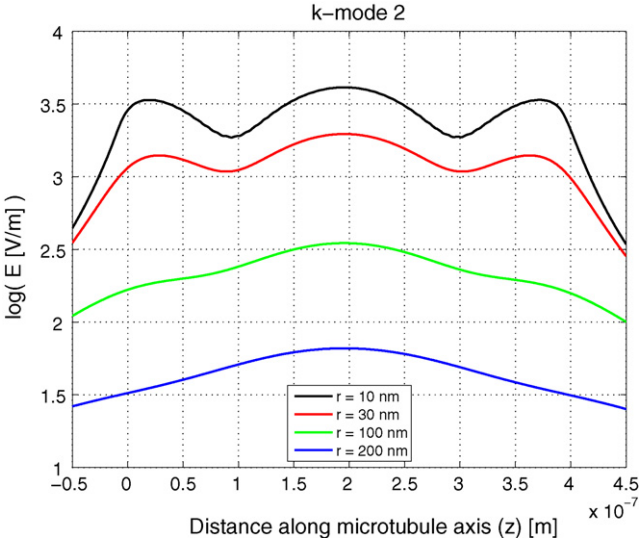

Fig. 17. Electric field intensity along the lines parallel to microtubule axis at the distance r from microtubule wall, mode 2. Microtubule is located from $z = 0$ to 400 nm.

to 1 μm from MT). So there is basically no difference in the field geometry for various frequencies.[7] With changing frequency the magnitude of the intensity may change due to permittivity and conductivity relaxations. Increasing frequency has an effect on effective current created by dipole oscillations ($Id = \omega p$), so the generated intensity would be higher if the amplitude of the vibrations does not decrease.

Discussing dipole moment separately; the generated intensity increases linearly with increasing dipole moment p magnitude. Amount of power in MT vibrations will influence effective value of dipole moment oscillating component p_a. Effective oscillating dipole moment would be increased if more power is supplied into the vibrations. If the amount of the oscillating charge is fixed,

[7] Actually, there would be frequency dependence of the field geometry since wavenumber of vibration modes is bound to frequency of oscillations by dispersion relations. However, in the case of optical branch of longitudinal oscillations the dispersion relation is rather flat, i.e. the function of frequency on wavenumber is almost constant.

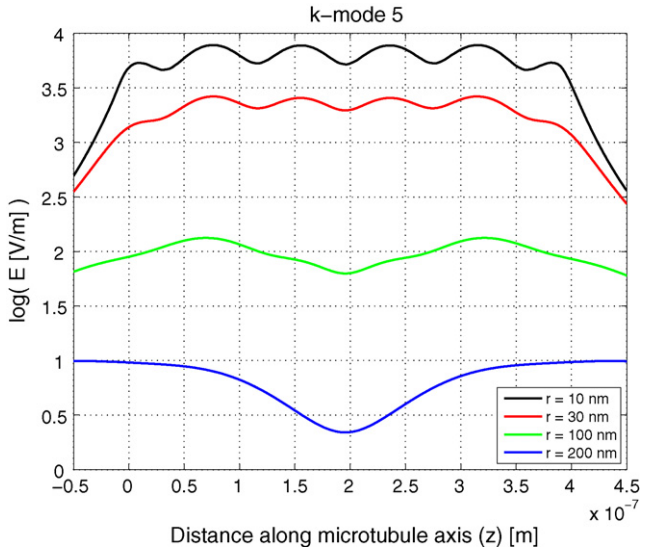

Fig. 18. Electric field intensity along the lines parallel to microtubule axis at the distance r radially from microtubule axis, mode 5. Microtubule is located from $z = 0$ to 400 nm.

increased dipole moment would correspond to the greater oscillating distance. However, for different frequencies, there is different amount of charge available for oscillations, given by the mobility of charge.

In a special case of strong energy condensation in certain microtubule vibration modes, electric field generated at certain frequency could be higher by several orders of magnitude and could exert force at the correspondingly greater distance. This kind of phenomenon may be transient only. Nevertheless, it may be involved in cellular interactions, if not by force interaction then by information transfer.

Only optical branches of vibrations can contribute significantly to electric field generation since in these kind of modes neighbor particles (monomers of tubulin) oscillate against each other. Actually, transverse (Kittel, 1976) and longitudinal (Berreman, 1963) optical modes in ionic crystals are responsible for electromagnetic field absorption. We can see the reciprocity of electromagnetic field absorption and generation in these processes. Acoustic longitudinal branch could also effectively contribute to the electric field generation in the MT near the limit of the Brillouin zone, where the k vector is already large (vibration wavelength short) so that particles in the lattice oscillate against each other.

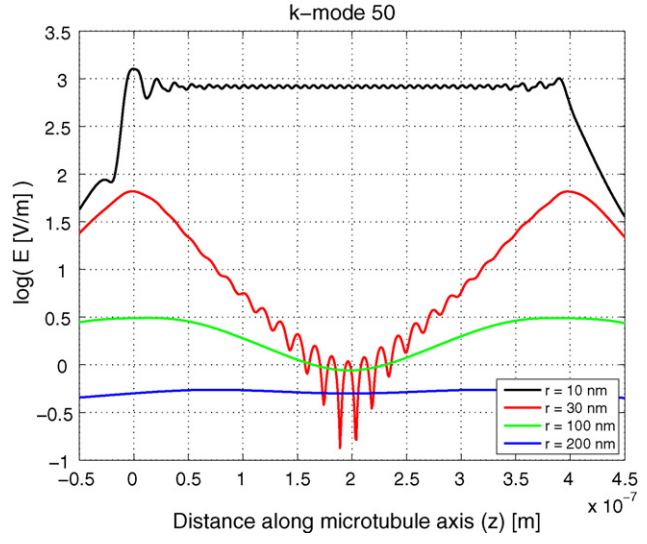

Fig. 19. Electric field intensity along the lines parallel to microtubule axis at the distance r from microtubule, mode 50. Microtubule is located from $z = 0$ to 400 nm. The slight asymmetry seen at the $r = 10$ nm is due to protofilament shift.

Microtubule associated proteins (MAPs) may also influence MT vibrations acting like a nodes imposing minimum of vibration amplitude (adding the mass to the binding point). This will influence generated field geometry, frequency of vibrations and the transfer of vibrations to other structures bound to the other end of MAPs.

In case of excitation of higher vibration modes, there will be regions of electric field with spatially oscillating direction of electric field vector. The dense distribution of regions with opposite field vector direction renders a problem for direct measurement of electric oscillations. Point detector needs to be used to resolve spatial regions of opposite direction of electric field vector.

We also studied the impact of the MT model with real lattice (protofilaments shifted to each other), which corresponds to realistic model of MT lattice compared to nonshifted models of MT (see supplementary material). For the low mode numbers ($n < N/2$), where N is the number of tubulin heterodimers in the MT, there was a small difference in the electric field around MT between the model with protofilaments (lattice) shifted and not shifted. However, the differences become significant for the growing mode number. The break in the symmetry introduced by protofilament shift changes the field geometry. The difference between the models with shifted and not shifted lattice are most pronounced for the higher mode number ($n > N/2$).

Vibrations of microtubules or of other electrically polar cellular structures may be the underlying mechanism generating the electric oscillations which were observed around living cells in kHz to MHz region (Pohl et al., 1981; Phillips et al., 1987; Hölzel, 2001; Pokorný et al., 2001; Jelínek et al., 2009).

We calculated and compared behavior of the electric field generated by random and coherent oscillations of microtubules. While random oscillations occur naturally without any special assumptions, the process where coherence of oscillations arise needs to be touched. Fröhlich's theory (Fröhlich, 1968a,b, 1980) describes a system of oscillators with energy supply, linear and nonlinear coupling with heat bath. If sufficient energy supply is provided to this system, condensation of energy occurs in lowest mode leading to its coherent excitation. Thus, coherent oscillations in microtubules described in this paper can be based on Fröhlich's theory. Numerous works have been inspired by Fröhlich's theory, for review see, e.g. Pokorný and Wu (1998), Hyland and Rowlands (2006) and Cifra (2009). Recently, Reimers et al. (2009) and McKemmish et al. (2009) presented analysis of Penrose–Hameroff orchestrated objective reduction (Orch OR) model of brain activity (Penrose and Hameroff, 1995; Hameroff, 1998; Hagan et al., 2002) with conclusion, that the model is founded on incorrect assumptions, in particular on Fröhlich's coherence, the essential requirement for Orch OR function. McKemmish et al. (2009) claimed that Fröhlich's coherence time is not long enough and that biochemical energy is too small to facilitate coherent condensation which follows from analysis in McKemmish et al. (2009). However, as described closer in comment by Pokomý (submitted for publication), authors of (McKemmish et al., 2009; Reimers et al., 2009) did not take into account the main sources of energy in the cell ("wasted" energy from mitochondria – see Section 1.2 this paper) and the fact that coherence may be strongly raised by

1. Weak damping due to organization of water (Fuchs et al., 2007, 2008, 2009; Giuliani et al., 2009) in strong static electric field around mitochondria (Tyner et al., 2007).

2. Interactions between individual Fröhlich's systems (Pokomý, submitted for publication).
3. Higher order nonlinear terms (Pokorný, 1982; Pokorný et al., 1986a,b).

If Fröhlich's theory of coherent excitations is reconsidered in the light of the facts in comment of Pokomý (submitted for publication), the disclaim of the Orch OR proposal of the brain function by Reimers et al. (2009) on the basis of insufficient coherence (McKemmish et al., 2009) does not seem to be justified.

5. Conclusions

Based on previous works (Pokorný and Wu, 1998; Pokorný, 1999; Pokorný et al., 1997, 1998; Havelka and Cifra, 2009a; Havelka, 2008), we have analyzed electric oscillations excited by vibrations of microtubule. Our model corresponds to optical branches of longitudinal vibrations.

The coherent vibrations of MT generate greater electric field in greater distance than random vibrations.

It was also found that the lattice shift of protofilaments has increasingly significant influence on the field geometry for the lattice vibration modes which wavelength is shorter than two tubulin heterodimer dipoles. This suggests necessity to model higher vibrations modes taking into account lattice shift, which is the real case.

More realistic oscillatory component of dipole moment based on experimental values of static dipole moment and amplitude of mechanical vibrations has been estimated than in previous works (Pokorný, 1999; Havelka and Cifra, 2009a).[8] Using more realistic dipole moments electric field intensity around microtubules is about two orders of magnitude lower than calculated in previous works (Pokorný and Wu, 1998; Pokorný, 1999; Pokorný et al., 1997, 1998; Havelka and Cifra, 2009a; Havelka, 2008). Nevertheless, the electric field generated by microtubules may contribute to self-organization of biological processes also under these conditions.

[8] Previously, Pokorný has estimated oscillatory tubulin dipole moment at 100 MHz as $p = e \cdot d$, where e is elementary charge and d length of tubulin heterodimer (8 nm). It yields the value of $p = 1.48.10^{-27}$ C m $\simeq$ 500 D, the value of the static dipole moment. In our previous work, we have only taken the value of the total static dipole moment ~1000 D.

18.1 Introduction

The prevailing view of neural information processing is based on passive properties of the membrane derived from the application of linear cable theory to dendrites, e.g., [114]. Recent studies, however, have suggested nonlinear models that accommodate new experimental evidence that appears to be inconsistent with this classical view. In particular, conventional theories do not satisfactorily explain: (a) significant fluctuations of synaptic efficacy over short periods of time in response to a recent burst of activation, e.g., [54], (b) a variety of active ion-channels capable of affecting the local membrane electric properties, and (c) nonlinear responses localized to specific dendritic sites, pointing to highly specialized mechanisms correlated with specific inputs. On the other hand, nonlinearities inherent in the new models, e.g., [74,133], give rise to a wider repertoire of (computational) capabilities, such as multiplication, fast correlation, etc. Moreover, experimental and theoretical support for conductive properties of protein filaments and the ionic clouds around them is becoming available, which indicates a far more complex picture of the signaling and information processing phenomena in neurons and other cells.

In this chapter, we suggest that functional electrodynamic interactions between cytoskeletal structures and ion-channels are central to the neural information processing mechanism. These interactions are supported by long-range ionic wave propagation along microtubule networks and actin filaments, and exhibit subcellular control of ionic channel activity, hence impacting the computational capabilities of the whole neural function. Cytoskeletal biopolymers, including actin filaments (AFs) and microtubules (MTs), constitute the backbone of wave propagation, and in turn interact with membrane components to modulate synaptic connections and membrane channels. Indeed, only recently clear functional interactions between these cytoskeletal structures have become apparent. Association of MTs with AFs in neuronal filopodia appears to guide microtubule growth, and plays a key role in neurite initiation [28]. This is further evidenced by the presence in neurons of proteins that interact with both MTs and F-actin, and proteins that can mediate signaling between both types of filaments. This is likely used to control microtubular invasion. The microtubule associated proteins MAP1B and MAP2, for example, are known to interact with actin in vitro, e.g., [146]. Cross-linking, MAP2 and/or MAP1B is highly probable to associate with both types of filaments contributing to the guidance of MTs along AF bundles. Extensive evidence exists confirming a direct interaction between AFs and ion channels, and a regulatory functional role associated with actin. Thus it is clear that the cytoskeleton has a direct connection to membrane components, in particular channels and synapses.

In the following, we demonstrate how each individual cytoskeletal component is capable of supporting both ionic and electronic wave propagation. In particular, we present a molecular dynamics model of the dendritic microtubule network (MTN) where arrays of MTs are interconnected by MAP2s. In this model, ionic waves propagate along the MTN and interact with C-termini of MTs to generate collective modes of behavior. Also in this chapter, a biophysical model of nonlinear ionic wave propagation along AFs is presented, supported by experimental evidence. Finally, we describe a model for a direct regulation of ion-channels and synaptic strength by AFs and networks of MTs that control the electrical response of the dendrite in particular, and the neuron in general. We begin this chapter by providing a general overview of the structure and function of a nerve cell, emphasizing the role of cytoskeletal filaments, ion channels, and their interactions.

18.2 The Neuron

The neuron is the quintessential communicating cell. A great variety of neural subtypes can be found interconnected to one another in complex electrochemical circuits via multiple synaptic connections. Thus, the amount of information processing by a neural circuit depends on the number of such connections or synapses. Neurons are highly polarized cells, whose level of morphological complexity increases during maturation into distinct subcellular domains. A typical neuron possesses three functional domains. These are the cell body or *soma* containing the nucleus and all major cytoplasmic organelles, a single axon, which extends away from the soma and takes cable like properties, and a variable number of dendrites, different

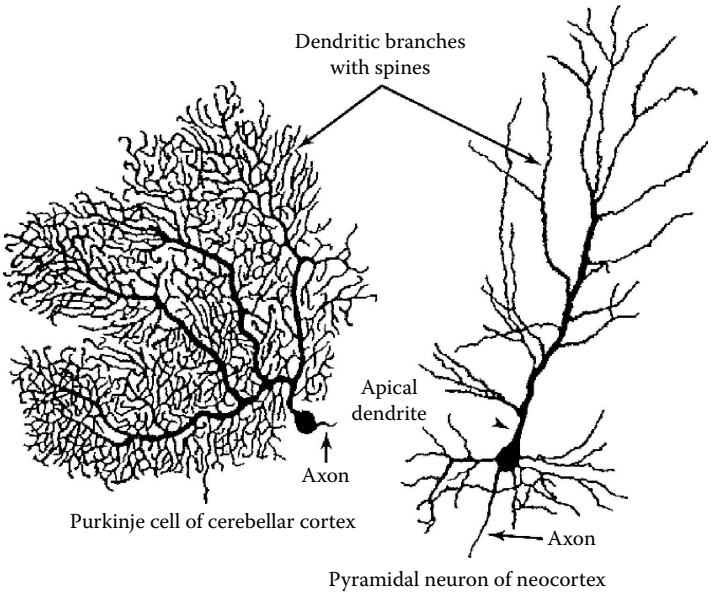

FIGURE 18.1 Two prominent examples of nerve cells.

in shape and complexity, which emanate from the soma. The axonal terminal region, where the synapse contacts it with other cells, displays a wide range of morphological specialization (see Figure 18.1).

Two major types of synapses can be found: (a) asymmetric, responsible for the transmission of excitatory impulses, and (b) symmetrical, present in inhibitory synapses. Turning morphology into a functional feature, the soma and dendritic tree are the major domains of receptive inputs. Thus, both the dendritic arborization and the axonal ramifications confer a high level of sub-cellular specificity in the localization of particular synaptic contacts on a given neuron. The extent to which a neuron may be interconnected largely depends on the three-dimensional spreading of the dendritic tree. Dendrites contain a large number of dendritic spines, which are small sac-like organelles, projecting from the dendritic trunk. Dendritic spines are more abundant in highly arborized cells such as pyramidal neurons, and scarcer in lowly interconnected smaller-sized dendritic tree inter-neurons.

Spines are the dendritic regions where most excitatory inputs are found, such that each spine contains one asymmetric synapse. The number of excitatory inputs can be correlated with the number of spines present in the dendrite. Dendritic spines are complex saccular enlargements, containing ribosomes, and cytoskeletal structures, including actin, and α- and β-tubulin. Electrically speaking, a single neuronal circuit is closed such that afferent inputs reaching the soma and the dendritic tree are transferred to the axon at the other pole of the cell which, in turn, is responsible for transmitting efferent neural information. Both the morphology of the axon and its course through the nervous system are correlated with the type of information processed by a particular neuron, and by its interconnectivity with other neurons. While the axon leaves the soma with a small swelling known as the axon hillock, some neurons protrude the axonal projection from the main dendrite instead. Cytoskeletal components are highly relevant in the structure/function of the neuron. The axonal hillock contains large "parallel" bundles of MTs. Axons are also located with other cytoskeletal structures, such as neurofilaments, which are more abundant in axons than in dendrites. The dynamics in cytoskeletal structures is central to our contention that information can be processed and "delivered" to the synaptic function by changes in the cytoskeletal structures.

Dendrites are the principal element responsible for synaptic integration and for the changes in synaptic strengths that take place as a function of neuronal activity. While dendrites are the principal sites for excitatory synaptic input, little is still known about their function. The activity patterns inherent to

the dendritic tree-like structures, such as in integration of synaptic inputs, are likely based in the wide diversity of shapes and sizes of the dendritic arborizations [116]. Some dendrites are unipolar, while others are multipolar; some have many orders of branching, while others have only one or two; and some branch primarily in two dimensions, while others have complex three-dimensional structures. The size and complexity of dendritic trees increase during development, which has been associated with the ability of the neural system to organize and process information [49]. The majority of synapses, both excitatory and inhibitory, terminate on dendrites, so it has long been assumed that dendrites somehow integrate the numerous inputs to produce single electrical outputs. It is increasingly clear that the morphological functional properties of dendrites are central to its integrative function. Branching in this context is essential to the increasingly complex ability of the neuron to respond to developmental complexity. Nerve branching and complexity are controlled by both external and internal cues. Of current interest to this are substrate and electromagnetic fields, while also recognized are the chemical gradients involved in local adaptation. Highly relevant to adaptation is cytoskeletal dynamics, as the dendritic cytoskeleton plays a central role in the process of ramification, filopodia formation, and more specialized neuronal activity such as long-term potential (LTP) and long-term depression (LTD) circuit dynamics, including memory formation.

The electrotonic or passive properties of dendrites became of great importance to our understanding of dendritic integration of synaptic signals. Early hypotheses were supported by work on motor neurons [34] and sensory receptors [38,67]. In that action, potentials were initiated in the axon hillock region as a result of the graded or algebraic summation of EPSPs and IPSPs occurring in various parts of the neuron. Because of the relatively short space constant calculated for motor neurons [18], it was predicted that excitatory post-synaptic potentials from synapses on the distal portions of dendrites would be ineffective in firing a neuron. Rall [115] revolutionized the field of dendrite physiology by using cable theory for the study of neurons and their dendrites. Action potentials initiated in dendrites by synaptic stimulation were later observed propagating in both directions at velocities of around 0.3 m/s. [7,21,43]. Direct intracellular recordings from dendrites of cerebellar Purkinje cells [84], cortical neurons [57], and hippocampal neurons [153] confirmed that action potentials could be initiated and propagated in dendrites. Very little is known, however, about the active, or voltage-dependent, properties of dendrites, and many questions remain unanswered. Such as the types of ion channels present in dendrites, location, and how active properties alter synaptic integration.

The firing of action potentials elicits characteristic M-shaped Ca^{2+} profiles across the neuron. The Ca^{2+} rise is small in the soma, highest in the proximal apical and basal dendrites, and small again in the distal apical dendrites [62,100,118–120]. The spatial distribution of Ca^{2+} channels explains the distinct Ca^{2+} rise in various cell locations but rather reflects the propagation into the dendrites of trains of action potentials. Imaging with Na^{+}-sensitive dyes has yielded similar patterns, suggesting that Ca^{2+} influx into the dendrites is driven by Na^{+} influx into the dendrites which is driven by Na^{+}-dependent action potentials [62]. Ca^{2+}-dependent action potentials have been demonstrated in hippocampal neurons and dendrites [131]. Most of the action potential induced Ca^{2+} entry is mediated by voltage-gated Ca^{2+} channels [100]. Multiple types of voltage-gated Ca^{2+} channels have been demonstrated in hippocampal neurons [36,40,68,101]. Based on the addition of specific Ca^{2+} channel blockers, the presence of L-, N-, P-, Q-, R-, and T-type Ca^{2+} channels has been reported [16]. This channel distribution may contribute to spike-triggered Ca^{2+} entry into the soma and apical dendrites. Both low-voltage activated (LVA) channels and at least one high-voltage activated (HVA) channel seem to be most predominant in regions of the dendrite at least a 100 mm from the soma. Experimental results strongly suggest a heterogeneous distribution of different types of voltage-gated Ca^{2+} channels within the soma and dendrites of hippocampal neurons [152]. The presence of Na^{+} channels in distal dendrites helps explain the back-propagation of action potentials well into the dendritic tree [88,89,138,139,141]. Action potential propagation in dendrites is rather low, and susceptible to the effects of cable filtering.

A most prominent feature of dendritic ion channel regulation is the potential boosting and enhancement of distal synaptic events. Voltage-gated Na^{+} and Ca^{2+} channels may play an important role in amplifying the magnitude of EPSPs towards the soma. However, channel regulation may also be important for

dendritic interactions in the immediate vicinity of the synaptic input. Voltage-gated channels may alter the local input resistance and time constant, which in turn would influence both spatial and temporal summation of EPSPs and IPSPs, thus conveying highly nonlinear interactions; signal amplification [64,137]. Thus, the nonlinear properties of dendrites may serve as electronic devices. In addition to providing an output, the action potentials elicited by synaptic input, whether initiated at the local synaptic sites or at the axon hillock and back-propagated into the dendrites, would essentially reset the dendritic membrane potential. Action potentials might also provide feedback or an associative signal to other synapses active just before or just after the action potential.

Back-propagating action potentials may also provide feedback to dendritic synapses after a neuronal output has occurred. Ca^{2+} signals are implicated in post-synaptically-induced synaptic plasticity such as short-term potentiation (STP) [92], LTP, and LTD [8,15]. Actin has long been postulated to play important roles in neuronal morphogenesis. High concentrations of actin have been found in the leading edge of the growth cones of developing neurons, and in synapses of mature neurons. Actin filament dynamics also plays a role in a number of related phenomena, including axon initiation, growth, guidance, and branching, in the morphogenesis and stability of dendrites and dendritic spines in synapse formation and stability. Neurons conduct two types of cytoplasmic growth processes in axons and dendrites, both of which are functionally and morphologically distinct, but are developmentally led from the growth cone. Growth cones are composed of finger-like filopodia and veil-like lamellipodia that help the growing processes explore their environment. Axons travel long distances, and upon reaching their targets, produce terminal branches where the growth cones are converted into pre-synaptic terminals. Dendrites usually do not extend such long distances, but often branch extensively, giving rise to dendritic trees. Upon proper contact with axons, post-synaptic dendritic specializations create functional synapses by opposition with the pre-synaptic terminals of axons. These are localized to small protrusions on their dendritic trees called dendritic spines, which are the site of most excitatory synapses. In the mammalian brain these multiple synaptic connections are believed to play important roles in learning and memory. Thus, neural morphogenesis requires changes in both the underlying cytoskeleton and specific interactions with the plasma membrane. To generate a membrane protrusive structure such as an axon, coordinated changes in actin and microtubular organization are required. Growth cones of developing neurons, for example, rapidly extend and retract filopodia by concentred changing in cytoskeletal dynamics, namely bundled AFs in filopodia, and composed of a cross-linked actin network in lamellipodia [80,81,155]. In this section, we have outlined the main features of signaling taking place within a neuron. Major emphasis was placed on the role played by the cytoskeleton in the neuron's structure, growth, and internal signaling. The next section discusses the main biophysical properties of the cytoskeleton.

18.3 The Cytoskeleton

The cytoskeleton is a major component of all living cells. It is made up of three different types of filamental structures, including actin-based microfilaments (MFs), intermediate filaments (IFs) (e.g., neurofilaments, keratin), and tubulin-based microtubules (MTs). All of them are organized into networks, which are interconnected through numerous particular proteins, and which have specific roles to play in the functioning of the cell. The cytoskeletal networks are mainly involved in the organization of different directed movements in cell migration, cell division, or in the internal transport of materials. Polymerization of MFs is responsible for cell migration and for the remodeling of the leading edge of cells. Molecular motors are protein complexes associated with the cytoskeleton and drive organelles along MTs and MFs in a "vectorial" transport.

MTs are some of the most basic and important cytoskeletal elements in the morphological scheme of neurons. As for the case of cytochalasins in actin structures, the addition of microtubular modifying agents was first used to assess the role of MTs in axon elongation. Microtubular disrupting agents affect axons first and have no early effects on growth cones and filopodia, suggesting that MTs provide support for the axon. Conversely, microtubular invasion may be a critical element in the formation of neurite projections. Initially, expanded lamellipodia first undergo segmentation at certain spots where MTs accumulate in an

ordered array [27,144,156] and gradually "migrate away" from the cell body. These lamellipodia transform into nascent growth cones. Neurite elongation takes place as the MTs in the shaft become compressed into a narrower bundle. In cultured hippocampal and cortical neurons, this process most likely implies the coordinated control of the major cytoskeletal components, including actin, MTs, and associated proteins.

Thus, MTs are essential for neurite development. One particular aspect of microtubular involvement in neurite outgrowth is vesicular transport. Most membrane insertion occurs at the growth cone of axons [22,24]. MAP-stabilized MTs, form parallel or antiparallel arrays, which might act as compression resistant struts inside neurites [61]. Because MTs constantly invade the actin cytoskeleton in lamellipodia of epithelial [125] and neuroblastoma cells [27], such a mechanical role for MTs could also be important during de novo neurite initiation. Neurite-like protrusions, for example, can be induced in non-neuronal cells by the exogenous expression of stabilizing proteins such as MAP2 and tau [72,79,157]. Spontaneous neurite initiation is dependent on both the presence and the dynamic properties of MTs.

A number of proteins associate with MTs, including MT motors, kinases, so-called "structural" MAPs, which alter microtubule structure, and specialized MAPs, which bind to microtubule plus or minus ends. Members of the MAP2/tau family have long been proposed to be important regulators of neurite behavior [10,48,151]. MAP2 and tau stabilize MTs by reducing catastrophe and promoting rescues, leading to prolonged growth periods and thus enhanced net microtubule accumulation [32,45,75]. MAP2 and tau stabilize MTs by binding along the outer ridges of protofilaments [2].

F-actin and MTs cytoskeletal networks are typically thought to fulfill separate, independent cellular roles. Highly dynamic actin networks are known for their role in cell spreading and contraction. The more stable MT cytoskeleton is known for its importance in cell division and organelle trafficking. However, recent studies provide important roles for the actin cytoskeleton in cell division and trafficking and for MTs in the generation and plasticity of cellular morphology. A direct physical association between both cytoskeletons has been suggested, because MTs often preferentially grow along actin bundles and transiently target actin-rich adhesion complexes.

Association of MTs with actin cables in filopodia appears to guide microtubule growth along the most efficient path anti-parallel to retrograde flow [130]. Thus, specific coupling between MTs and actin bundles presumably promotes MT advance. Proteins that are able to interact with both MTs and F-actin, or proteins that can mediate signaling between both cytoskeletons likely control the regulation of MT invasion. This is further strengthened by specific microtubule association of the microtubule-associated proteins MAP1B and MAP2, both known to interact with actin in vitro [20,109,128,134,146]. Furthermore, MAP2 binds to F-actin and efficiently induces actin bundle formation [51,129]. It is likely that by crosslinking, MAP2 and/or MAP1B associated with both cytoskeletons could be involved in the guidance of MTs along actin filament bundles. Alternatively, MAPs could shuttle from MTs to actin and could alter F-actin behavior by actively crosslinking AFs.

The effect of changes in the cytoskeleton on ion channel activity has been the focus of recent attention. Most studies have employed drugs that selectively stabilize or destabilize either AFs or MTs, with resulting effects on specific ion channel activity, either as changes in whole cell conductance or single channel activity by the patch clamping techniques. Although direct binding of specific cytoskeletal proteins to individual channel proteins remains to be demonstrated, recent work in which exogenous purified actin has been added to the cytoplasmic side of channels excised from the cell membrane has in numerous cases directly confirmed an effect of cytoskeletal filaments. A body of earlier evidence suggested that various cytoskeletal components, including actin and actin-associated proteins, anchor, co-localize, and regulate both the spatial stability as well as the function of ion transport proteins. It is possible that actin either binds directly to the channels, or that actin may first interact with actin-binding proteins, which in turn regulate (by binding or other indirect interaction) ion channel function. Independent studies demonstrated that membrane-resident CFTR is functionally regulated by AF organization, which may also involve a direct interaction with actin. Thus, ion channel may be controlled by direct and indirect cytoskeletal interactions.

Before we present an integrated view of the conductive properties of the active and passive structural blocks of the cytoskeleton, we should review the current state of knowledge regarding their conductive properties.

18.4 Overview of Biological Conductivity

Cope [19] has presented a detailed review of the applications of solid-state physics concepts to biological systems. He divided the discussion into seven groups. The first involves semiconduction of electrons across enzyme particles as a rate-limiting process in cytochrome oxidase, evidenced by kinetic patters of enzymes and microwave Hall measurements. Second, pn-junction conduction electrons were suggested by kinetics of photobiological free radicals in the eye and in photosynthesis. Their I-V characteristics conform to the diode equation:

$$I = I_0 exp(V/kT) \tag{18.1}$$

Third, there may be a connection between superconduction and growth in nerves. Fourthly, phonons and polarons are involved in mitochondrial phosphorylation. Next, piezoelectricity and pyroelectricity may be involved in the growth of nerves and bone structures. Then, infrared electromagnetic waves may transmit energy in lipid bilayers of nerves and mitochondria. Finally, complex sodium and potassium ions in structured cell water may be analogous to valence band electrons in semiconductors, free cations being analogous to conduction electrons. The ionic process in cell water resembles electronic conduction in seminconductors. For dried proteins or DNA, Szent-Gyorgi[142] noticed that their conductivities obeyed the relationship:

$$\sigma = \sigma_0 exp(-E_a/kT) \tag{18.2}$$

With activation energies E_a on the order of 1 eV. The presence of water may cause considerable changes in conductivities, (for example, in cytochrome oxidase this may be reduced to 0.3 eV).

Adessi *et al.* [1] have provided a theoretical treatment of transmission through a poly(g)DNA molecule. They found that there was a modification of the rise of a B-DNA form, which can induce a shift of the conduction channel towards a valence one. They found that deformation of the backbone of the molecule has a significance on the hole transport. Furthermore, the presence of ionic species (e.g., Na) in the surrounding of the molecule can create new conduction channels. In photo-excitation experiments, hole transport occurs through coherent transport at short distances and long-range incoherent or hopping transport at large distances. Fink *et al.* [39] studied the metallic behavior in λ DNA using an electron projection technique. Superconducting behavior has been observed by Kasumov *et al.* [66]. Porath *et al.* [111] observed semiconductor behavior with a poly(g)-poly(c)DNA molecule. A scanning force microscope has been used by de Pablo *et al.* [26] to observe insulating behavior. This paper models a single poly(g) DNA lying between electrodes, and transmission was computed with a Landauer–Buettiker formalism based on Green's functions. The electronic properties of O_2-doped DNA have been studied by Mehrez *et al.* [96], who suggested that DNA conduction is affected by O_2-doping, in particular hole doping. However, ab initio atomic structure calculations of O_2-doped DNA indicate negligible charge transfer. The absence of dc conductivity in λ DNA has been investigated by de Pablo *et al.* [26]. First principles electronic structure calculations indicate a minimum DNA resistance of 10^{16} Ω per molecule, and a minimum resistivity of 10^4 Ωm. However, lower energy electron bombardment may dramatically increase conductivity and with electron energies between 50 and 200 eV may lead to metallic conduction with a resistance of 2×10^8 Ω. Fink *et al.* [39] discussing DNA and conducting electrons stated that I-V characteristics of DNA indicate ohmic-like behavior with a resistance of 2 $M\Omega$ for a 600 nm-long DNA rope corresponding to $\rho = m\Omega$ cm. These authors speculate that DNA may be semiconducting, insulating, or metallic simultaneously depending on the arrangement of molecules in the structure. Endres *et al.* [37] discussed the quest for high-conductance DNA saying that DNA conduction is an unsolved problem first enunciated by Eley and Spivey [35]. Experimental outcomes range from insulating to semiconducting to even superconducting, and the uncertainties depend on: (a) contacts between the electrodes and the DNA and (b) differences in the molecules (sequence, length, arrangement, preparation) within the DNA. It appears that drying DNA can lead to conformations with localized electronic high states, although hole doping of the backbone by counter-ions might also be possible. Wet DNA may support electrical current due to solvent impurity

states in the large high-Π^* energy gap. Davies and Inglesfield [25] discussed the embedding method for conductance of DNA calculations. It is believed that the pathway for transport in DNA runs through the bases in the center of the double helix molecule. The dominant transport mechanism for DNA appears to be coherent hopping. Calculations show extreme sensitivity to the choice of contact orbitals.

Marechal [95] discussed the transfer of protons as a third fundamental property of hydrogen bonds. The importance of the cooperative resonance types in cyclic structures is stressed. Proton transfers along H-bonds have been discussed as a mechanism of vital importance for chains, helices, and in cyclic structures such as rings. Consta and Kapral [17] discussed proton transfer in mesoscopic molecular systems. Proton transfer rates and mechanics are studied theoretically with solvent molecules in solution. The proton transfer occurs as a result of orientational fluctuations on the cluster's surface. The environment influences solvent effects and reaction rates. The rate constant was established to be 1/59 ps at 260 K and for the bond length fixed at 2 Å. Morowitz [102] discussed proton semiconductors and energy transduction in biological systems. He presented the possibility of protochemistry paralleling electrochemistry. ATP synthesis was discussed as coupled to proton transport assuming a gated protein semiconductor across a membrane. Protein conduction in biological structures involves the water of hydration and protein molecules.

Ripoll *et al.* [121] investigated ionic condensation and signal transduction. Ion condensation on biopolymers at a critical value of the charge density may lead to intra-cellular signaling due to the diffusion of condensed counter-ions in the near region along cytoskeletal filaments. A feedback mechanism was proposed between condensation/decondensation of calcium and the activation of calcium-dependent enzymes. This is shown to create coherent patters of protein phosphorylation. It was postulated that ion condensation operates in signal transduction. In the case of polymer ionics [117], the conductivity depends on temperature via the formula:

$$\sigma T = Aexp[-B/(T - T_o)] \tag{18.3}$$

indicating activated hopping. The concept of the Fermi level in solution has been extended by Bockris and Khan [9] through the introduction of a reversible potential for a redox couple.

Unfortunately, measurements of conductivity of biopolymers (including MTs) are fraught with difficulties due to their structural heterogeneity, strong dependence on the environmental conditions (pH, ionic concentration, temperature, etc.), and the inherent liquid state of the sample. Nonetheless, attempts have been made recently to measure resistance values of MTs, both intrinsically and as ionic conduction cables. Fritzsche *et al.* [41] made electrical contacts to single MTs following dry-etching of a substrate containing gold microelectrodes. Their results indicate intrinsic resistance of a 12 micron-long MT to be in the range of 500 megaohms, giving a value of resistivity of approximately 40 mega-ohms/micron in their dry state. The same group performed measurements on gold-coated MTs [42] which were covered with a 30-nm layer of gold following sputtering. The resistance of the thus metallized MTs was estimated to be below 50 ohms, (i.e., originated entirely due to the metallic coating). Minoura and Muto [99] measured the ionic conductivity of MTs using an electro-orientation method under an alternating electric field. The ionic MT conductivity was calculated as $1.5 + / - 0.5$ mS/m, which is approximately 15 times greater than that of the buffer solution. This was attributed to the counter-ion polarization and is consistent with another recent study of ionic conductivity along MTs. Furthermore, Goddard and Whittier [47] reported their measurements of RF reflectance spectroscopy of samples containing the buffer solution, free tubulin in buffer, MTs in buffer, and finally, MTs with MAPs in buffer. The sample size in each case was 5 ml. The concentration of tubulin was 5 mg/ml and in the last case the concentration of MAP2 and the tau protein was 0.3 mg/ml. The average DC resistance reported by these authors was (a) 0.999 $k\Omega$ (buffer), (b) 0.424 $k\Omega$ (tubulin), (c) 0.883 $k\Omega$ (MTs), and (d) 0.836 $k\Omega$ (MTs + MAPs). It's not straightforward to translate these results into resistivity of MTs without making assumptions about their geometrical arrangement and connectivity. However, assuming all tubulin being polymerized in case (c) and a uniform distribution of MTs forming a combination of parallel and series networks, one can find the resistance of a 10 μm–long MT, forming a basic electrical element in such a circuit, to have approximately an 8 $M\Omega$ resistance. This compares very favorably to an early theoretical estimate of MT conductivity based on the Hubbard model with electron hopping between tubulin monomers. This model predicted the resistance of a 1-μm MT

to be in the range of 200 $k\Omega$, hence a 10-μm MT would be expected to have an intrinsic resistance of 2 $M\Omega$, within the same order of magnitude as the result reported by Goddard and Whittier [47]. While direct experimental analysis of intrinsic conductivity of the various cytoskeletal components is still nebulous, theoretical modeling of these effects is very well developed. The next section presents our current understanding of the intrinsic conductivity of MTs.

18.5 Intrinsic Electronic Conductivity of Microtubules

Microtubules (MTs) are ubiquitous in eukaryotic cell biology. Their primary role is to serve as the cellular scaffold and act as a corridor for the transport of vesicles through the cell by motor proteins. The interest in MTs stems from their involvement in a number of crucial cellular processes including mitosis and, more recently, the discovery of their role in the communication between the exterior of the cell and the nucleus [46,94]. The special arrangement of MTs just prior to chromosone separation makes them an ideal candidate for mediating a signal of some sort, which would cause the coordinated breakage of sister chromatids. In the axons of nerve cells, the MTs are arranged in bundles, parallel to the axon [56]. These groups of MTs span the entire length of the axon and might serve to carry signals from the cell body to the nerve terminus or vice versa. No mechanism for this sort of direct feedback is known. We demonstrate here that the MT may be able to conduct a current along its length through a process of electron hopping between binding sites on each dimer.

The MT is made up of a protein called tubulin. Each subunit contains α-tubulin and β-tubulin monomers joined together to form a dimer. The dimers are connected end to end to form a protofilament. These protofilaments, usually 13 in number, are wrapped up to form a hollow tube, the MT. The dimers are themselves 5 nm in diameter and have a length of about 8 nm. A MT has an outer diameter of 25 nm and an inner diameter of 15 nm (see Figure 18.2).

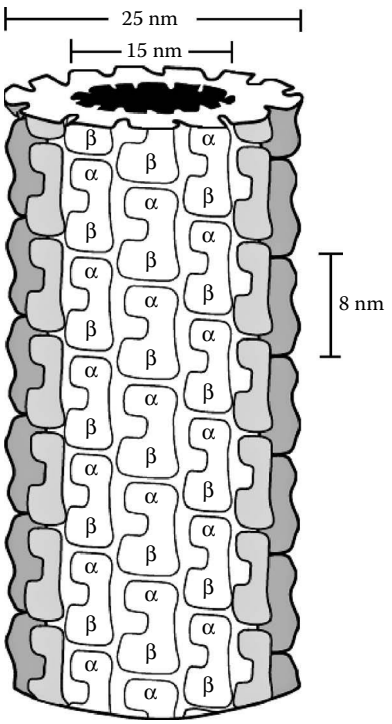

FIGURE 18.2 Structure of a typical microtubule demonstrating how it is formed by a special arrangement of tubulin dimers.

The tubulin dimer of which the MT is composed has at least two different conformational states [58]. That is, while the amino-acid chain of the protein remains fixed, its three-dimensional shape may change. It is believed that these conformational changes are the result of hydrolysis and an associated charge movement from one binding site within the molecule to another. It is precisely this charge movement that may lead to the conduction through the polymer.

One may take a semi-classical view of the movement of electrons along the protofilament. We ignore the fact that the protofilament is nearly one-dimensional and consider its *bulk* properties. Assuming two conduction electrons for each tubulin dimer, the conduction electron density is

$$\begin{aligned} n_0 &= 2/(8nm \times 5nm \times 5nm) \\ &= 1.0 \times 10^{19}/cm^3. \end{aligned} \tag{18.4}$$

In comparison with other materials, this value is slightly higher than typical semi-conductor concentrations, usually $10^{13} - 10^{17}/cm^3$, but is much less than typical metals, which have a conduction electron density of $10^{22} - 10^{23}/cm^3$. However, the electrons are expected to have relatively low mobilities unless they are excited from the ground state configuration. The excitation energy is a function of both the number of electrons within the protofilament and its size. Suppose that the mobility of excited electrons is at least similar to the mobility of electrons within semiconductors, such as Si where the electron mobility, μ_e, is about 1300 $cm^2\ V^{-1}\ s^{-1}$. The electrical conductivity σ is given in a semi-classical model by the well-known formula

$$\sigma = ne\mu_e \tag{18.5}$$

where e is the electron charge and n is the conduction electron density given by

$$n = n_0 e^{-\Delta/\kappa T} \tag{18.6}$$

where n_0 represents the total number of electrons. If we assume that the gap between valence and conduction bands, Δ, is about 0.40 eV, then at physiological temperature, some of the carriers will be excited and should be available to conduct. Applying the preceding formula (18.6), a conductivity of about 10^{-2} (in SI units) is expected for the protofilament.

$$\sigma \sim (10^{25} e^{-0.40/0/026})(1.6 \times 10^{-19})(0.13) \sim 0.04\Omega^{-1} m^{-1} \tag{18.7}$$

However, if the hybridization of electronic orbitals lowers the gap to a value closer to zero, the expected conductivity would be significantly higher:

$$\sigma \sim (10^{25})(1.6 \times 10^{-19})(0.13) \sim 2 \times 10^5 \Omega^{-1} m^{-1} \tag{18.8}$$

These values should be compared to values in excess of 10^8 for copper and other good conductors, and 10^7 for lesser conductors and semi-metals. Typical semi-conductors such as Si and Ge have intrinsic conductivities of $10^{-3} - 10^{+1}$ at room temperature, but when heavily doped, the conductivity may rise to between 10^4 and 10^5.

In order to model the MT as a semiconductor, the individual tubulin dimer must first be physically analyzed. The $\alpha\beta$-tubulin dimer is comprised of about 890 amino acids which represents about 13000 nuclei. A gross simplification which we introduce is to treat each monomer as having an effective site energy for electronic binding. Fluctuations of the site energy on scales less than the monomer spacing are therefore washed out. It is convenient to model this system as two quantum wells separated by a potential barrier. The two wells represent two binding sites for an electron, which may hop between the monomers, resulting in the change of molecular conformation. We can estimate the relevant parameters of the well depth and the well width from kinetic studies and with a knowledge of the molecule's overall geometry. Once the bound states and their energies are known for this system, this knowledge may be applied to a

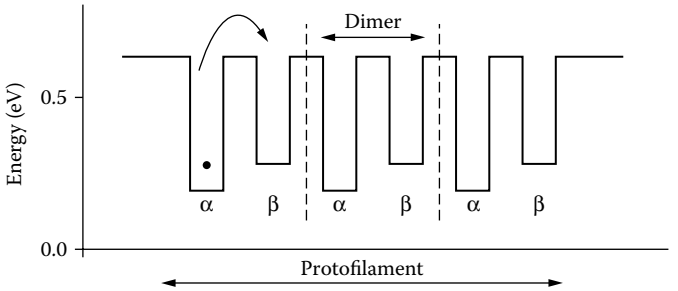

FIGURE 18.3 A one-dimensional chain of quantum wells representing the energy profile along a MT protofilament where the α and β monomers have alternating site energies.

second-quantization scheme. This procedure allows us to make progress without specifically requiring us to solve for the wavefunction of the system.

A 1D chain of quantum double wells is pictured in Figure 18.3. For simplicity, we are initially making each binding site have the same energy. If this is related to GTP hydrolysis, they may differ by about 0.17 eV (4 kcal/mol) [59]. This is roughly the quantity of energy stored in the lattice when GTP is hydrolyzed to GDP [13,60]. The barrier height between dimers has been estimated from kinetic data. The bond strength must be somewhat larger than the hydrolysis energy delivered to the lattice or else hydrolysis of the dimers would cause immediate disassembly. Hopping along the protofilament by electrons presumably has an energy comparable to this binding energy. We have estimated 0.4 eV for intra-dimer hopping and 1.0 eV for the inter-dimer hopping. What may be varied in the model, is the central barrier which must be overcome for each tubulin dimer to change conformation. If it is nearly as large as the barrier to electron movement between dimers, then the protofilament will look like a chain of single quantum wells rather than double quantum wells because the difference between the α and β monomers will not be distinguished. However, if the central barrier is too small, the chain will again look like a series of single quantum wells since the effect of the barrier would be negligible. The depth of the deeper well, f_1, has been selected as 0.4 eV initially. Given the value, we assumed a 25% difference in well depths. If f_1 is much larger, the dimer nature of the protofilament is lost because the wells are effectively the same depth.

The results for the single electron eigenstates of a double quantum-well may be found using a transfer matrix method for the time-independent 1D Schrodinger equation in each interval in which the piece-wise constant potential is defined as

$$\hat{H}\psi = \frac{\hat{p}^2}{2m}\psi + \hat{V}\psi = E\psi \tag{18.9}$$

The oscillatory solution

$$\psi(x) = A\cos(kx) + B\sin(kx) \tag{18.10}$$

applies to $E > V$ where

$$k = a\sqrt{2m(E-V)}/\hbar \tag{18.11}$$

while for $E < V$, the solutions are exponentially damped

$$\psi(x) = Ae^{\kappa x} + Be^{-\kappa x} \tag{18.12}$$

where

$$k = \sqrt{2m(V-E)}/\hbar \tag{18.13}$$

Now, matching conditions for the wave function and its derivative are applied at each interface. This gives a 2×2 matrix relating the coefficients in the wave function expansion according to

$$\begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = \begin{pmatrix} {}^{2,1}M_{11} & {}^{2,1}M_{12} \\ {}^{2,1}M_{21} & {}^{2,1}M_{22} \end{pmatrix} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} \tag{18.14}$$

In the preceding equation, the superscript to the left of the M denotes which coefficients are being linked. The subscripts indicate the matrix element. In an iterated fashion, one eventually arrives at the following:

$$\begin{pmatrix} A_n \\ B_n \end{pmatrix} = \begin{pmatrix} {}^{n,1}M_{11} & {}^{n,1}M_{12} \\ {}^{n,1}M_{21} & {}^{n,1}M_{22} \end{pmatrix} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} \tag{18.15}$$

Now, for bound states $A_1 = B_n = 0$ so that the wavefunction decays outside the region of the quantum wells:

$$B_n = 0 \quad \Rightarrow \quad {}^{n,1}M_{22} = 0 \tag{18.16}$$

Given the choices for our quantum double well (width, $a = 2$ nm; and height, $V = 1.0$ eV), one finds that there are two bound states for this dimer problem. As the number of dimers is increased, one resorts to numerical analysis. In Figure 18.4, the energy of the two bound states is plotted as the energy of the central barrier is varied. The lowest energy state is the symmetric wavefunction, which increases in energy sharply as the central barrier is increased. The second bound state is the antisymmetric wavefunction it has a node within the barrier, hence its energy increases only marginally.

The energy calculation for a sequence of n such dimers leads to the development of bands as hybrid orbitals develop across the polymer. Roughly speaking, one band is of hybridized symmetric orbitals and the higher lying band of hybridized antisymmetric orbitals. The separation of the two bands and the spread of each individual band determine the values of the parameters which shall be used in the tight-binding Hubbard model used to model the polymer.

The second-quantized Hamiltonian for a many-electron multidimer system becomes

$$\hat{H} = \sum_{i,\sigma} \epsilon_i \hat{c}^{\dagger}_{i\sigma} \hat{c}_{i\sigma} + \sum_{i \neq j,\sigma} t_{ij} \hat{c}^{\dagger}_{i\sigma} \hat{c}_{j\sigma} \tag{18.17}$$

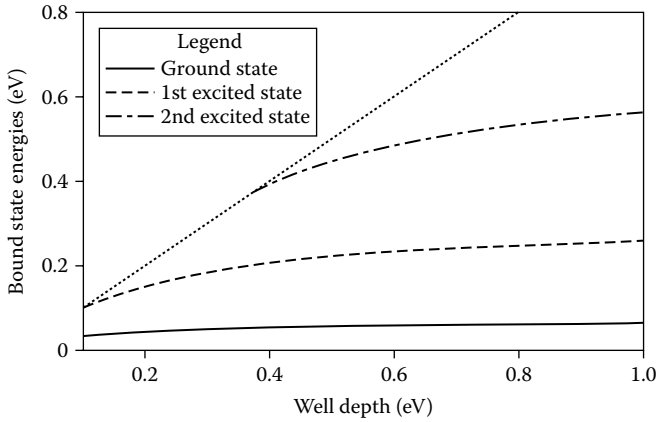

FIGURE 18.4 Variation of the bound state energies with the depth of the double quantum wells, $f_1 = f_2$. The straight line indicates where the bound state energy is equal to the well depth.

where the operators $\hat{c}^{\dagger}_{i\sigma}$ and $\hat{c}_{i\sigma}$ are the usual fermion creation and annihilation operators, and where i runs from 1 to $2n$ representing the two sites on each of the n dimers. The ϵ_i represent the potential energy at each site and the kinetic terms t_{ij} account for hopping from one site to another. There are two different kinds of interactions depending on whether an electron hops within a dimer, or between dimers. Hence, this kinetic parameter has two different values along the chain. Since there are no interactions between the states with $+\frac{1}{2}$ spin and those with $-\frac{1}{2}$ spin, the state space may be divided into two identical subspaces labeled by the electron spin. In each of these subspaces, the matrix corresponding to this chain of dimers is tri-diagonal and may be diagonalized to determine the itinerant eigenstates of the system. The coefficient t_d which represents the movement of an electron within a dimer causes the eigenstates to be split into two bands by an amount, $2t_d$. Within each of these bands, the coefficient t_l of the inter-dimer hopping, causes these two single electron bands to broaden each to about $2t_l$. Now, although the preceding description is qualitative, clearly whenever $t_d \sim t_l$, these bands will overlap and transitions between the states will be important.

Considering the band formation in the quantum well formulation, we can assign values to t_d and t_l. The two bands are separated by about 0.40 eV, so $t_d \sim 0.20$ eV, and using the bottom band to estimate t_l it widens until it is about 0.10 eV thick, so $t_l \sim 0.05$ eV.

The Hubbard model is the simplest second quantized model to capture all of the essential features of a real system of interacting particles [82]. In this model, electrons are the fundamental excitations. All states may be built up from the vacuum using the fermion creation operators. Once the number of sites is selected, n, and the number of electrons is determined, e, there are

$$\binom{2n}{e} = \frac{2n!}{e!(2n-e)!} \tag{18.18}$$

distinct electronic states. These states are built up by applying in normal order each of the combinations of e-electron states.

The second quantized Hamiltonian for the Hubbard model with electron–electron interactions is conventionally written as

$$\hat{H} = \sum_{i,\sigma} \epsilon_i \hat{c}^{\dagger}_{i\sigma} \hat{c}_{i\sigma} + \sum_{i \neq j,\sigma} t_{ij} \hat{c}^{\dagger}_{i\sigma} \hat{c}_{j\sigma} + \sum_{i} U_i \hat{c}^{\dagger}_{i\uparrow} \hat{c}_{i\uparrow} \hat{c}^{\dagger}_{i\downarrow} \hat{c}_{i\downarrow} \tag{18.19}$$

The last term accounts for electron–electron repulsion now that we have gone to a many electron system. In our simple model, this is limited to an onsite interaction. To this point, we have made each of the site energies equivalent ($\epsilon_i = \epsilon, \forall i$). In what follows, $U = 2.0$ eV which is the energy associated with two bare electrons lying about 0.7 nm apart. This choice seems reasonable within a well of width 2.0 nm. We try to solve the problem by considering the electron–electron term as a perturbation to study how it affects the electronic states of the dimer. The Hamiltonian in the absence of the final U-term may be diagonalized by the following unitary transformation:

$$\alpha^{\dagger}_{1'\sigma} = \frac{1}{\sqrt{2}}(c^{\dagger}_{1\sigma} + c^{\dagger}_{2\sigma}) \tag{18.20}$$

$$\alpha^{\dagger}_{1'\sigma} = \frac{1}{2\sqrt{2}}(c^{\dagger}_{1\sigma} - c^{\dagger}_{2\sigma}) \tag{18.21}$$

The linear combination of operators is simple because we have made the site energies ϵ_1 and ϵ_2 equal. These new operators are easily shown to obey the usual anticommutation relations for fermions and are said to be in the itinerant or distributed electron basis. The Hamiltonian may now be rewritten in terms of these new operators, as

$$\hat{H} = \sum_{\sigma}(\epsilon + t)\alpha^{\dagger}_{1\sigma}\alpha_{1\sigma} + \sum_{\sigma}(\epsilon - t)\alpha^{\dagger}_{2\sigma}\alpha_{2\sigma} + \frac{1}{2}\sum_{\sigma \neq \sigma'} V_{ijlm}\alpha^{\dagger}_{i\sigma}\alpha^{\dagger}_{j\sigma'}\alpha_{l\sigma'}\alpha_{m\sigma} \tag{18.22}$$

the vacuum state is represented by $|\Omega>$. Acting with our Hamiltonian on this basis gives us the matrix form of the Hamiltonian:

$$\hat{H} = \begin{pmatrix} 2(\epsilon+t)+\frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} & \frac{(U_2-U_1)}{4} & 0 & \frac{(U_1+U_2)}{4} \\ 0 & 2\epsilon & 0 & 0 & 0 & 0 \\ \frac{(U_1-U_2)}{4} & 0 & 2\epsilon+\frac{(U_1+U_2)}{4} & -\frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} \\ \frac{(U_2-U_1)}{4} & 0 & -\frac{(U_1+U_2)}{4} & 2\epsilon+\frac{(U_1+U_2)}{4} & 0 & \frac{(U_2-U_1)}{4} \\ 0 & 0 & 0 & 0 & 2\epsilon & 0 \\ \frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} & \frac{(U_2-U_1)}{4} & 0 & 2(\epsilon-t)+\frac{(U_1+U_2)}{4} \end{pmatrix}$$

The Hamiltonian is then diagnolized in order to determine its eigenstates. In the absence of the Coulomb repulsion ($U = 0$), the electrons are localized on the $2'$ site with energy $2(\epsilon - t)$, the gap to the first excited state being $2t$. However, as U is increased, the effect of the Coulomb interaction raises the energy of the ground state relative to the excited singlet states, which do not feel the Coulomb repulsion. Consequently, the gap between the ground state and the first excited state is actually reduced through the introduction, as shown in Figure 18.5. Thus, when conductivity is being considered, it is important to bear in mind that the gap is reduced by the presence of the electron–electron interactions.

To this point, we have made each of the site energies equivalent, ($\epsilon_i = \epsilon$), and the electron repulsion the same at all sites ($U_i = U$). The lone complication lies within the kinetic term, where the hopping parameter will depend on the two sites between which the electron hops. However, since we first consider the MT protofilament, it shall initially be a constant as well, $t = 0.4$ eV, where the choice comes from the separation of the energy bands in the 1D Schrödinger picture.

Since the Hamiltonian conserves both the particle number and the overall spin of each state, we are free to work in subspaces enumerated by the spin of the states it contains. This reduces the problem slightly since it is possible to consider individually the spin $+1$, spin 0, and spin -1 systems separately in a two-electron system. In addition, the symmetry implies that the spin $+1$ and spin -1 systems have the same conductive properties. We also find that the ground state is always a state consisting of the lowest possible total spin.

When the inter-dimer hopping term is small relative to the intra-dimer hopping term $t_{inter} < t_{intra}$, the form of the ground state is independent of the number of dimers. In each case, the ground state is a linear combination of singlet states on each dimer. The singlet states are those where two electrons are

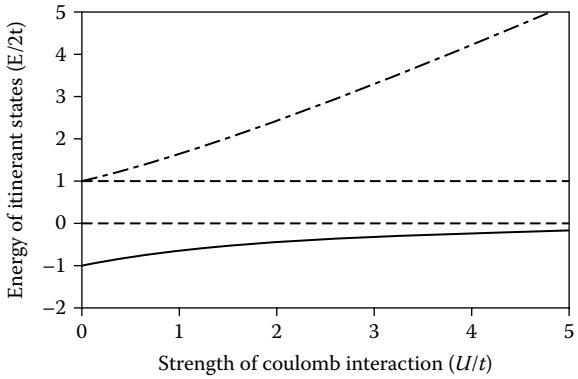

FIGURE 18.5 Energy of the itinerant states as a function of U/t with the energy plotted in units of $2t$.

paired on an individual binding site, or where the state consists of the anti-symmetric combination of an up-electron and a down-electron on neighboring binding sites of the dimer. When the inter-dimer hopping parameter is increased, the density of states becomes more uniform between the ground state and the highest energy eigenstate. With the gap between the ground state and the first excited state of the system becoming diminished. Since the hopping term within a dimer is largest, the system prefers to have two electrons with the same spin within the same dimer in the ground state.

For electronic conductivity, the band formation importantly depends upon the hopping parameter between dimers. When this parameter is small relative to the intra-dimer hopping, $t_{inter}/t_{intra} \sim 0.1$, there remains a rather large gap between the ground state and the first excited state of about $2t_{intra}$ which is reduced as the repulsion term increases. However, when the hopping between dimers is equal to the hopping within dimers, $t_{inter} \sim t_{intra}$, the gap is minimized. In the event that $t_{inter} > t_{intra}$, we would effectively have to relabel the dimers and would then return to the picture where $t_{inter} < t_{intra}$.

Kubo was the first to derive formulae for the electrical conductivity in solids, and his derivation is applied to our case in the present section [77]. In the Coulomb gauge, we write the vector potential for a uniform electric field along the direction of the chain, $A(t)$, as

$$A(t) = \frac{cE(t)}{-i\omega} e^{i\omega t}, \tag{18.23}$$

Adding a field-coupling term to the Hubbard Hamiltonian and using a canonical transformation gives [91]

$$\hat{H}_0' = -t \sum_{i\sigma} [\hat{c}_{i\sigma}^{\dagger} \hat{c}_{i+1\sigma} e^{-ieA(t)/c} + \hat{c}_{i\sigma}^{\dagger} \hat{c}_{i-1\sigma} e^{ieA(t)/c}]. \tag{18.24}$$

where a is the lattice spacing and c is the speed of light. Expanding to second order in the vector potential, we find

$$\hat{H}_A = \frac{A}{c} \hat{j} - e \frac{A^2}{c^2} a^2 \hat{H}_0, \tag{18.25}$$

where

$$\hat{j} = i\mathrm{Eat} \sum_{i\sigma} (\hat{c}_{i\sigma}^{\dagger} \hat{c}_{i+1\sigma} - \hat{c}_{i\sigma}^{\dagger} \hat{c}_{i-1\sigma}). \tag{18.26}$$

So, the energy of the original system is corrected to this order and the interaction term is proportional to the current.

Suppose a time-dependent external electric field is applied to a solid:

$$E_{\alpha}^{\mathrm{ext}}(r,t) = \Xi_{\alpha}^{\mathrm{ext}} e^{iq\cdot r - i\omega t}, \tag{18.27}$$

where α represents the Cartesian coordinate directions. In a linear response theory, the induced current is proportional to the applied electric field:

$$J_{\alpha}(r,t) = \sum_{\beta} \sigma_{\alpha\beta}'(q,\omega) \Xi_{\beta}^{\mathrm{ext}} e^{iq\cdot r - \omega t}, \tag{18.28}$$

where $\sigma_{\alpha\beta}'$ is a parameter relating the observed current density to the applied field's direction, its periodicity, and frequency. However, the symbol appearing in (18.28) is not the conductivity we seek. Rather, we want the conductivity which represents the response to the total electric field in the solid, a quantity that can be measured. This conductivity takes into account all of the currents, induced by the external fields, that

create their own electric fields. Thus, we seek $\sigma_{\alpha\beta}$ that relates the macroscopic electric field to the currents of the system.

$$J_\alpha(r,t) = \sum_\beta \sigma_{\alpha\beta}(q,\omega) E_\beta e^{iq\cdot r - i\omega t} \tag{18.29}$$

$$E_\alpha(r,t) = \Xi_\alpha e^{iq\cdot r - i\omega t} \tag{18.30}$$

$$\sigma_{\alpha\beta} = Re(\sigma_{\alpha\beta}) + i\,Im(\sigma_{\alpha\beta}) \tag{18.31}$$

We write the Hamiltonian of the system as $\hat{H} + \hat{H}'$ where the latter term contains the electric field, which we shall introduce as a time-dependent perturbation. The evolution of the operators is given as follows [30]:

$$\hat{j}(x,t) = e^{i\hat{H}t}\hat{j}(x)e^{-i\hat{H}t}. \tag{18.32}$$

where $\hat{H}$ is the unperturbed Hamiltonian. Thus, the interaction picture is adopted. The Kubo formula for electrical conductivity gives the result in terms of a current–current correlation function:

$$\sigma_{\alpha\beta}(q,w) = \frac{1}{\omega}\int_0^\infty dt e^{i\omega t} < \Omega|\hat{j}^\dagger_\alpha(q,t)\hat{j}_\beta(q,0) - \hat{j}_\beta(q,0)\hat{j}^\dagger_\alpha(q,t)|\Omega > + i\frac{n_0 e^2}{m\omega}\delta_{\alpha\beta} \tag{18.33}$$

where $|\Omega >$ is the ground state of the system, which has not been perturbed by the electric field. The first term in (18.33) is known as the incoherent contribution to the conductivity. Now, we use (18.32) in the preceding equation and use the fact that the basis we are using is that of the eigenstates. Consequently, with proper normalization the new expression for the real part of the conductivity is [90]

$$\sigma(\omega) = \frac{\pi}{Z}\frac{(1-e^{-\beta\omega})}{\omega}\sum_{n,m} e^{-\beta E_m}| < n|\hat{j}_\alpha|m > |^2\delta[\omega - (E_n - E_m)] \tag{18.34}$$

The DC conductivity is calculated by a procedure [90,91], which employs the sum rule

$$\int_0^\infty \sigma'(\omega)d\omega = -\frac{\pi e^2}{2}a^2 < K > \tag{18.35}$$

where

$$\sigma'(\omega) = D\delta(\omega) + \sigma_{kubo}(\omega) \tag{18.36}$$

and $< K >$ is the expectation value of the kinetic energy term of the Hamiltonian. The strategy of computing $\sigma(\omega)$, and subsequently the Drude contribution, at either zero or finite temperature is reasonably straight forward. The first step is to construct the matrix corresponding to the Hamiltonian [Equation (18.19)] in a subspace which is defined by the geometry of the lattice, the number of electrons, and the total electron spin. This leads to serious computational difficulties since for a moderately sized lattice of say ten dimers and eight electrons of arbitrary spin, the corresponding space is about 77 million states. A matrix of dimension 77 million square has about 5.9×10^{15} elements. Obviously, working on a moderately sized lattice, we are restricted to a low concentration of electrons. Due to electron-hole symmetry, we are also able to study the nearly filled situation. It is useful to keep in mind the relationship

$$\lambda = \frac{1240nm \cdot eV}{\text{Energy}}. \tag{18.37}$$

So that in the plots following, the visible light range is between 1.75 eV and 3.10 eV. Energies larger than this range correspond to ultraviolet, and those smaller to infrared wavelengths. Since cells respond to light in the near-infrared [4], and centrioles comprised of MTs are proposed to be the site of light detection [5], absorption in this energy range is of great interest to cell biology. These energies should also be compared

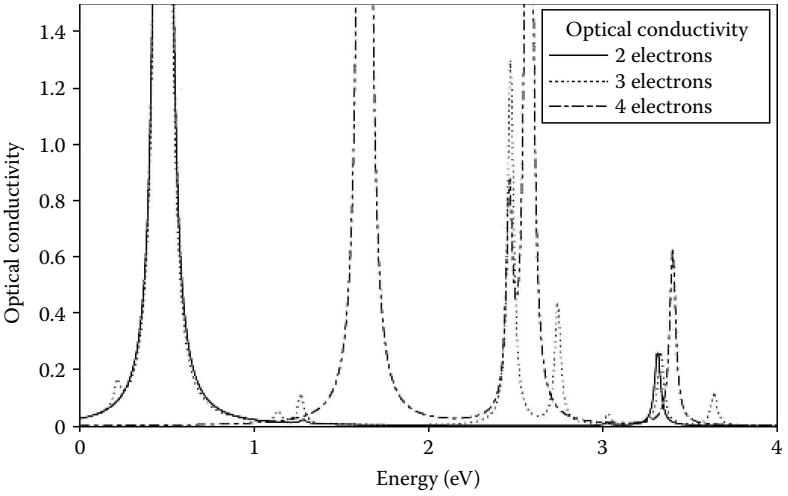

FIGURE 18.6 Optical conductivity of the two dimer system with two, three, and four electrons.

to the energy available from ATP and GTP hydrolysis, which are 0.49 eV and 0.22 eV, respectively. These values provide limits for the interactions of chemical energy in the conduction process.

At zero temperature, the linear polymer results are summarized concisely by saying that there is no DC conductivity that agrees with the previous modeling of Hubbard systems [44].

The following results for the 1D chain of tubulin dimers represent the AC conductivity. There are peaks in $\sigma(\omega)$, also known as the optical conductivity, which correspond to excitations between electronic states of the polymer. Electronic excitation results in electron redistribution and hence the development of a current. We have selected $\epsilon = 0.02$ eV to present our results, which is roughly kT and is smaller than the three energy scales in the Hubbard model, t, U, and $4t^2/U$ [82] so we expect to be able to pick out features corresponding to specific transitions in the predicted optical spectra.

We shall begin with two dimers and $t = 0.4$ eV, $U = 2.0$ eV, and equal site energy on the α and β monomer sites. This system can support up to eight electrons. The results for these systems are presented in Figure 18.6. The predicted spectra for the two and three electron cases are quite similar. The differences include a new but small peak in the three electron spectrum at an energy just below the major peak, and variations in the detail of the absorption band centered about 2.6 eV. However, the qualitative similarity of the two spectra is remarkable in terms of band locations. Contrast these two cases with the four-electron system that corresponds to half-filling. The difference is that the peak in the optical conductivity spectrum increases dramatically from about 0.48 eV to 1.64 eV. This change indicates how the half-filled case is special. The ground state in this system largely consists of electrons spread out to minimize the Coulombic energy. Exciting this system by moving any particular electron will come at the cost of greatly increasing the electron–electron repulsion and, consequently, the location of the required excitation energy corresponds roughly to U.

As the length of the polymer is increased, results remain qualitatively similar. In the three-dimer structure, results are shown for the conductivity in Figure 18.7(a) and for the integrated conductivity in Figure 18.7(b). Once again, the spectra are quite similar for all fillings aside from the half-filled case which consists of six electrons. The shift of the conductivity to higher energies can be clearly seen as the filling fraction increases towards half filling. We now present results where the broadening parameter, ϵ, and the temperature have been varied to see the effect that they have on the results. Figure 18.8 demonstrates that as the width is decreased, the spectrum becomes sharper. Note how the two peaks in this simple spectrum that occur near 2.5 eV are successively blended into a band as the ϵ is increased. Peaks represent transitions from one specific electron configuration to another and are weighted with the associated conductivity.

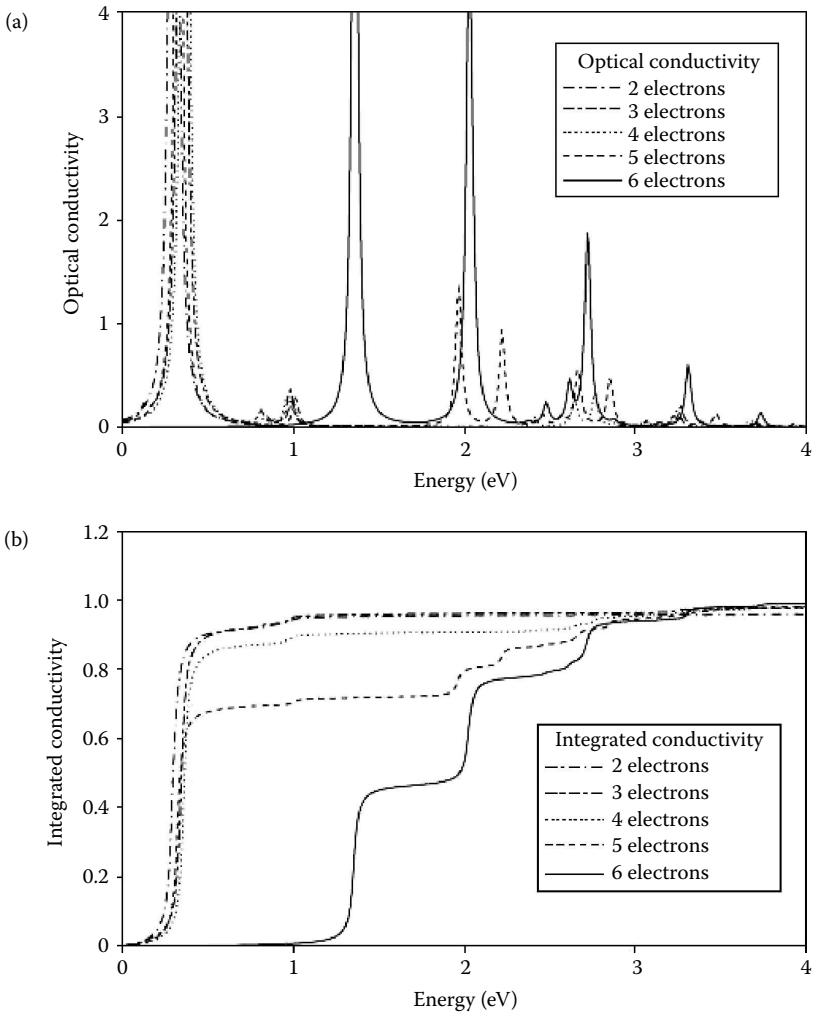

FIGURE 18.7 (a) Optical conductivity of the three-dimer system from two electrons through half filling. (b) Integrated optical conductivity of the three-dimer system shows that indeed the protofilament is an insulator. The gap for excitation of the half-filled polymer is seen easily here.

The effect of changing the temperature is to excite electron configurations other than the ground state. Consequently, transitions from one excited state to another can now contribute to the conductivity. Figure 18.9 shows how this often reduces the gap to conduction: all the major peaks in the 300 K spectrum shift slightly towards lower energies in the 3000 K spectrum, but many more features develop as well as states that previously did not contribute to conductivity may make transitions to excited states. Physiological temperature of 300 K ($kT = 0.026$ eV) is small relative to the system's energy scales, consequently lowering the temperature further causes very little change to the spectrum.

If the α-tubulin and β-tubulin sites have different energies, then the MT A and B lattices can be distinguished. The effect of this change on the optical spectrum seems to be small when individual protofilaments are considered. In addition, the sum rule shows that protofilaments remain insulators. There are a few parameters we can consider individually and which can be compared as the size of the system changes: the threshold to conductivity, and the expectation value of the kinetic energy operator. The threshold to conductivity is simply the location of the first absorption peak in the optical spectrum.

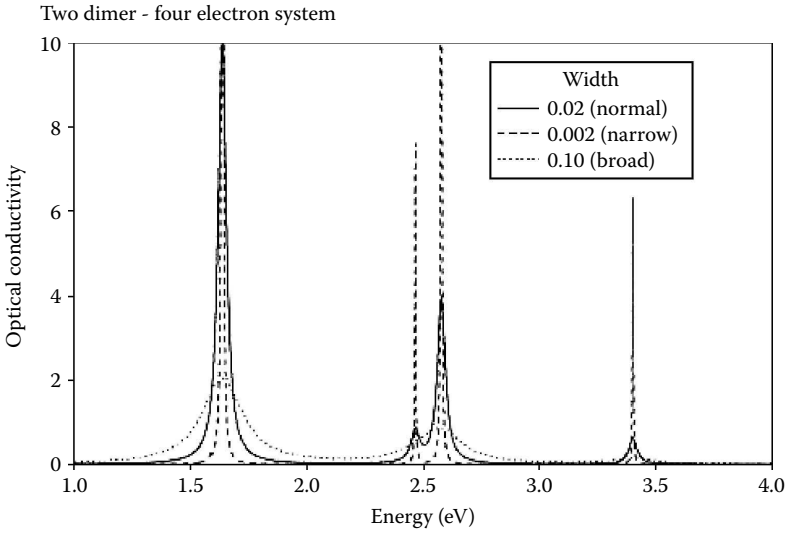

FIGURE 18.8 Optical conductivity spectrum variation with the broadening parameter.

It is a decreasing function of the polymer length. Starting at 0.48 eV for the two-dimer system, it seems to drop a little faster than $1/n$ for systems consisting of n dimers and containing two electrons. The fitted value in Figure 18.10 varies $\alpha 1/n^{1.4}$. Extrapolating to larger values of n, this gap appears certain to fall into the range where these excited states could be thermally excited. The protofilament then develops a finite DC conductivity at finite temperature. It is interesting that although the first peak does move towards zero, the fraction of the conductivity it contains is gradually diminished. Some of the conduction continues to reside in a peak located close to t in the energy spectrum. In the 2D lattice, there is a phase transition in the dimensionality. DC conduction becomes possible even at zero temperature. However, we shall still be concerned about the boundary conditions since calculations are being performed on a small lattice.

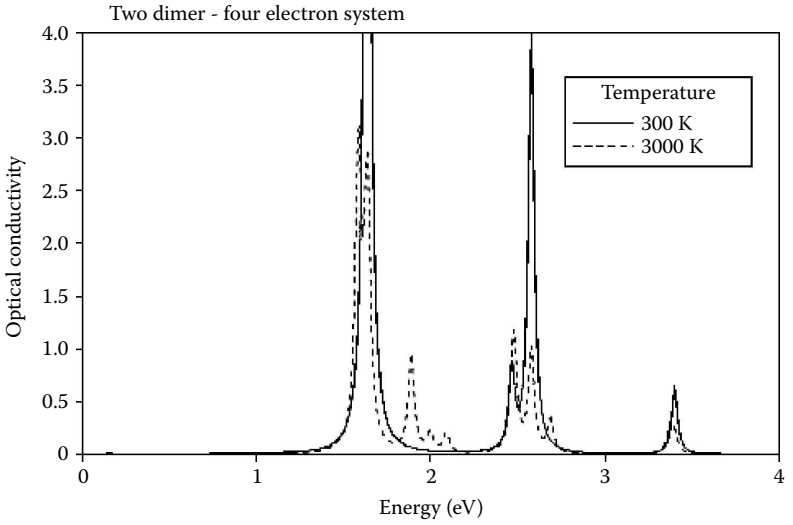

FIGURE 18.9 The variation of the optical conductivity spectrum with temperature is shown.

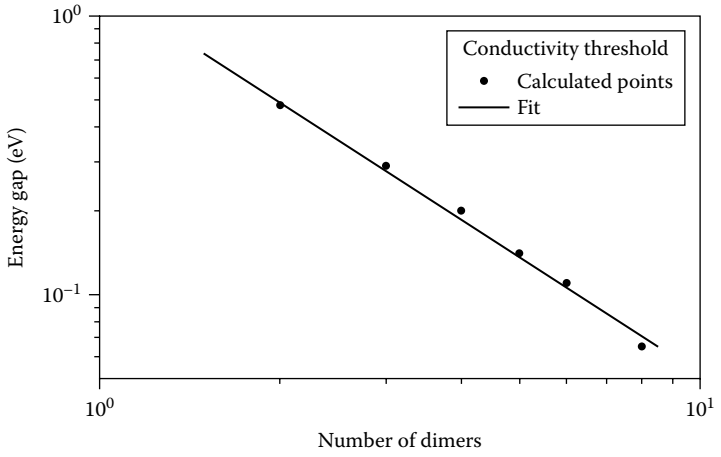

FIGURE 18.10 Threshold to conduction as a function of protofilament length.

Consider the kinetic energy/electron that has been calculated in a Hubbard model with our parameters for t and U and with either one, two or three protofilaments. Figure 18.11 demonstrates how the kinetic energy of each electron approaches the limit of $2t$ or 0.80 eV as the size of the system increases. We can easily see that for more than about 20 electron sites, the average kinetic energy of each electron starts to approach the infinite limit and we expect that the results obtained from our model should converge to the long protofilament limit in a similar manner. In particular, we are considering 28 electron sites in our MT model, which span three protofilaments. While this is not the ideal situation, the boundary conditions are not expected to create huge effects in our results. We are also using open boundary conditions since they minimize the boundary effects when compared with a variety of periodic boundary conditions.

The unit cells depicted in Figure 18.12 are the basis for the calculations. In the A lattice used for the calculations, the α-dimers connect to β-dimers along the $\bar{3}$-start helix, both within the lattice and at the seam when the MT is wrapped up. In the B lattice, the connections are $\alpha - \alpha$ or $\beta - \beta$ along the $\bar{3}$-start helix and never $\alpha - \beta$. For comparison, calculations have also been carried out with a flat tubulin sheet, specifically an A lattice MT lacking periodic boundary conditions in the lateral direction. This simulates the

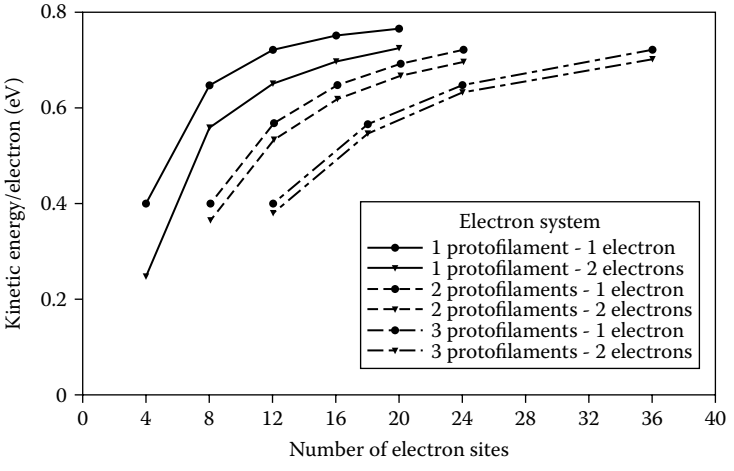

FIGURE 18.11 Kinetic energy per electron as a function of system size.

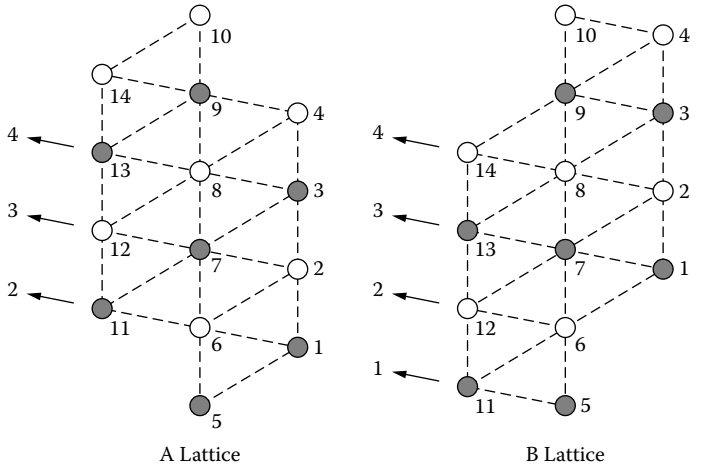

FIGURE 18.12 Lattice unit cells for conductivity calculations. The unit cell on the left corresponds to the MT A lattice, while that on the right corresponds to the MT B lattice.

MT when it has been unwrapped. We recall that the MT lattice is triangular and has three distinct hopping directions. Since protofilaments are strongly bound together along their length but relatively weakly bound to other protofilaments, one also expects the hopping parameter to be much smaller when an electron moves between protofilaments. The calculations have been carried out with the same parameters as in the one-dimensional case, $U = 2.00$ eV, $t = 0.40$ eV along the protofilaments and the site energies have been set equal to zero for all sites. The value of the hopping parameter along the $\bar{3}$-start helix is called t_ℓ (left) and that along the 8-start helix that connects diagonally from a monomer in a direction up and to the right is called t_r (right).

We consider first the results of the MT lattice which has not rolled up to form a tube but is that of a tubulin sheet where $t_r = 0$ and only the value of t_l is varied (see Figure 18.13). Since $t_r = 0$, the nature of the lattice remains rectangular to this point. When $t_l = 0$, this particular system is equivalent to individual protofilaments. The two peaks in the optical spectrum arise from the fact that the protofilaments have different lengths. The absorption peaks of 0.22 eV and 0.40 eV correspond roughly to those of the two-dimer and three-dimer, two electron cases discussed earlier in the chapter. The difference here is that the two electrons are spread over three protofilaments and consequently the effect of the electron repulsion is reduced. However, as t_l is increased from zero, the entire lattice becomes accessible and the protofilament character of the optical spectrum is lost. The two peaks of the t_l spectrum coalesce into a single peak with a large activation energy. A second but smaller absorption peak forms just above 0.50 eV. In the plot of the integrated conductivity, we can see that there is also a smaller peak at 0.16 eV when $t_l = 0.10$ eV. The source of this peak is an absorption for conduction along the direction of t_l. When t_l is increased to 0.40 eV, this peak occurs at 0.61 eV. Thus, this peak seems to occur at roughly $1.5t_l$. The activation energy for conduction along the protofilament axis also increases but is not as sensitive to t_l. Finally, examination of the integrated conductivity demonstrates that the total absorption combines such that the Drude weight remains zero.

The results in Figure 18.14 show a difference between an individual protofilament and a tubulin sheet. The behavior here is inconsistent with that of an insulator since the Drude weight is non-zero. In the optical conductivity, we find that the largest peak occurs at the same location in all directions but with different weightings. The first line traces the results for $t_r = 0.00$ eV and has peaks at 0.38 eV and 0.61 eV. Once the third hopping direction is allowed, the peak absorption is raised slightly to 0.43 eV for $t_r = 0.10$ eV and a smaller peak forms at 0.74 eV. The lower peak consists mainly of hopping along the protofilament while the second peak consists largely of hopping along the t_l direction, which also corresponds to a large

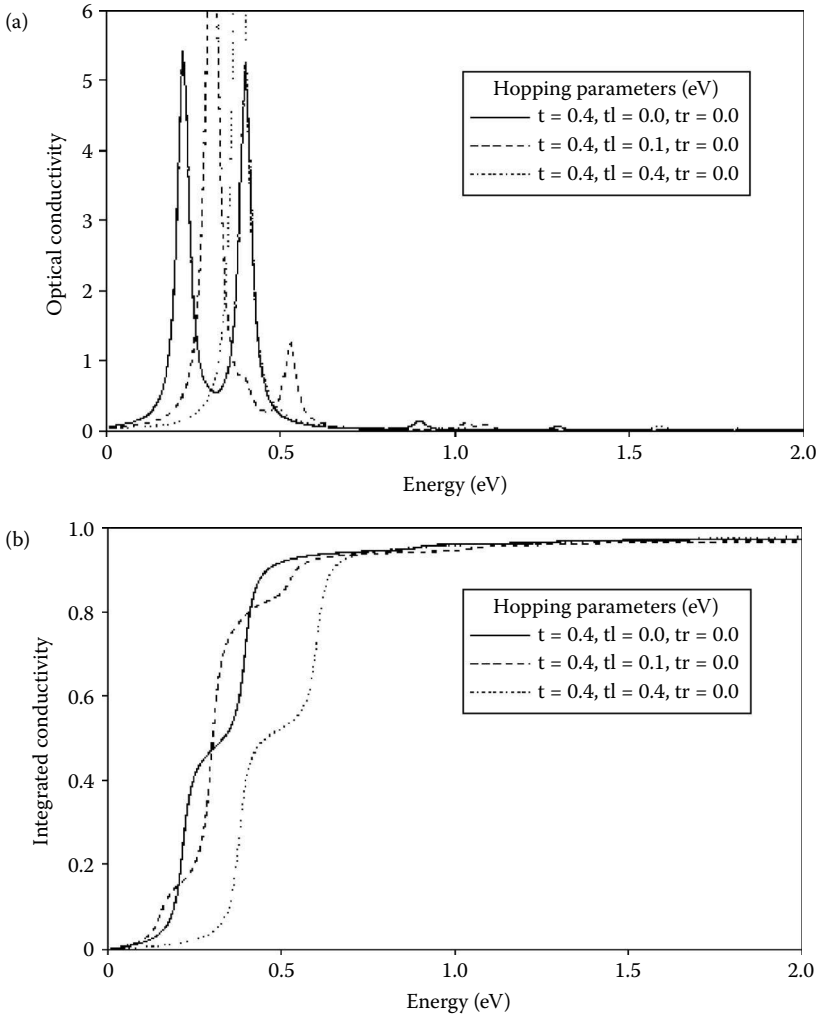

FIGURE 18.13 (a) Optical conductivity along the protofilament axis of the tubulin sheet consisting of a 14-site lattice with two electrons while $t_r = 0$ and t_l is varied. (b) Integrated conductivity of the tubulin sheet with two electrons while $t_r = 0$ and t_l is varied.

hopping parameter. Once t_r is raised to 0.40 eV so that it has the same magnitude as the other hopping parameters, there is only a single peak at 0.70 eV.

The effect of applying the MT A lattice boundary conditions to our system is shown in Figure 18.15, where we see that changing only t_l to a finite quantity while still maintaining t_r as zero is sufficient to result in a non-zero Drude weight. Thus, the periodic boundary conditions in the lateral direction seem to act in a manner similar to the additional hopping directions of the unwrapped lattice. When the kinetic parameters between protofilaments are set to zero, the optical conductivity spectrum shows there are two large absorption peaks at about 0.23 eV and 0.40 eV. As t_l increased, these peaks move higher in energy and the second peak becomes smaller in integrated weight. Eventually, once $t_l = t$, there is a single large peak near 0.47 eV. Introduction of the third hopping direction serves only to raise further the absorption peak, up to 0.70 eV in the case where the hopping parameter is 0.40 eV in all directions.

From Figure 18.15 one can see that more conduction results in the B lattice for a small t_l, such as 0.1 eV, than in the MT A lattice, by comparing it with Figure 18.16. However, even the positioning of absorption

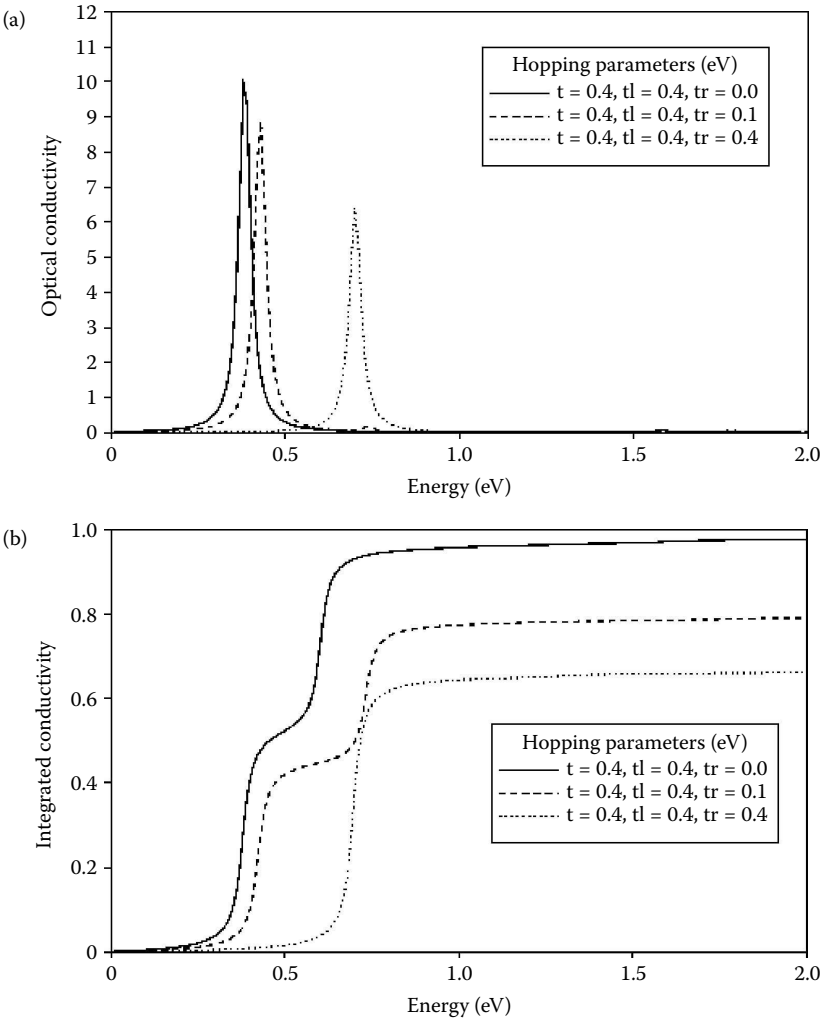

FIGURE 18.14 (a) Optical conductivity along the protofilament axis of the unwrapped 14-site lattice with two electrons while $t_l = 0.4$ and t_r is varied. (b) Integrated conductivity of the unwrapped 14-site lattice with two electrons while $t_l = 0.4$ and t_r is varied.

peaks is similar in the two lattices. Again, it is sufficient for only one of t_l or t_r to be non-zero for the Drude weight to be finite.

Finally, we compare the MT A and B lattices with the unwrapped tubulin sheet as well as with individual protofilaments of tubulin dimers. There is an interesting geometrical interpretation to the results, which shows that the MT A and MT B lattices have identical conduction properties when $t_l = t_r$. This is because in our calculations we have considered all monomers to have the same site energy. Consequently, the B lattice can be viewed as an A lattice with the opposite helicity but the same structure. The sign of the system's helicity does not affect the conduction properties along the major axis. The unwrapped MT lattice is not as good a conductor since some of the hopping freedom has been removed from the lattice but does remain conducting, provided that both t_l and t_r are non-zero.

If we consider the case where one of t_l or t_r is quite small, however, the wrapping of the lattice is much more important. As discussed earlier, the unwrapped tubulin sheet is an insulator while the MT A and B lattices may carry electrons. This observation is especially interesting given that MTs have been observed to zip up and essentially change their structure from a tube to that of a sheet *in vivo*.

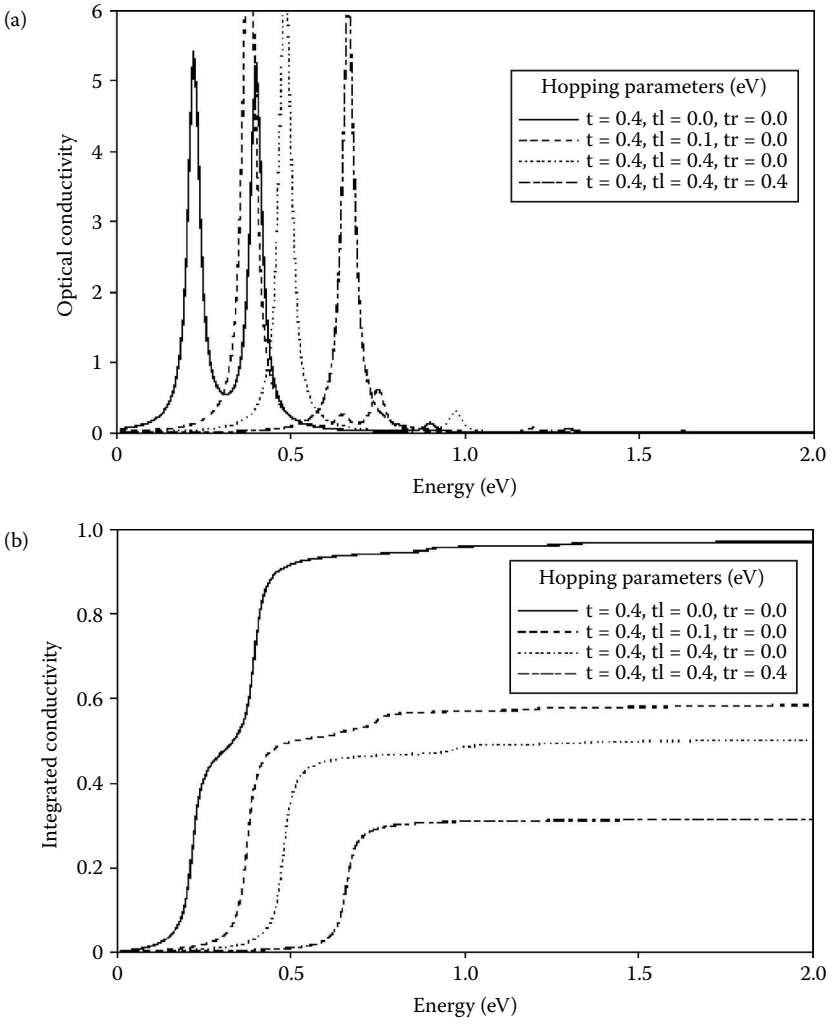

FIGURE 18.15 (a) Optical conductivity along the protofilament direction of the 14-site MT B lattice with two electrons. (b) Integrated conductivity of the 14-site MT B with two electrons shows a non-zero weight for finite t_l.

Our calculations based on the Hubbard model of electron hopping show that the MT is not an insulator, but that instead its conductivity depends on the lattice geometry and whether the MT is wrapped up or not. How well or poorly does one expect the MT to conduct relative to known semi-conductors? Referring back to Equations (18.35) and (18.36), the DC conductivity of the MT is simply given by D as

$$\frac{D}{2} = -\frac{\pi e^2}{2} a^2 < K > - \int_0^\infty \sigma_{kubo}(\omega) d\omega. \tag{18.38}$$

In this equation, the constants can be factored, and what remains is the fraction that can be read from the graphs presented earlier. The Kubo fraction (KF) is the limit of the integral as the frequency tends to infinity.

$$\frac{D}{2} = -\frac{\pi e^2}{2} a^2 < K > (1 - KF). \tag{18.39}$$

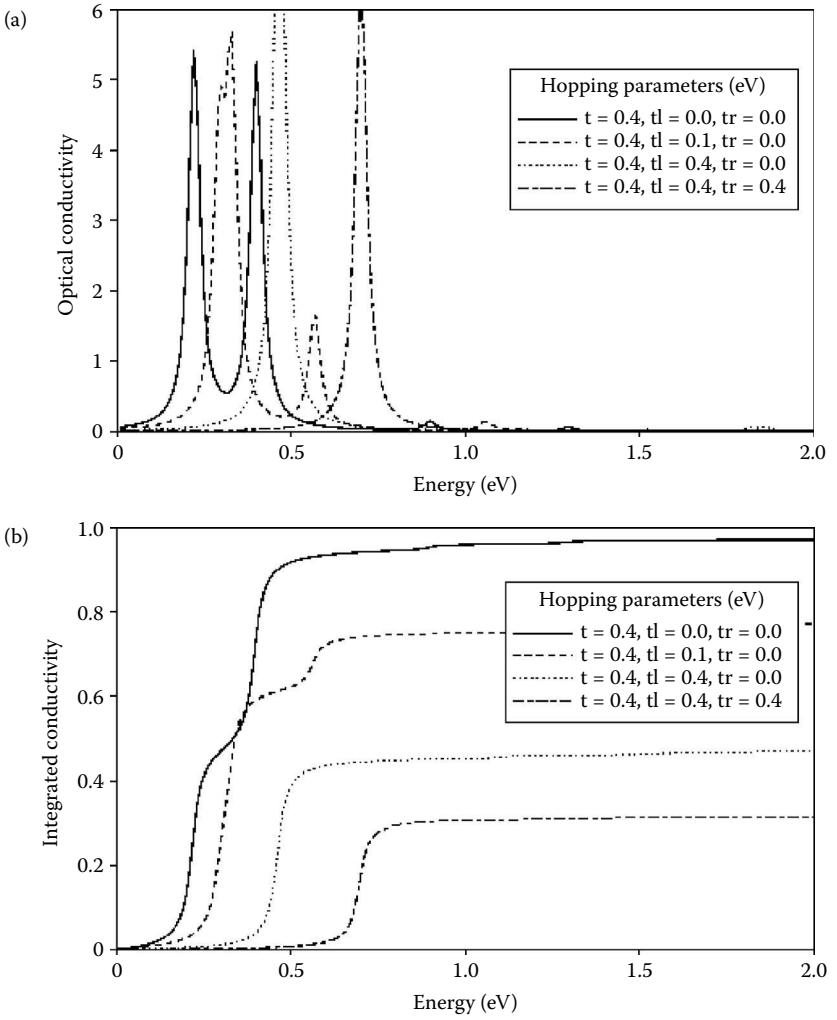

FIGURE 18.16 (a) Optical conductivity along the protofilament direction of the 14-site MT A lattice with two electrons. (b) Integrated conductivity of the 14-site MT A lattice with two electrons shows a non-zero Drude weight for finite t_1.

By returning constants of the system so that the dimensionality of D is correct, we find

$$D = -\frac{\pi n e^2 a^2}{\hbar} \frac{< K >}{t} (1 - KF). \tag{18.40}$$

Finally, we are in a position to predict the conductivity of individual MTs of varying lattice types. For the following calculations, the electron density has been taken to be of two electrons within the lattice of 14 dimers and corresponds to a density of $1.8 \times 10^{18}/cm^3$. Thus, the results must assume that the conductivity remains constant as the length of the polymer is extended, provided the degree of filling remains the same.

The values in Table 18.1 should be compared with the conductivity of metals, such as copper ($6 \times 10^7\, \Omega m^{-1}$) and iron ($1 \times 10^7\, \Omega m^{-1}$). Indeed the values can also be compared to the intrinsic semiconductors germanium ($2.5\, \Omega m^{-1}$) and silicon ($4 \times 10^{-4}\, \Omega m^{-1}$). Given these comparisons, the MT may indeed be quite a good semi-conductor given our assumptions. What is particularly interesting is the

TABLE 18.1 Calculated Conductivity and Resistance of a 1-μm Polymer Composed of Tubulin Dimers

Tubulin Structure	Conductivity ($\Omega^{-1}m^{-1}$)	Resistance
Individual Protofilament	Non-Conducting	
Tubulin sheet ($t_1 = t_r = 0.04\ eV$)	9.4×10^3	$418k\ \Omega$
Tubulin sheet ($t_l = t_r = 0.1\ eV$)	2.0×10^4	$195k\ \Omega$
Tubulin sheet ($t_1 = t_r = 0.4\ eV$)	6.3×10^4	$62k\ \Omega$
MT (A lattice, $t_l = t_r = 0.04\ eV$)	1.8×10^4	$219k\ \Omega$
MT (A lattice, $t_l = t_r = 0.1\ eV$)	4.5×10^4	$87k\ \Omega$
MT (A lattice, $t_l = t_r = 0.4\ eV$)	1.6×10^5	$25k\ \Omega$
MT (B lattice, $t_l = t_r = 0.04\ eV$)	1.9×10^4	$211k\ \Omega$
MT (B lattice, $t_l = t_r = 0.1\ eV$)	4.7×10^4	$84k\ \Omega$
MT (B lattice, $t_l = t_r = 0.4\ eV$)	1.6×10^5	$24k\ \Omega$

way the conduction properties depend on the lattice and the particular boundary conditions. The situation can be compared to carbon nanotubes which have a similar size and structure to MTs. In addition, theoretical consideration of nanotube structure predicts that the conduction properties depend on the boundary conditions. In the case of nanotubes, this means the way in which the graphene sheet is wrapped up to form the nanotube. It is quite interesting that particular sets of boundary conditions produce a semi-conducting nanotube while the appropriate choice of wrapping the nanotube gives rise to metallic conduction [31].

The ability to change from an insulator to a conductor by a simple geometrical change could be biologically relevant even without observing a single electron to be conducted along the MT since it is the conductivity property that affects the way the cell views and responds to external electromagnetic fields. Specifically, the reflectivity of MTs to electromagnetic fields is high when they are conducting, and, consequently, they could act to direct infrared signals to the interior of the centrosome. Since the centrioles are maintained at right angles to each other, the cell would be able to determine the location in latitude and longitude of a light source if the MTs are conducting [4,5]. Peaks in the AC conductivity are all at energies significantly above the thermal activation threshold so no conductivity is expected along a darkened MT, but photoconduction in the infrared-visible range is possible. Therefore, it is possible this photo-activated conduction has functional repercussions. In addition to the intrinsic semiconducting behavior of MTs, and possibly AFs, these protein filaments possess very intensely active cable properties when immersed in an ionic buffer solution. In the next section, we discuss the ionic conductivity effects of AFs.

18.6 Actin Filaments Support Nonlinear Ionic Waves

Several experiments [12,83] indicate the possibility of ionic wave generation along AFs. As the condensed cloud of counter-ions separates the filament core from the rest of the ions in the bulk solution, we expect it to act as a dielectric medium between the two. It has both resistive and capacitive components associated with each monomer that makes up the AF. Ion flow is expected to occur at a radial distance from the surface of the filament approximately equal to the Bjerrum length. An inductive component is proposed to emerge due to the actin's double-stranded helical structure that induces the ionic flow in a solenoidal manner. Due to the presence of the sheath of counter-ions around the AF, these polymers act as biological "electrical wires" [83], and have been modeled as nonlinear inhomogeneous transmission lines propagating nonlinear dispersive solitary waves. Recently, Lader *et al.* [78] applied an input voltage pulse with an amplitude of approximately 200 mV and a duration of 800 μs to an AF, and measured electrical signals at the opposite end of the AF, indicating that AFs support ionic waves in the form of axial nonlinear currents. In an earlier experiment [83], the wave patterns observed in electrically stimulated single AFs were remarkably similar to recorded solitary waveforms for electrically stimulated nonlinear transmission lines [85]. Considering the AFs highly nonlinear complex physical structure and the thermal fluctuations of the counter-ionic

cloud [105], the observation of soliton-like ionic waves is consistent with the idea of AFs functioning as biological transmission lines.

The electro-conductive medium is a condensed cloud of ions surrounding the polymer and separated from it due to the thermal fluctuations in the solution. The distance beyond which thermal fluctuations are stronger than the electrostatic attractions or repulsions between charges in solution is defined as the so-called Bjerrum length, λ_B. With the dielectric constant of the medium denoted by ε, the Bjerrum length is given by

$$\frac{e^2}{4\pi\varepsilon\varepsilon_0\lambda_B} = k_B T \tag{18.41}$$

for a given temperature T in Kelvin. Here e is the electronic charge, ε the dielectric constant, ε_0 the permittivity of the vacuum, and k_B is Boltzmann's constant. For a temperature of 293 K, we find that $k_B = 7.13 \times 10^{-10} m$. Counter-ion condensation occurs when the mean distance between charges, b, is such that $\lambda_B B/b = S > 1$. Each actin monomer carries an excess of 14 negative charges in vacuum, and accounting for events such as protonation of histidines, and assuming there to be 3 histidines per actin monomer, there exist 11 fundamental charges per actin subunit [143]. Assuming an average of 370 monomers per μm, we find there is approximately $4e/nm$. Thus, we expect a linear charge spacing of $b = 2.5 \times 10^{-10} m$ so $S = 2.85$. As the effective charge, q_{eff}, or renormalized rod charge is the bare value divided by S, we find $q_{eff} = 3.93e/monomer$. Consequently, it can be shown that approximately 99% of the counter-ion population is predominantly constrained within a radius of $8nm$ [110] around the polymer's radial axis [158]. Significant ionic movements within this "tightly bound" ionic cloud are therefore allowed along the length of the actin, provided that it is shielded from the bulk solution [104,107].

The physical significance of each of the components of the electrical network, and additional details, are described in [148]. For actin in solution, a key feature is that the positively charged end assembles more quickly than the negatively charged end [135]. This results in an asymmetry in the charges at the ends of the filaments and F-actin's electric polarization. Actin monomers arrange themselves head to head to form actin dimers resulting in an alternating distribution of electric dipole moments along the length of the filament [73]. We assume, therefore, that there is a helical distribution of ions winding around the filament at approximately one Bjerrum length. This corresponds to a solenoid in which a fluctuating current flows as a result of voltage gradient between the two ends.

The capacitive element of the electric circuit is obtained following the observation of oppositely charged layers surrounding the filament surface. We envisage the protein surface's negative charge to be distributed homogeneously on a cylinder defining the filament surface. Furthermore, positive counter-ionic charges in the bulk are expected to form another cylinder at a radius greater than the AF itself, approximately one Bjerrum length, λ_B, away from the actin surface, which includes the condensed ions. The permittivity, ε_0, is given by $\varepsilon = \varepsilon_0\varepsilon_r$ where ε_r is the relative permittivity which we take to be that of water, i.e., $\varepsilon_r = 80$. We take the length of an actin monomer typically as $a = 5.4\ nm$ and the radius of the actin filament, r_{actin}, to be $r_{actin} = 2.5\ nm$ [14]. The next step is to consider a cylindrical Gaussian surface of length a whose radius is r such that $r_{actin} < r < r_{actin} + \lambda_B$.

Applying of Gauss's law for the total charge enclosed in the cylinder, we have the following expression for the capacitance

$$C_0 = \frac{2\pi\varepsilon a}{ln(\frac{r_{actin}+\lambda_B}{r_{actin}})} \tag{18.42}$$

With the parameters given previously, we estimate the capacitance per monomer is $C_0 = 96 \times 10^{-6}\ pF$. The resistive part is obtained from Ohm's law. Taking into account the potential difference and the current I, the magnitude of the resistance, $R = V/I$, for an actin filament is given by

$$R = \frac{\rho ln(\frac{r_{actin}+\lambda_B}{r_{actin}})}{2\pi l} \tag{18.43}$$

where ρ is the resistivity. Typically, for K^+ and Na^+, intracellular ionic concentrations are 0.15 M and 0.02 M, respectively [147]. Kohlrausch's law states that the molar conductance of a salt solution is the sum of the conductivities of the ions comprising the salt solution. Thus

$$\sigma = \Lambda_0^{K^+} c_{K^+} + \Lambda_0^{Na^+} c_{Na^+} = 1.21(\Omega m)^{-1} \tag{18.44}$$

Using this with $\rho = \sigma^{-1}$, the resistance estimate becomes $R = 6.11\ M\Omega$, which is much lower than pure water since $R_{water} = 1.8x10^6\ M\Omega$.

To describe the properties of the whole filament, we simply connect n subcircuits, as described earlier, to obtain an effective resistance, inductance, and capacitance, respectively, such that:

$$R_{eff} = \left(\sum_{i=1}^{n} \frac{1}{R_{2,i}} \right)^{-1} + \sum_{i=1}^{n} R_{1,i} \tag{18.45}$$

$$L_{eff} = \sum_{i=1}^{n} L_i \tag{18.46}$$

and

$$C_{eff} = \sum_{i=1}^{n} C_{0,i} \tag{18.47}$$

where $R_{1,i} = 6.11 \times 10^6\ \Omega$, $R_{2,i} = 0.9x10^6\ \Omega$ such that $R_{1,i} = 7R_{2,i}$. Note that we have used $R_{1,i} = R_1$, $R_{2,i} = R_2$, $L_i = L$, and $C_{0,i} = C_0$. For a 1 μm of the AF, we find

$$R_{eff} = 1.2 \times 10^9\ \Omega \tag{18.48}$$

$$L_{eff} = 340 \times 10^{-12}\ H \tag{18.49}$$

$$C_{eff} = 0.02 \times 10^{-12}\ F \tag{18.50}$$

This solenoidal flow geometry leads to an equivalent electrical element possessing self-inductance. From Faraday's law, we can derive an effective inductance for the actin filament in solution by

$$L = \frac{\mu N^2 A}{l} \tag{18.51}$$

where l is the length of the F-actin and A is the cross-sectional area of the effective coil given by

$$A = \pi (r_{actin} + \lambda_B)^2 \tag{18.52}$$

The number of turns is approximated by simply working out how many ions could be lined up along the length of a monomer. We would then be approximating the helical turns as circular rings lined up along the axis of the F-actin. We also take the hydration shell of the ions into account in our calculation. The hydration shell is then the group of water molecules oriented around an ion. It can be shown that $L = 1.7pH$ for the length of the monomer.

The electrical model of the AF is an application of Kirchhoff's laws to one section of the effective electrical circuit that is coupled to neighboring monomers. Taking the continuum limit [148] for a large number of monomers along an AF, we derive the following equation which describes the spatio-temporal

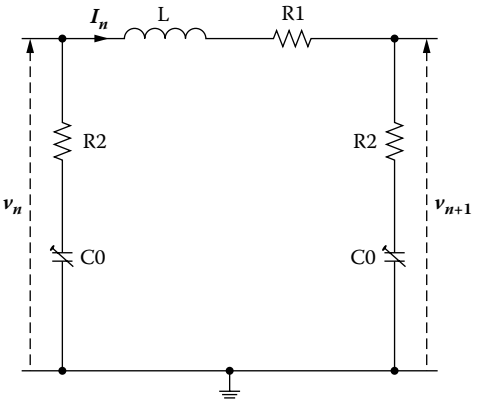

FIGURE 18.17 An equivalent electrical circuit for a segment of an actin filament.

behavior of the potential along the AF:

$$LC_0\frac{\partial^2 V}{\partial t^2} = a^2(\partial_{xx}V) + R_2C_0\frac{\partial[a^2(\partial_{xx}V)]}{\partial t} - R_1C_0\frac{\partial V}{\partial t} + R_1C_0 2bV\frac{\partial V}{\partial t} \tag{18.53}$$

Motivated by this picture, physical properties of the ionic distribution along a short stretch of the polymer (the average pitch 35 to 40 nm) have been modeled by Tuszynski *et al.*, [148] as an electrical circuit with non linear components (see Figure 18.17). The main elements of the circuit are: (a) a non linear capacitor associated with the spatial charge distribution between the ions located in the outer and inner regions of the polymer; (b) an inductance due to the helical geometry of the filament; and (c) a resistor due to the viscosity imposed by the solution.

From Kirchhoff's laws, one can derive an equation governing the propagation of voltage along the filament (see [148]). One of the key aspects in this model is the nonlinearity of the associated capacitance [86,150] that eventually gives rise to the self-focusing of the ionic waves. The equations developed for the model originate from the application of Kirchhoff's laws to the RLC resonant circuit of a model actin monomer in a filament. Perhaps the most important finding is the existence of the traveling wave, which describes a moving transition region between a high and low ionic concentration due to the corresponding inter-monomeric voltage gradient. The velocity of propagation was estimated to range between 1 and 100 ms^{-1} depending on the characteristic properties of the electrical circuit model. It is noteworthy that these values overlap with action potential velocities in excitable tissues [55].

Analysis of the model described earlier reveals the possibility of stationary waves in time that may lead to the establishment of spatial periodic patterns of ionic concentration. As mentioned previously, Lader *et al.* [78] applied an input voltage pulse with an amplitude of approximately 200 mV and a duration of 800 μs to an AF, and measured electrical signals at the opposite end of the AF, indicating that AFs support ionic waves in the form of axial nonlinear currents. In an earlier experiment [83], the wave patterns observed in electrically stimulated single AFs were similar to recorded solitary waveforms for electrically stimulated nonlinear transmission lines [85]. Considering the AFs highly nonlinear physical structure and thermal fluctuations of the counter-ionic cloud [105], the observation of soliton-like ionic waves is consistent with the idea of AFs functioning as biological transmission lines.

This section only provides an indication as to a realistic model of actin that can support soliton-like ionic traveling waves. Modeling relies on data constrained by experimental conditions, and/or assumptions made, including the charge density, which is calculated based on the net surface charges of actin. It should also be considered that soliton velocity is directly proportional to the magnitude of the stimulus, which in a biological setting has not been formally described. Actin interacts with a number of ion channels of different ionic permeability and conductance. Thus, it is expected that channel opening, single channel

currents, and other channel properties, including the resting potential of the cell, may significantly modify the amplitude and velocity of the soliton-supported waves. This should correlate with the velocity of the traveling waves along channel-coupled filaments. Other parameters that may play a role in this type of electrodynamic interaction are the local ionic gradients and the regulatory role of actin binding proteins, which can help "focus" the conductive medium, or otherwise impair wave velocity. The physical significance of each of the components of the electrical network (see Figure 18.17) and additional details, are described in [148]. MTs differ from AFs in several respects. One of the key differences is the presence of peptide chains called C-termini that protrude from their surface. In the following section, we outline their role in ionic wave conductivity along MTs.

18.7 Long-Range Spatio-Temporal Ionic Waves Along Microtubules

MTs are long hollow cylinders made of $\alpha\beta$-tubulin dimers [33], as described in Section 18.5. Recently, it has become apparent that neurons utilize MTs in cognitive processing. Both kinesin and MAP2 that associate with MTs have been implicated in learning and memory [69,154]. Dendritic MTs are implicated in particular, and it is highly probable that the precisely coordinated transport of critical proteins and mRNAs to the post-synaptic density via kinesin along MT tracks in dendrites is necessary for learning, as well as for LTP [70].

The following molecular dynamics (MD) simulation results focus on the C-termini of neighboring tubulins, whose biophysical properties have a significant influence on the transport of material to activated synapses. This affects cytoskeletal signal transduction and processing as well as synaptic functioning related to LTP. Using MD modeling we calculated conformation states of the C-termini protruding from the outer surfaces of MTs and strongly interacting with other proteins, such as MAP2 and kinesin [124]. To elucidate the biophysical properties of C-termini and gain insight into the role they play in the functioning of dendrites, we developed a quantitative computational model based on the currently available biophysical and biochemical data regarding the key macromolecular structures involved, including tubulin, their C-termini, and associated MAP2. In the proposed model of the C-termini microtubular network, the tubulin dimer is considered to be the basic unit. Each dimer is decorated with two C-termini that may either extend outwardly from the surface of the protofilament or bind to it in one of a few possible configurations.

The most dynamic structural elements of the system (i.e., its elastic and electric degrees of freedom) are envisaged as conformational states of the C-termini. Each state of the unbound C-terminus evolves so as to minimize the overall interaction energy of the system. The negatively charged C-termini interact with (a) the dimer's surface, (b) neighboring C-termini and (c) adjacent MAPs. While the surface of the dimer is highly negatively charged overall, it has positive charge regions that attract the C-termini causing them to bend and bind in a "downward" state. The energy difference between the two major metastable states is relatively small, on the order of a few $k_B T$ [112].

To simplify our calculations, we first used a bead-spring model representing the C-terminus as a sequence of beads with flexible connections. We have accounted for the electric field exerted by the dimer, the external field generated by the environment, and various short-range interactions within the simulated C-terminus, including interactions between the beads (i.e., Lennard–Jones potential, angular forces, etc.).

A simplified model of the interaction between MAP2 and its ionic environment via counter-ions was used to investigate the ability of MAP2 to function as a "wave-guide" that transfers the conformational change in a C-terminus state to an adjacent MT (see Figure 18.18). A perturbation applied to the counter-ions at one end of the MAP2 drives them out of equilibrium and initiates a wave that travels along the MAP2 (for details see [112]). Figure 18.18 (right) depicts the main result for a localized perturbation applied for a few picoseconds to the counter-ions near the binding site of MAP2. Wave propagation along the chain of $N = 50$ counter-ions is shown as a counter-ion displacement parallel to MAP2, u_i, where i denotes the i^{th} counter-ion. This perturbation along MAP2 propagates almost as a "kink" whose phase velocity has been found to be $v_{ph} \approx 2nm \cdot ps^{-1}$.

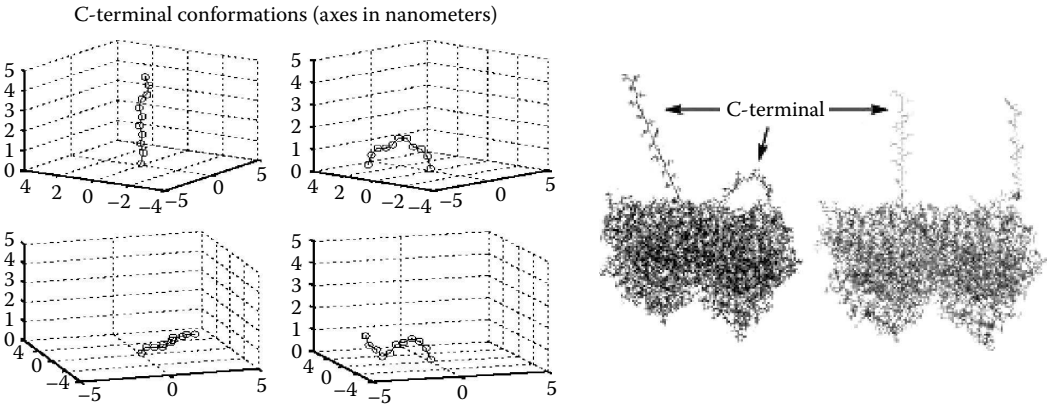

FIGURE 18.18 Examples of the conformational states of the C-termini in a tubulin dimer (right) and results from bead-spring model simulations (left).

Our simulations indicate the ability of an ionic wave to trigger a coupled wave of C-termini state changes from their upright to downward orientations. Four examples of "up" and "down" states of the C-termini obtained through bead-spring model simulations are shown in Figure 18.18 (left) and results from molecular dynamics simulations for an actual tubulin dimer are shown in Figure 18.18 (right). Calculations of the energy minimized positions of the individual beads representing the amino acids of the C-terminus in two equivalent forms reveal that the probability of the down position, which includes all cases of full or partial attachment, is 15%. This means that the system has two major states with a strong bias towards the stretched-up state.

In the remainder of this section, we present an MD simulation study of the interaction between MTs and MAP2, followed by preliminary experimental results of ionic wave conduction by MTs.

A simplified model of the interaction between MAP2 and its ionic environment via counter-ions was used to investigate the ability of MAP2 to function as a "biological wire" that transfers the conformational change in a C-terminus state to an adjacent MT (see Figure 18.19).

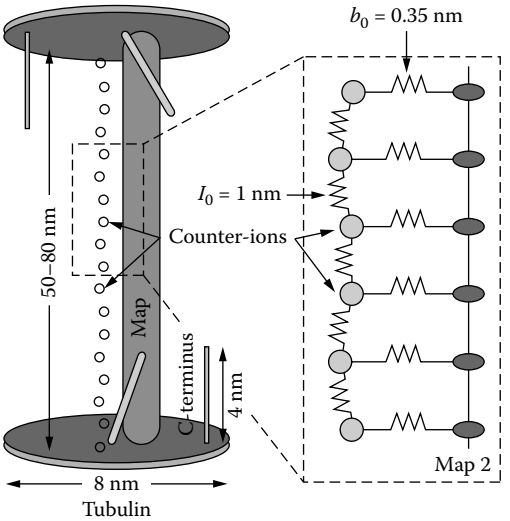

FIGURE 18.19 An illustration of a MT C-terminus conformational change transfer process. Ionic waves travel along an adjacent MAP via local perturbations to the bounded counter-ions.

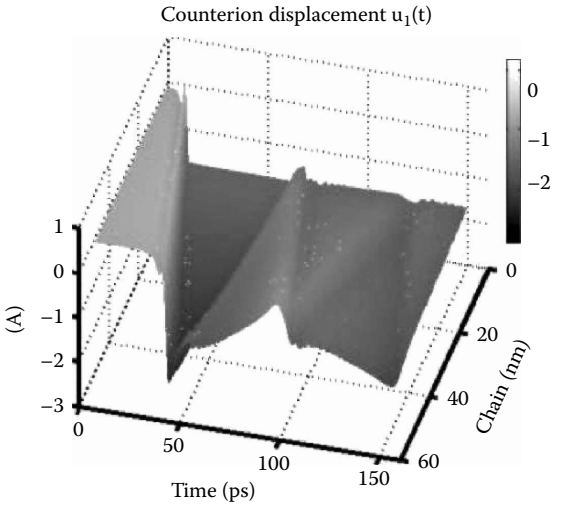

FIGURE 18.20 Propagation of a localized perturbation applied to counter-ions near the binding site of a MAP2.

A perturbation applied to the counter-ions at one end of the MAP2 drives them out of equilibrium and initiates a wave that travels along the MAP2 [112]. Figure 18.20 depicts the main result for a localized perturbation applied for a few picoseconds to the counter-ions near the binding site of a MAP2. Wave propagation along the chain of counter-ions is demonstrated as counter-ions displacement parallel to MAP2.

To validate the proposed model, we have conducted experiments on electro-stimulation of MTs in a solution. A detailed description of the experiment and its results has been published elsewhere [113]. Here we only describe the main aspects of the work on this phenomenon. Figure 18.21 depicts the experimental setup used. Isolated taxol-stabilized MTs have been shown to be able to amplify an electric signal applied to them through a micropipette. The input signal was of 5 to 10 msec duration, with amplitude in the range of $\pm$200 mV. The signal that arrived at the other end of the MT was more than twice as high as the signal recorded in a control experiment where the same two pipettes were immersed in a solution with no MT making contact to them. The calculated conductivity of MTs was found to be on the order of 10 nS, indicating a high level of ionic conductivity along an MT. By comparison, for a typical ion channel, the corresponding value ranges between 5 and 200 pS.

The results of the MD modeling previously described raise the possibility of transmitting electrostatic perturbations collectively among neighboring C-termini, and from C-termini on one MT to those C-termini on another MT via MAP2. The importance of collective conformational states of C-termini and of transmitting perturbations among the C-termini as a novel information processing mechanism operating at a subneuronal level is clear. MAP2 and kinesin bind near to the C-termini on tubulin and the electrostatic properties of C-termini affect this binding [2,145]. Hence the conformational states of the C-termini must

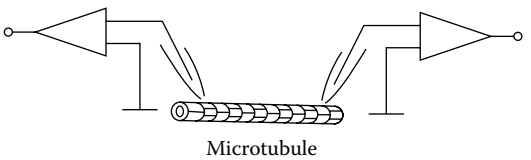

FIGURE 18.21 Schematic representation of the experimental set-up used for the measurements of a MTs ionic conductivity. The MT is attached to two micropipettes that are connected to signal amplifiers.

at some point be taken into account in order to understand neural processing that depends on transport of synaptic proteins inside of neurons. Kim and Lisman [71] have shown that inhibition of MT motor proteins reduces an AMPA receptor-mediated response in hippocampal slice. This means that a labile pool of AMPA-receptors depends on MT dynamics, and MT-bound motors determine the amplitudes of excitatory postsynaptic currents (EPSC). A walking kinesin carries with it a protein or an mRNA molecule. Since kinesin binds to a MT on a C-terminus, as it steps on it, it brings the C-terminus to the MT surface and makes it ineffective in binding for the next kinesin over a period of time that it takes the C-terminus to unbind and protrude outside. From this we can deduce that long stretches of C-termini in the upright position are going to be most efficient at transporting kinesin and kinesin cargo while C-termini that lie flat are expected to be most efficient at detaching kinesin. Thus, in considering the trafficking of many kinesins, collective electrostatic effects of C-termini become crucially important. Collective states that correspond to transport strategies that will send optimal numbers of kinesin molecules to synaptic zones are likely to occur when synapses are activated (e.g., when synapses are generating EPSCs). One type of kinesin cargo associated with learning and memory is the NMDA receptor, which is well known to be associated with LTP. The PSD might be expected to require replenishment of NMDA receptors at a later time than AMPA receptors are replenished (see [71]). Kinesin protein (specifically KIF17) actively transports NMDA receptor 2B subunits (NR2B) to the region of the PSD [52]. Once NR2B is in the vicinity of an active synapse it dissociates from kinesin and then becomes associated with the PSD, presumably using actin transport as an intermediary step. Hence, kinesin-mediated transport of NMDA receptors along MTs has a built-in negative feedback mechanism: whenever too many NMDA receptors are transported to the synaptic site (often located on a spine head), then those NMDA receptors can initiate proteolytic breakdown of MAP2. The latter event would be expected to reduce further transport of NMDA receptors to the synaptic site. The signal transduction molecule CaMKII is also critical for learning and LTP. Similar to the NMDA receptor, CaMKII is transported to active synapses via a kinesin-mediated transport mechanism. However, it appears to be the mRNA for CaMKII to a larger extent than the protein that is transported to spines, since dendrites are enriched with polyribosomes and CaMKII mRNA [140]. Ribosomes are redistributed from dendrites to spines with LTP [106]. Local translation of CaMKIIα in dendrites appears to be necessary for the late phase of LTP: fear conditioning and spatial memory [98]. Moreover, changes in synaptic efficacy are often accompanied by changes in morphology; reorganization of underlying MTs is a fundamental factors for these morphological changes. Having discussed the individual properties and roles played by AFs and MTs in subcellular conduction processes, we now turn to an integrated view of their functioning within a cell. The next several sections discuss this issue in depth.

18.8 Dendritic Cytoskeleton Information Processing Model

Our current hypothesis states that the cytoskeletal biopolymers constitute the backbone for ionic wave propagation that interacts with, and regulates, dendritic membrane components, such as ion channels to effectively control synaptic connections. Figure 18.22 depicts a portion of the dendritic shaft where MTs are decorated by C-termini and interconnected by MAP2 (thick line). Connections between MTs and AFs are shown as well as two types of synaptic bindings. On the upper left side, actin bundles bind to the post-synaptic density (PSD) of a spineless synapse. On the lower right side, a spiny synapse is shown, where actin bundles enter the spine neck and bind to the PSD, which at the other end, is connected to the MTN.

We envision a mechanism in which a direct regulation of ion channels and thus synaptic strength by AFs and associated cytoskeletal structures controls and modifies the electrical response of the neuron. In this picture, MTs arranged in networks of mixed polarity receive signals in the form of electric perturbations, from synapses via AFs connected to MTs by MAP2 [122], or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT [108]. As discussed next, the MTN may be viewed as a high-dimensional dynamic system where the main degrees of freedom are related to the conformational state of the C-termini. The input signals perturb the current state of the system that continues to evolve. Hypothetical integration of the preceding ideas is outlined as follows. Electrical signals arrive at the PSD

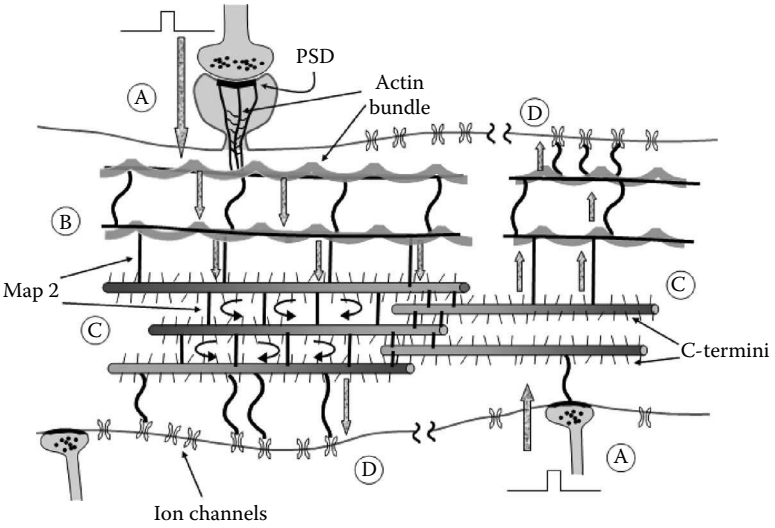

FIGURE 18.22 A scheme of the dendritic shaft with MTs arranged in networks of mixed polarity that receive signals in the form of electric perturbations from synapses via AFs connected to MTs by MAP2, or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT. A spiny synapse is depicted in the bottom right where an actin bundle enters the spine neck.

via synaptic transmission, which in turn elicits ion waves along the associated AFs at the synaptic spine. These dendritic input signals propagate in the form of ionic waves through AFs to the MTN where they serve as input signals. The MTN, operating as a large high-dimensional state machine, evolves these input states, e.g., by dynamically changing C-termini conformation. The output from the MTN is the state of the system that may propagate via AFs to remote ion-channels. These output functions are assumed to regulate the temporal gating state of voltage-sensitive channels. This process subsequently regulates the membrane conductive properties and controls the axon hillock behavior by changing the rate, distribution, and topology of open/close channels. The overall functions of the dendrite and neuron can thus be regulated in this manner.

The attractiveness of the concept that the cytosol, with its cytoskeletal structures, may behave as a large dynamical system is clear since it provides a means for real-time computation without the need for stable attractor states. Moreover, the output is relatively insensitive to small variations in either the MTN (cytoskeletal networks) or the input patterns. It should be noted that the temporal system's state evolves continuously, even without external inputs. Recent perturbations, however, have a long-term effect on the MTN trajectories, i.e., there is a memory effect inherent to this system (not to be mistaken with synaptic LTP, which has a much longer time scale). The output from the MTN may converge at or near ion channels to regulate their temporal behavior. The issue of adaptation requires a feedback mechanism that will, at least locally, enable the change of the output function. In the context of neuronal function, with a focus on processivity, synaptic strengthening, LTP, and memory enhancement, the output function may simply reflect an effect of the MTN on synaptic channel function, such that the desired state of the channel appears to have a higher probability of being open/close upon the presentation of the associated input pattern. One possibility is a Hebbian-based response where more frequent activity of certain subdomains of the MTN output states gives rise to a higher/lower density of AFs connecting to corresponding channels.

We now explain how this integrative view may serve as a regulatory (adaptive) mechanism. The input level denoted by A in Figure 18.22 is associated with external electric perturbations passing through membranes, mainly synaptic inputs arriving from other neurons. These signals arrive at the cytoskeleton and directly affect MTNs, and/or actin filaments (bundles), in spiny synapses. However, the actin cytoskeleton is responsible for the propagation of signals to the MTN (see level B). These propagated signals (level C)

are in turn used as inputs to the MTN, viewed as a dynamic system. We further propose that the MTN generates diverse phase space trajectories in response to different input vectors. The requirements from such a system are not too restrictive since the output-state is not an attractor of the system. In other words, information processing at this level is not necessarily based on attractor dynamics but rather on real-time computations. This proposition relies on the observed ability of the MTN to propagate signals and on the specific topological features of MTNs in dendrites, in which shorter MTs of mixed polarity are interconnected by MAP2s. The output from the MTN would be a function of the evolved state vector in certain areas accessed by actin filaments and/or directly linked to ion channels (see both possibilities at level D). These output signals may modify the temporal channel activity, either by directly arriving from the MTN to the channels, or mediated by actin filaments. Hence, the channel-based synaptic membrane conductance is regulated, in particular in the axon hillock region, which is, in most cases, responsible for the generation of action potentials.

The idea that a nonspecific high-dimensional dynamical system may serve as a reservoir of trajectories in the context of liquid state machines (LSMs), has recently been suggested as an explanation for the existence of microcircuits in the brain [87]. The basic structure of an LSM is an excitable medium (hence "liquid") and an output function that maps the current liquid state. The liquid must be sufficiently complex and dynamic to guarantee a universal computational power. This is sufficient to ensure that different input vectors lead to separate trajectories. A network of spiking neurons and a recurrent neural network has been used as a "liquid", whereas the output (readout) function has been implemented by simple perceptrons, threshold functions, or even linear regression functions. Clearly, simpler readout functions restrict the ability of the whole system to capture complex nonlinear dependencies.

18.9 The Inter-Relation Between the Neural Cytoskeleton and the Membrane

Usually, F-actin and microtubular cytoskeletal networks are thought to fulfill separate, independent cellular roles. Highly dynamic actin networks are known for their role in cell motility, in particular the spreading of the leading edge and contraction. The more stable MT cytoskeleton is best known for its importance in cell division and organelle trafficking. However, recent studies provide a more unified role, ascribing important roles to the actin cytoskeleton in cell division and trafficking and important roles for MTs in the generation and plasticity of cellular morphology. Coordination between the actin- and MT- based cytoskeletons has been recently observed during cellular migration and morphogenesis, processes that share some similarities with neurite initiation [28]. A direct physical association between both cytoskeletons has been suggested, because MTs often preferentially grow along actin bundles and transiently target actin-rich adhesion complexes. In neurons, certain plakins and neuron-specific MAPs, like MAP1B and MAP2, may play a role in linking MTs and AFs, helping in the transition from an undifferentiated state to neurite-bearing morphology.

MAP1B and MAP2 are both known to interact with actin in vitro [20,109,128,134,146]. It is likely that by crosslinking, MAP2 and/or MAP1B associated with both cytoskeletons could be involved in guidance of MTs along AF bundles. Alternatively, MAPs could shuttle from MTs to actin and could alter F-actin behavior by actively crosslinking AFs.

Little is known, however, about interactions between neuronal ion channels and the cytoskeleton. Recently, whole-cell and single channel recordings showed that acute disruption of endogenous AFs with cytochalasin D activated voltage-gated K^+ currents in these cells, which was largely prevented by intracellular perfusion with the AF-stabilizer agent, phalloidin. Interestingly, the direct addition of actin to excised, inside-out patches activated, and/or increased single K^+ channels. Thus, acute changes in actin-based cytoskeleton dynamics regulate voltage-gated ion channel activity in bipolar neurons. This may be indicative of a more general and quite appealing mechanism by which cytoskeletal structures control feedback mechanisms in neuronal channels.

Recent theoretical and experimental studies of the electrical properties of AFs and MTs in solution revealed their capability to act as biopolymer wires [83,148]. This means that these protein polymer

filaments are capable of conducting nonlinear ionic waves and even amplifying the signal with respect to the conducting solution [112]. We conjecture a mechanism in which a direct regulation of ion channels and thus synaptic strength by AFs and associated cytoskeletal structures controls and modifies the electrical response of the neuron. According to this scenario (see Figure 18.22), MTs arranged in networks of mixed polarity receive signals in the form of electric perturbations from synapses via AFs connected to MTs by MAP2 [122], or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT [108]. These signals propagate in the form of ionic waves. Specific physical properties of the propagating ionic waves will be discussed in sections that follow.

18.10 Relationship to Cognitive Functions

Transport of proteins and receptors in neurons is likely to have an electromagnetic basis to the extent that this function is possibly a result of MT computation. The perspective advanced in this chapter is that a specific fingerprint defined by a particular electromagnetic state of a microtubular array potentially corresponds to a unique unit of cognition (e.g., a basic visual parameter). Recently, it has been shown that visual components can be represented musically [23]; hence, the idea that one common type of energy underlies divergent perceptual and cognitive processes appears likely. Activation of one electromagnetic fingerprint could, in turn, activate another electromagnetic fingerprint, irrespective of sensory input. Moreover, the subjective feels of this widespread pattern of electromagnetic energy can be specified according to those key physical properties of MTs that influence the transport of proteins to synapses. Factors influencing kinesin-mediated transport include the protein conformation of tubulin and the nature of the C-termini (see [112,136]).

Not only is the conformational state of tubulin critical to effective transport, motor proteins appear to alter albeit temporarily, the conformation of tubulin. Kinesin binding and that of MAP, tau, significantly alter the direction of the protruding protofilament ridges along MTs, which in turn influences their further binding abilities [127]. More than mere local adaptation to binding, MTs may alter their conformation ahead of kinesin processivity [76], supporting the notion of long-range cooperative effects between tubulin dimers located along longitudinal protofilaments of MTs. These biochemical relationships have consequences for electromagnetic fields. The dipole moment of tubulin depends on its configuration in the MT [53,97]. Thus, electromagnetic fields among MTs could, in theory, be induced or inhibited by synaptic inputs that affect the protein conformation of tubulin directly or through alterations in kinesin or MAP binding. Synaptic effects upon MTs could be mediated through ionic currents, by propagation via actin filaments [148], or by signal transduction cascades resulting in the phosphorylation of MAPs [126].

Due to lengthwise electric dipoles of tubulin dimers, information in the form of traveling waves propagated along microtubular tracks can, in principle, be transmitted between synapses with high fidelity (see [149]). MAP2 bridges keep microtubular arrays within the dendritic core parallel and antiparallel by aligning portions of polarized MTs. The antiparallel alignment of MTs, which specifically occurs in dendrites, would severely attenuate any electromagnetic field generated by MTs. However, during enhanced kinesin-mediated transport, as is likely to occur with heightened synaptic activity, MAP2 bound to the MT would be perturbed and may even temporarily detach from the MT. A similar phenomenon might also occur due to dynein-mediated transport, which occurs largely in the opposite direction to that of kinesin-mediated transport. Assuming that at least some MAP2 stays attached to the antiparallel MTs, keeping the dendritic array intact, any net unidirectional transport along the MT array should increase the strength of the electromagnetic field associated with the fingerprint and should further result in the spread of that electromagnetic field to adjacent MTs. Once a sufficient number of MTs were engaged in dynamically sending and receiving complementary electromagnetic energies, whole neuronal compartments (e.g., dendrites) might be expected to interact. Due to the parallel/antiparallel arrangement of MTs in cortical dendrites and the ability of electromagnetic fields to pass from one dendrite to adjacent dendrites, information could, in principle, pass between neurons when such electromagnetic fields were sufficiently amplified as a result of changes in the binding of MAPs or kinesin.

While it is true that there are some 100 billion neurons and some 100 trillion synapses in the human cerebral cortex, so too does each sensory field afford the luxury of extremely high resolution. The fovea of the retina, for example, contains roughly 1 million receptor cells that relay information to the cerebral cortex, diverging to eventually drive the synaptic activity of at least 1 billion cortical cells. Although the mammalian cortex has many neurons, and even more synapses, its connectivity can be readily grasped by one recurrent theme: repetitive high-resolution topographic representation. Despite this simple organizational plan, cells in cortical areas, in particular cells in higher sensory or association areas, inexplicably show correlated responses during cognitive tasks. Experience alters the basic structure of dendrites, and as a consequence, it should also alter any electromagnetic fields generated by MTs as a result of transport proteins moving along them. As described earlier, a rearrangement of the cytoskeleton occurs during early development, with learning, and with neurodegeneration underlying dementia.

Although models of changes in synaptic efficacy, e.g., long-term potentiation or depression (LTP or LTD), offer great potential as memory mechanisms (see [93]), one often overlooked problem is that large numbers of synapses are affected in concert. If only a few synapses are changed with each memory, then the entire cortical system would have a near unlimited capacity, but if many synapses participate in each memory, as seems to be the case for LTP, then there could be a serious saturation effect. This relates back to the topographic organization of the cerebral cortex. Strictly synaptic models (electrochemical) suggest that complex neural networks increase synaptic weights (i.e., neurons that fire together wire together). Nonetheless, visual cortical regions, for example, do not have massively random interconnections among all parts of the visuotopic map, thereby making many of the changes in synaptic efficacy necessary for encoding complex perceptual features impossible.

The biophysical properties of MTs are just beginning to be understood at molecular and atomic levels, and recent empirical evidence suggests interesting effects occur between MTs under certain experimentally induced conditions. Two groups, one led by Watt Webb at Cornell and another led by Paul Campagnola and William Mohler at the University of Connecticut, observed that MTs give rise to intense second-harmonic generation: a frequency doubling upon exposure to a sapphire laser in the 880-nm range. (Other frequencies were partially effective.) MTs were one of the few biological materials having electric dipoles that constructively interfered with the dipoles of neighboring MTs [11,29]. This occurred for parallel MTs in axons, but not for antiparallel MTs in dendrites. Could such a phenomenon be expected to occur with natural learning or upon exposure to oscillatory input, an LTP-inducing tetanus or various pharmacological agents? To the extent that these induce electromagnetic energy, it is conceivable. In addition to being sensitive to electromagnetic radiation, MTs may themselves produce this kind of energy. Second-harmonic generation by MTs is consistent with their ferroelectric properties. In second-harmonic generation, the most strongly enhanced wavelength is 880-nm, supporting the frequently overlooked reports of electromagnetic signaling by cells. Guenther Albrecht-Buehler [5] observed electromagnetic energy in the near infrared region overlapping the 880 nm value that was generated by centrioles for the purpose of cell-to-cell communication, leading him to suggest that: "... one of the functions of MTs may be to play the role of cellular 'nerves'." Infrared light in this range of wavelengths also induces cell aggregation [6]. Since frequency (and hence wavelength) determines the long-range effect of dielectric polarization of a given MT, one would expect this effect to be length-dependent. The distance between MTs was shown to be critical in second-harmonic generation by MTs.

18.11 The Potential for Bioelectronic Applications and Neuromorphic Computing

Traditionally, biologists viewed the cell as a "fluid mosaic bag" containing enzymes, organelles, etc. Recent work has focused on finding the proteins that come together in this cellular "soup" and proceed to effect a change corresponding to a particular biological function. Through the molecular-level analysis of these protein-protein interactions, recent work in various labs has proceeded to build a model of "systems biology," in which these biochemical reactions that have been individually characterized can be brought together to form a cohesive whole, a synergistic dynamics network. From this knowledge, we hope to extract

useful information that will affect fields as diverse as nanotechnology, biotechnology, and materials science. Inside each cell, there is an elaborate network that serves a multitude of functions. It is an intracellular "highway" that provides a roadway for motor proteins to carry cargo and travel along in their journey to extend axonal length, for example. It controls synapses, and dendrite outgrowth. It is responsible for pulling the chromosomes apart during mitosis, for cell motility, etc.

As man-made engineered systems become more and more miniaturized, the push to build "nano-machinery" is driving physicists and engineers towards biomimetics, (i.e., the branch of engineering that mimics biological materials). This is highly feasible and much progress has been made in this area. However, due to the limitations inherent in trying to build mechanical devices on such a small scale, there is still much to learn. It is conceivable that through our better understanding of the cell's individual functional and structural components we will be able to advance medicine and technology beyond even our wildest dreams. One area that may undergo a major paradigm shift as a result of it is computer engineering.

As we enter into the 21st century, the dawn of the exciting new world of computational biotechnology is upon us and we are poised for a new generation of computers that do not have to be told what to do, but have the power to learn on their own. The development of a biological computer that is fast, small, and evolvable is no longer considered science fiction. Scientists are combining biological materials with the latest silicon-based technology in an effort to give us not only electronic devices that are smaller, but are also more flexible in terms of structure and function.

Ironically, our brain can serve as proof of concept. Many scientists now believe that individual neurons display wiring patterns and communication powers that resemble a human computer, and therefore may provide the framework for the design of a biological computer. The brain is composed of 10 billion neurons, each of which may be communicating with 1000 others. The neuron transmits electric signals along its arms, or 'axons'. Inside each axon a parallel architecture of microtubules is interconnected with other proteins, not unlike the parallel computer's wiring. In fact, the structure of microtubules may have evolved towards optimal computational efficiency. The piezoelectric properties of these protein filaments allow them to bend as a result of electric fields or currents which makes them ideal candidates as regulators of synaptic plasticity, a mechanism that could explain the popular principle of "use it or lose it." Thus, seldom used synaptic connections would be switched off in favor of more active ones. Biologist Guenter Albrecht-Buehler [3] demonstrated that cells perceive their environment through a tiny organelle called the centriole, composed of microtubules that were shown to interact with electromagnetic radiation. To further display that microtubules themselves can be conductive, the German biotechnology group, led by Eberhard Unger [41,42] succesfully conducted required experiments and is now working on building nanoelectronic components using these and other proteins. Simultaneously, ideas of combining biological and silicon-based materials in hybrid arrangements are gaining more and more support for future bioelectronic applications. Work is underway at various labs around the world to develop a biological chip. The main objective is to design nanoelectronic components using hybrid protein–silicon structures with arrays of proteins as biological oscillators that can be stimulated by electrodes or acoustic couplers. This will provide an analog circuit with rich dynamics.

DNA computers are unlikely to become stand alone competitors for electronic computers. But digital memory in the form of DNA and proteins is a real possibility with exquisitely efficient editing machines that navigate through the cell, cutting and pasting molecular data into the stuff of life. Beyond that, the innate intelligence built into DNA molecules could help fabricate tiny, complex structures: in essence, using computer logic not to crunch numbers but to build things, an idea conceived of by Caltech's Winfree and Rothemund [123]. A single test tube of DNA tiles could perform about 10 trillion additions per second (about a million times faster than an electronic computer). Interfacing DNA or protein-based hybrid structures with living cells will enable a host of medical and technological applications including non-invasive diagnostic and therapeutic medical applications and computational devices.

One major component of this framework is a protein-based subcellular structure called a microtubule, to which we have devoted a large portion of this chapter. Microtubules are composed of 13 protofilaments, arranged in a spiral pattern, and each protofilament is composed of subunits of tubulin. Each tubulin possesses one of two conformational states: either both monomers can align, or one monomer can shift

30° relative to the vertical axis. Based on the conformation an individual tubulin exists in at a given moment, the conformation of its nearest neighbors can be altered as well. This conformational change can be transmitted throughout the microtubule in a similar manner as patterns are transmitted through cellular automata programs. In addition, as we argued earlier in this chapter, tubulin can have several electronic states as well as dipolar states, some of which can be conceivably linked to the conformations of C-termini and the counter-ion clouds around them. The idea that we could input an electric, chemical, or mechanical signal and generate another one at the output end of the system brings computing or information processing to mind. We believe that ordered protein arrays can function as a programmable processor or even a computer either inside cells such as neurons or as nano-scale devices.

Nanotechnology could and should take advantage of biology in a completely novel manner, (i.e., instead of building materials that mimic biological components, we could use the components themselves). In the case of microtubules and tubulin, rather than purify it from traditional sources such as cow or pig brains, tubulin can be readily cloned into an expression vector, and purified from bacteria in mass quantities. Then, purified tubulin of a predetermined sequence (and thus with desirable biophysical and biochemical characteristics) can be routinely polymerized to form microtubules with specific structural and functional properties. Following that, the microtubules produced could be stabilized in a polymer gel capable of undergoing a phase transition at a particular value of the control parameter such as temperature, applied pressure, pH, or ionic concentration. This would then trigger a signal that would initiate computational processes carried out by individual microtubules or their assemblies interconnected by MAPs or even connected to actin filaments in architecures that could mimic subneuronal designs. This technology could also be applied to sensors or artifical intelligence systems in building an evolvable computer. The only limitations in this endeavor are those imposed by our imagination and our ability to dream up new applications.

18.12 Discussion

Considering the abundance of MTNs and AFs in axons and dendritic trees, the findings and theoretical models described earlier may have important consequences for our understanding of the signaling and ionic transport at an intracellular level. Extensive new information (see [63]) indicates that AFs are both directly [14] and indirectly linked to ion channels in both excitable and non-excitable tissues, providing a potentially relevant electrical coupling between these current generators (i.e., channels), and intracellular transmission lines (i.e., AFs and MTs). Furthermore, both filaments are crucially involved in cell motility and, in this context, they are known to be able to rearrange their spatial configuration. In nerve cells, AFs are mainly located in the synaptic bouton region, whereas MTs are located in both dendrites and the axon. Again, it would make sense for electrical signals supported by these filaments to help trigger neurotransmitter release through a voltage-modulated membrane deformation leading to exocytosis [132]. Actin is also prominent in post-synaptic dendritic spines, and its dynamics within dendritic spines has been implicated in the post-synaptic response to synaptic transmission. Kaech *et al.*, [65] have shown that general anesthetics inhibit this actin mediated response. Among the functional roles of actin in neurons, we mention in passing glutamate receptor channels, which are implicated in long-term potentiation. It is therefore reasonable to expect ionic wave propagation along AFs and MTs to lead to a broad range of physiological effects.

In summary, this chapter broadly described the physical conditions that enable cytoskeletal polymers such as AFs and MTs to act as electrical transmission lines for ion flows along their lengths and along MAP-mediated interconnections between adjacent filaments. In the case of AFs, we propose a model in which each protein subunit is equivalent to an electric circuit oscillator. The physical parameters used in the model were evaluated based on the molecular properties of the polymer. Using the general conductivity rules that apply to electrical circuits we analyzed the properties of ionic waves that propagate along AFs and compared these values to those observed in earlier experiments. In the context of the role played by MTs in neurons, we described the dynamics of C-termini states. We discussed both individual MTs and their networks, including the interactions with ions and signal transmission via MAPs. Recent experiments

on ionic conductivity along AFs and MTs show the validity of the basic assumptions postulated in our models. In light of these results, we conjectured a new dendritic signaling mechanism that involves ion waves along protein filaments which may travel without significant decay over tens of microns, potentially affecting the function of synapses and ion channels.

We proposed a new model for information processing in dendrites based on electrical signaling involving the cytoskeleton. This model predicts that the dendritic cytoskeleton, including MTs and AFs plays an active role in computations affecting neuronal function. These cytoskeletal filaments are affected by, and regulate, ion channel activity. A molecular dynamics description of the C-termini protruding from the surface of a MT has revealed the existence of several conformational states, which lead to collective dynamical properties of the neuronal cytoskeleton. These collective states of the C-termini on MTs have been shown to have a significant effect on the ionic condensation and ion cloud propagation with physical similarities to those recently found in actin-filaments. We have been able to then provide an integrated view of these phenomena in a bottom-up scheme that demonstrates how ionic wave propagation along cytoskeletal structures may impact channel functions, and thus neuronal computational capabilities.

The possibility of an evolvable, dynamic, and responsive electrical circuitry within the cell provided by actin and MT filaments could be of enormous consequence to our understanding of the way cells operate internally and interact with their environment. In particular, it would cast an entirely new light on cell differentiation, cell division, and cell–cell communication. While an integrated theory of this type of behavior is far from being constructed, its individual elements are gradually taking shape.

18.1 Introduction

The prevailing view of neural information processing is based on passive properties of the membrane derived from the application of linear cable theory to dendrites, e.g., [114]. Recent studies, however, have suggested nonlinear models that accommodate new experimental evidence that appears to be inconsistent with this classical view. In particular, conventional theories do not satisfactorily explain: (a) significant fluctuations of synaptic efficacy over short periods of time in response to a recent burst of activation, e.g., [54], (b) a variety of active ion-channels capable of affecting the local membrane electric properties, and (c) nonlinear responses localized to specific dendritic sites, pointing to highly specialized mechanisms correlated with specific inputs. On the other hand, nonlinearities inherent in the new models, e.g., [74,133], give rise to a wider repertoire of (computational) capabilities, such as multiplication, fast correlation, etc. Moreover, experimental and theoretical support for conductive properties of protein filaments and the ionic clouds around them is becoming available, which indicates a far more complex picture of the signaling and information processing phenomena in neurons and other cells.

In this chapter, we suggest that functional electrodynamic interactions between cytoskeletal structures and ion-channels are central to the neural information processing mechanism. These interactions are supported by long-range ionic wave propagation along microtubule networks and actin filaments, and exhibit subcellular control of ionic channel activity, hence impacting the computational capabilities of the whole neural function. Cytoskeletal biopolymers, including actin filaments (AFs) and microtubules (MTs), constitute the backbone of wave propagation, and in turn interact with membrane components to modulate synaptic connections and membrane channels. Indeed, only recently clear functional interactions between these cytoskeletal structures have become apparent. Association of MTs with AFs in neuronal filopodia appears to guide microtubule growth, and plays a key role in neurite initiation [28]. This is further evidenced by the presence in neurons of proteins that interact with both MTs and F-actin, and proteins that can mediate signaling between both types of filaments. This is likely used to control microtubular invasion. The microtubule associated proteins MAP1B and MAP2, for example, are known to interact with actin in vitro, e.g., [146]. Cross-linking, MAP2 and/or MAP1B is highly probable to associate with both types of filaments contributing to the guidance of MTs along AF bundles. Extensive evidence exists confirming a direct interaction between AFs and ion channels, and a regulatory functional role associated with actin. Thus it is clear that the cytoskeleton has a direct connection to membrane components, in particular channels and synapses.

In the following, we demonstrate how each individual cytoskeletal component is capable of supporting both ionic and electronic wave propagation. In particular, we present a molecular dynamics model of the dendritic microtubule network (MTN) where arrays of MTs are interconnected by MAP2s. In this model, ionic waves propagate along the MTN and interact with C-termini of MTs to generate collective modes of behavior. Also in this chapter, a biophysical model of nonlinear ionic wave propagation along AFs is presented, supported by experimental evidence. Finally, we describe a model for a direct regulation of ion-channels and synaptic strength by AFs and networks of MTs that control the electrical response of the dendrite in particular, and the neuron in general. We begin this chapter by providing a general overview of the structure and function of a nerve cell, emphasizing the role of cytoskeletal filaments, ion channels, and their interactions.

18.2 The Neuron

The neuron is the quintessential communicating cell. A great variety of neural subtypes can be found interconnected to one another in complex electrochemical circuits via multiple synaptic connections. Thus, the amount of information processing by a neural circuit depends on the number of such connections or synapses. Neurons are highly polarized cells, whose level of morphological complexity increases during maturation into distinct subcellular domains. A typical neuron possesses three functional domains. These are the cell body or *soma* containing the nucleus and all major cytoplasmic organelles, a single axon, which extends away from the soma and takes cable like properties, and a variable number of dendrites, different

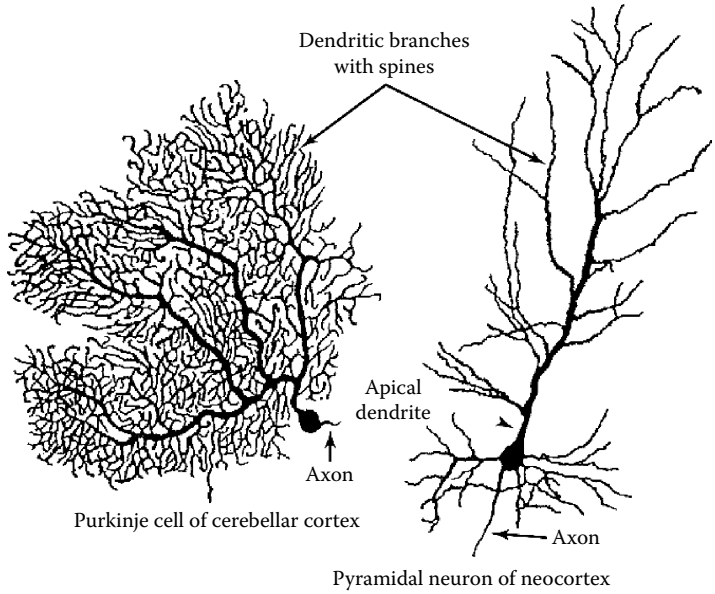

FIGURE 18.1 Two prominent examples of nerve cells.

in shape and complexity, which emanate from the soma. The axonal terminal region, where the synapse contacts it with other cells, displays a wide range of morphological specialization (see Figure 18.1).

Two major types of synapses can be found: (a) asymmetric, responsible for the transmission of excitatory impulses, and (b) symmetrical, present in inhibitory synapses. Turning morphology into a functional feature, the soma and dendritic tree are the major domains of receptive inputs. Thus, both the dendritic arborization and the axonal ramifications confer a high level of sub-cellular specificity in the localization of particular synaptic contacts on a given neuron. The extent to which a neuron may be interconnected largely depends on the three-dimensional spreading of the dendritic tree. Dendrites contain a large number of dendritic spines, which are small sac-like organelles, projecting from the dendritic trunk. Dendritic spines are more abundant in highly arborized cells such as pyramidal neurons, and scarcer in lowly interconnected smaller-sized dendritic tree inter-neurons.

Spines are the dendritic regions where most excitatory inputs are found, such that each spine contains one asymmetric synapse. The number of excitatory inputs can be correlated with the number of spines present in the dendrite. Dendritic spines are complex saccular enlargements, containing ribosomes, and cytoskeletal structures, including actin, and α- and β-tubulin. Electrically speaking, a single neuronal circuit is closed such that afferent inputs reaching the soma and the dendritic tree are transferred to the axon at the other pole of the cell which, in turn, is responsible for transmitting efferent neural information. Both the morphology of the axon and its course through the nervous system are correlated with the type of information processed by a particular neuron, and by its interconnectivity with other neurons. While the axon leaves the soma with a small swelling known as the axon hillock, some neurons protrude the axonal projection from the main dendrite instead. Cytoskeletal components are highly relevant in the structure/function of the neuron. The axonal hillock contains large "parallel" bundles of MTs. Axons are also located with other cytoskeletal structures, such as neurofilaments, which are more abundant in axons than in dendrites. The dynamics in cytoskeletal structures is central to our contention that information can be processed and "delivered" to the synaptic function by changes in the cytoskeletal structures.

Dendrites are the principal element responsible for synaptic integration and for the changes in synaptic strengths that take place as a function of neuronal activity. While dendrites are the principal sites for excitatory synaptic input, little is still known about their function. The activity patterns inherent to

the dendritic tree-like structures, such as in integration of synaptic inputs, are likely based in the wide diversity of shapes and sizes of the dendritic arborizations [116]. Some dendrites are unipolar, while others are multipolar; some have many orders of branching, while others have only one or two; and some branch primarily in two dimensions, while others have complex three-dimensional structures. The size and complexity of dendritic trees increase during development, which has been associated with the ability of the neural system to organize and process information [49]. The majority of synapses, both excitatory and inhibitory, terminate on dendrites, so it has long been assumed that dendrites somehow integrate the numerous inputs to produce single electrical outputs. It is increasingly clear that the morphological functional properties of dendrites are central to its integrative function. Branching in this context is essential to the increasingly complex ability of the neuron to respond to developmental complexity. Nerve branching and complexity are controlled by both external and internal cues. Of current interest to this are substrate and electromagnetic fields, while also recognized are the chemical gradients involved in local adaptation. Highly relevant to adaptation is cytoskeletal dynamics, as the dendritic cytoskeleton plays a central role in the process of ramification, filopodia formation, and more specialized neuronal activity such as long-term potential (LTP) and long-term depression (LTD) circuit dynamics, including memory formation.

The electrotonic or passive properties of dendrites became of great importance to our understanding of dendritic integration of synaptic signals. Early hypotheses were supported by work on motor neurons [34] and sensory receptors [38,67]. In that action, potentials were initiated in the axon hillock region as a result of the graded or algebraic summation of EPSPs and IPSPs occurring in various parts of the neuron. Because of the relatively short space constant calculated for motor neurons [18], it was predicted that excitatory post-synaptic potentials from synapses on the distal portions of dendrites would be ineffective in firing a neuron. Rall [115] revolutionized the field of dendrite physiology by using cable theory for the study of neurons and their dendrites. Action potentials initiated in dendrites by synaptic stimulation were later observed propagating in both directions at velocities of around 0.3 m/s. [7,21,43]. Direct intracellular recordings from dendrites of cerebellar Purkinje cells [84], cortical neurons [57], and hippocampal neurons [153] confirmed that action potentials could be initiated and propagated in dendrites. Very little is known, however, about the active, or voltage-dependent, properties of dendrites, and many questions remain unanswered. Such as the types of ion channels present in dendrites, location, and how active properties alter synaptic integration.

The firing of action potentials elicits characteristic M-shaped Ca^{2+} profiles across the neuron. The Ca^{2+} rise is small in the soma, highest in the proximal apical and basal dendrites, and small again in the distal apical dendrites [62,100,118–120]. The spatial distribution of Ca^{2+} channels explains the distinct Ca^{2+} rise in various cell locations but rather reflects the propagation into the dendrites of trains of action potentials. Imaging with Na^{+}-sensitive dyes has yielded similar patterns, suggesting that Ca^{2+} influx into the dendrites is driven by Na^{+} influx into the dendrites which is driven by Na^{+}-dependent action potentials [62]. Ca^{2+}-dependent action potentials have been demonstrated in hippocampal neurons and dendrites [131]. Most of the action potential induced Ca^{2+} entry is mediated by voltage-gated Ca^{2+} channels [100]. Multiple types of voltage-gated Ca^{2+} channels have been demonstrated in hippocampal neurons [36,40,68,101]. Based on the addition of specific Ca^{2+} channel blockers, the presence of L-, N-, P-, Q-, R-, and T-type Ca^{2+} channels has been reported [16]. This channel distribution may contribute to spike-triggered Ca^{2+} entry into the soma and apical dendrites. Both low-voltage activated (LVA) channels and at least one high-voltage activated (HVA) channel seem to be most predominant in regions of the dendrite at least a 100 mm from the soma. Experimental results strongly suggest a heterogeneous distribution of different types of voltage-gated Ca^{2+} channels within the soma and dendrites of hippocampal neurons [152]. The presence of Na^{+} channels in distal dendrites helps explain the back-propagation of action potentials well into the dendritic tree [88,89,138,139,141]. Action potential propagation in dendrites is rather low, and susceptible to the effects of cable filtering.

A most prominent feature of dendritic ion channel regulation is the potential boosting and enhancement of distal synaptic events. Voltage-gated Na^{+} and Ca^{2+} channels may play an important role in amplifying the magnitude of EPSPs towards the soma. However, channel regulation may also be important for

dendritic interactions in the immediate vicinity of the synaptic input. Voltage-gated channels may alter the local input resistance and time constant, which in turn would influence both spatial and temporal summation of EPSPs and IPSPs, thus conveying highly nonlinear interactions; signal amplification [64,137]. Thus, the nonlinear properties of dendrites may serve as electronic devices. In addition to providing an output, the action potentials elicited by synaptic input, whether initiated at the local synaptic sites or at the axon hillock and back-propagated into the dendrites, would essentially reset the dendritic membrane potential. Action potentials might also provide feedback or an associative signal to other synapses active just before or just after the action potential.

Back-propagating action potentials may also provide feedback to dendritic synapses after a neuronal output has occurred. Ca^{2+} signals are implicated in post-synaptically-induced synaptic plasticity such as short-term potentiation (STP) [92], LTP, and LTD [8,15]. Actin has long been postulated to play important roles in neuronal morphogenesis. High concentrations of actin have been found in the leading edge of the growth cones of developing neurons, and in synapses of mature neurons. Actin filament dynamics also plays a role in a number of related phenomena, including axon initiation, growth, guidance, and branching, in the morphogenesis and stability of dendrites and dendritic spines in synapse formation and stability. Neurons conduct two types of cytoplasmic growth processes in axons and dendrites, both of which are functionally and morphologically distinct, but are developmentally led from the growth cone. Growth cones are composed of finger-like filopodia and veil-like lamellipodia that help the growing processes explore their environment. Axons travel long distances, and upon reaching their targets, produce terminal branches where the growth cones are converted into pre-synaptic terminals. Dendrites usually do not extend such long distances, but often branch extensively, giving rise to dendritic trees. Upon proper contact with axons, post-synaptic dendritic specializations create functional synapses by opposition with the pre-synaptic terminals of axons. These are localized to small protrusions on their dendritic trees called dendritic spines, which are the site of most excitatory synapses. In the mammalian brain these multiple synaptic connections are believed to play important roles in learning and memory. Thus, neural morphogenesis requires changes in both the underlying cytoskeleton and specific interactions with the plasma membrane. To generate a membrane protrusive structure such as an axon, coordinated changes in actin and microtubular organization are required. Growth cones of developing neurons, for example, rapidly extend and retract filopodia by concentred changing in cytoskeletal dynamics, namely bundled AFs in filopodia, and composed of a cross-linked actin network in lamellipodia [80,81,155]. In this section, we have outlined the main features of signaling taking place within a neuron. Major emphasis was placed on the role played by the cytoskeleton in the neuron's structure, growth, and internal signaling. The next section discusses the main biophysical properties of the cytoskeleton.

18.3 The Cytoskeleton

The cytoskeleton is a major component of all living cells. It is made up of three different types of filamental structures, including actin-based microfilaments (MFs), intermediate filaments (IFs) (e.g., neurofilaments, keratin), and tubulin-based microtubules (MTs). All of them are organized into networks, which are interconnected through numerous particular proteins, and which have specific roles to play in the functioning of the cell. The cytoskeletal networks are mainly involved in the organization of different directed movements in cell migration, cell division, or in the internal transport of materials. Polymerization of MFs is responsible for cell migration and for the remodeling of the leading edge of cells. Molecular motors are protein complexes associated with the cytoskeleton and drive organelles along MTs and MFs in a "vectorial" transport.

MTs are some of the most basic and important cytoskeletal elements in the morphological scheme of neurons. As for the case of cytochalasins in actin structures, the addition of microtubular modifying agents was first used to assess the role of MTs in axon elongation. Microtubular disrupting agents affect axons first and have no early effects on growth cones and filopodia, suggesting that MTs provide support for the axon. Conversely, microtubular invasion may be a critical element in the formation of neurite projections. Initially, expanded lamellipodia first undergo segmentation at certain spots where MTs accumulate in an

ordered array [27,144,156] and gradually "migrate away" from the cell body. These lamellipodia transform into nascent growth cones. Neurite elongation takes place as the MTs in the shaft become compressed into a narrower bundle. In cultured hippocampal and cortical neurons, this process most likely implies the coordinated control of the major cytoskeletal components, including actin, MTs, and associated proteins.

Thus, MTs are essential for neurite development. One particular aspect of microtubular involvement in neurite outgrowth is vesicular transport. Most membrane insertion occurs at the growth cone of axons [22,24]. MAP-stabilized MTs, form parallel or antiparallel arrays, which might act as compression resistant struts inside neurites [61]. Because MTs constantly invade the actin cytoskeleton in lamellipodia of epithelial [125] and neuroblastoma cells [27], such a mechanical role for MTs could also be important during de novo neurite initiation. Neurite-like protrusions, for example, can be induced in non-neuronal cells by the exogenous expression of stabilizing proteins such as MAP2 and tau [72,79,157]. Spontaneous neurite initiation is dependent on both the presence and the dynamic properties of MTs.

A number of proteins associate with MTs, including MT motors, kinases, so-called "structural" MAPs, which alter microtubule structure, and specialized MAPs, which bind to microtubule plus or minus ends. Members of the MAP2/tau family have long been proposed to be important regulators of neurite behavior [10,48,151]. MAP2 and tau stabilize MTs by reducing catastrophe and promoting rescues, leading to prolonged growth periods and thus enhanced net microtubule accumulation [32,45,75]. MAP2 and tau stabilize MTs by binding along the outer ridges of protofilaments [2].

F-actin and MTs cytoskeletal networks are typically thought to fulfill separate, independent cellular roles. Highly dynamic actin networks are known for their role in cell spreading and contraction. The more stable MT cytoskeleton is known for its importance in cell division and organelle trafficking. However, recent studies provide important roles for the actin cytoskeleton in cell division and trafficking and for MTs in the generation and plasticity of cellular morphology. A direct physical association between both cytoskeletons has been suggested, because MTs often preferentially grow along actin bundles and transiently target actin-rich adhesion complexes.

Association of MTs with actin cables in filopodia appears to guide microtubule growth along the most efficient path anti-parallel to retrograde flow [130]. Thus, specific coupling between MTs and actin bundles presumably promotes MT advance. Proteins that are able to interact with both MTs and F-actin, or proteins that can mediate signaling between both cytoskeletons likely control the regulation of MT invasion. This is further strengthened by specific microtubule association of the microtubule-associated proteins MAP1B and MAP2, both known to interact with actin in vitro [20,109,128,134,146]. Furthermore, MAP2 binds to F-actin and efficiently induces actin bundle formation [51,129]. It is likely that by crosslinking, MAP2 and/or MAP1B associated with both cytoskeletons could be involved in the guidance of MTs along actin filament bundles. Alternatively, MAPs could shuttle from MTs to actin and could alter F-actin behavior by actively crosslinking AFs.

The effect of changes in the cytoskeleton on ion channel activity has been the focus of recent attention. Most studies have employed drugs that selectively stabilize or destabilize either AFs or MTs, with resulting effects on specific ion channel activity, either as changes in whole cell conductance or single channel activity by the patch clamping techniques. Although direct binding of specific cytoskeletal proteins to individual channel proteins remains to be demonstrated, recent work in which exogenous purified actin has been added to the cytoplasmic side of channels excised from the cell membrane has in numerous cases directly confirmed an effect of cytoskeletal filaments. A body of earlier evidence suggested that various cytoskeletal components, including actin and actin-associated proteins, anchor, co-localize, and regulate both the spatial stability as well as the function of ion transport proteins. It is possible that actin either binds directly to the channels, or that actin may first interact with actin-binding proteins, which in turn regulate (by binding or other indirect interaction) ion channel function. Independent studies demonstrated that membrane-resident CFTR is functionally regulated by AF organization, which may also involve a direct interaction with actin. Thus, ion channel may be controlled by direct and indirect cytoskeletal interactions.

Before we present an integrated view of the conductive properties of the active and passive structural blocks of the cytoskeleton, we should review the current state of knowledge regarding their conductive properties.

18.4 Overview of Biological Conductivity

Cope [19] has presented a detailed review of the applications of solid-state physics concepts to biological systems. He divided the discussion into seven groups. The first involves semiconduction of electrons across enzyme particles as a rate-limiting process in cytochrome oxidase, evidenced by kinetic patters of enzymes and microwave Hall measurements. Second, pn-junction conduction electrons were suggested by kinetics of photobiological free radicals in the eye and in photosynthesis. Their I-V characteristics conform to the diode equation:

$$I = I_0 exp(V/kT) \tag{18.1}$$

Third, there may be a connection between superconduction and growth in nerves. Fourthly, phonons and polarons are involved in mitochondrial phosphorylation. Next, piezoelectricity and pyroelectricity may be involved in the growth of nerves and bone structures. Then, infrared electromagnetic waves may transmit energy in lipid bilayers of nerves and mitochondria. Finally, complex sodium and potassium ions in structured cell water may be analogous to valence band electrons in semiconductors, free cations being analogous to conduction electrons. The ionic process in cell water resembles electronic conduction in seminconductors. For dried proteins or DNA, Szent-Gyorgi[142] noticed that their conductivities obeyed the relationship:

$$\sigma = \sigma_0 exp(-E_a/kT) \tag{18.2}$$

With activation energies E_a on the order of 1 eV. The presence of water may cause considerable changes in conductivities, (for example, in cytochrome oxidase this may be reduced to 0.3 eV).

Adessi *et al.* [1] have provided a theoretical treatment of transmission through a poly(g)DNA molecule. They found that there was a modification of the rise of a B-DNA form, which can induce a shift of the conduction channel towards a valence one. They found that deformation of the backbone of the molecule has a significance on the hole transport. Furthermore, the presence of ionic species (e.g., Na) in the surrounding of the molecule can create new conduction channels. In photo-excitation experiments, hole transport occurs through coherent transport at short distances and long-range incoherent or hopping transport at large distances. Fink *et al.* [39] studied the metallic behavior in λ DNA using an electron projection technique. Superconducting behavior has been observed by Kasumov *et al.* [66]. Porath *et al.* [111] observed semiconductor behavior with a poly(g)-poly(c)DNA molecule. A scanning force microscope has been used by de Pablo *et al.* [26] to observe insulating behavior. This paper models a single poly(g) DNA lying between electrodes, and transmission was computed with a Landauer–Buettiker formalism based on Green's functions. The electronic properties of O_2-doped DNA have been studied by Mehrez *et al.* [96], who suggested that DNA conduction is affected by O_2-doping, in particular hole doping. However, ab initio atomic structure calculations of O_2-doped DNA indicate negligible charge transfer. The absence of dc conductivity in λ DNA has been investigated by de Pablo *et al.* [26]. First principles electronic structure calculations indicate a minimum DNA resistance of 10^{16} Ω per molecule, and a minimum resistivity of 10^4 Ωm. However, lower energy electron bombardment may dramatically increase conductivity and with electron energies between 50 and 200 eV may lead to metallic conduction with a resistance of 2×10^8 Ω. Fink *et al.* [39] discussing DNA and conducting electrons stated that I-V characteristics of DNA indicate ohmic-like behavior with a resistance of 2 $M\Omega$ for a 600 nm-long DNA rope corresponding to $\rho = m\Omega$ cm. These authors speculate that DNA may be semiconducting, insulating, or metallic simultaneously depending on the arrangement of molecules in the structure. Endres *et al.* [37] discussed the quest for high-conductance DNA saying that DNA conduction is an unsolved problem first enunciated by Eley and Spivey [35]. Experimental outcomes range from insulating to semiconducting to even superconducting, and the uncertainties depend on: (a) contacts between the electrodes and the DNA and (b) differences in the molecules (sequence, length, arrangement, preparation) within the DNA. It appears that drying DNA can lead to conformations with localized electronic high states, although hole doping of the backbone by counter-ions might also be possible. Wet DNA may support electrical current due to solvent impurity

states in the large high-Π^* energy gap. Davies and Inglesfield [25] discussed the embedding method for conductance of DNA calculations. It is believed that the pathway for transport in DNA runs through the bases in the center of the double helix molecule. The dominant transport mechanism for DNA appears to be coherent hopping. Calculations show extreme sensitivity to the choice of contact orbitals.

Marechal [95] discussed the transfer of protons as a third fundamental property of hydrogen bonds. The importance of the cooperative resonance types in cyclic structures is stressed. Proton transfers along H-bonds have been discussed as a mechanism of vital importance for chains, helices, and in cyclic structures such as rings. Consta and Kapral [17] discussed proton transfer in mesoscopic molecular systems. Proton transfer rates and mechanics are studied theoretically with solvent molecules in solution. The proton transfer occurs as a result of orientational fluctuations on the cluster's surface. The environment influences solvent effects and reaction rates. The rate constant was established to be 1/59 ps at 260 K and for the bond length fixed at 2Å. Morowitz [102] discussed proton semiconductors and energy transduction in biological systems. He presented the possibility of protochemistry paralleling electrochemistry. ATP synthesis was discussed as coupled to proton transport assuming a gated protein semiconductor across a membrane. Protein conduction in biological structures involves the water of hydration and protein molecules.

Ripoll *et al.* [121] investigated ionic condensation and signal transduction. Ion condensation on biopolymers at a critical value of the charge density may lead to intra-cellular signaling due to the diffusion of condensed counter-ions in the near region along cytoskeletal filaments. A feedback mechanism was proposed between condensation/decondensation of calcium and the activation of calcium-dependent enzymes. This is shown to create coherent patters of protein phosphorylation. It was postulated that ion condensation operates in signal transduction. In the case of polymer ionics [117], the conductivity depends on temperature via the formula:

$$\sigma T = Aexp[-B/(T - T_o)] \tag{18.3}$$

indicating activated hopping. The concept of the Fermi level in solution has been extended by Bockris and Khan [9] through the introduction of a reversible potential for a redox couple.

Unfortunately, measurements of conductivity of biopolymers (including MTs) are fraught with difficulties due to their structural heterogeneity, strong dependence on the environmental conditions (pH, ionic concentration, temperature, etc.), and the inherent liquid state of the sample. Nonetheless, attempts have been made recently to measure resistance values of MTs, both intrinsically and as ionic conduction cables. Fritzsche *et al.* [41] made electrical contacts to single MTs following dry-etching of a substrate containing gold microelectrodes. Their results indicate intrinsic resistance of a 12 micron-long MT to be in the range of 500 megaohms, giving a value of resistivity of approximately 40 mega-ohms/micron in their dry state. The same group performed measurements on gold-coated MTs [42] which were covered with a 30-nm layer of gold following sputtering. The resistance of the thus metallized MTs was estimated to be below 50 ohms, (i.e., originated entirely due to the metallic coating). Minoura and Muto [99] measured the ionic conductivity of MTs using an electro-orientation method under an alternating electric field. The ionic MT conductivity was calculated as $1.5 + / - 0.5$ mS/m, which is approximately 15 times greater than that of the buffer solution. This was attributed to the counter-ion polarization and is consistent with another recent study of ionic conductivity along MTs. Furthermore, Goddard and Whittier [47] reported their measurements of RF reflectance spectroscopy of samples containing the buffer solution, free tubulin in buffer, MTs in buffer, and finally, MTs with MAPs in buffer. The sample size in each case was 5 ml. The concentration of tubulin was 5 mg/ml and in the last case the concentration of MAP2 and the tau protein was 0.3 mg/ml. The average DC resistance reported by these authors was (a) 0.999 $k\Omega$ (buffer), (b) 0.424 $k\Omega$ (tubulin), (c) 0.883 $k\Omega$ (MTs), and (d) 0.836 $k\Omega$ (MTs + MAPs). It's not straightforward to translate these results into resistivity of MTs without making assumptions about their geometrical arrangement and connectivity. However, assuming all tubulin being polymerized in case (c) and a uniform distribution of MTs forming a combination of parallel and series networks, one can find the resistance of a 10 μm–long MT, forming a basic electrical element in such a circuit, to have approximately an 8 $M\Omega$ resistance. This compares very favorably to an early theoretical estimate of MT conductivity based on the Hubbard model with electron hopping between tubulin monomers. This model predicted the resistance of a 1-μm MT

to be in the range of 200 $k\Omega$, hence a 10-μm MT would be expected to have an intrinsic resistance of 2 $M\Omega$, within the same order of magnitude as the result reported by Goddard and Whittier [47]. While direct experimental analysis of intrinsic conductivity of the various cytoskeletal components is still nebulous, theoretical modeling of these effects is very well developed. The next section presents our current understanding of the intrinsic conductivity of MTs.

18.5 Intrinsic Electronic Conductivity of Microtubules

Microtubules (MTs) are ubiquitous in eukaryotic cell biology. Their primary role is to serve as the cellular scaffold and act as a corridor for the transport of vesicles through the cell by motor proteins. The interest in MTs stems from their involvement in a number of crucial cellular processes including mitosis and, more recently, the discovery of their role in the communication between the exterior of the cell and the nucleus [46,94]. The special arrangement of MTs just prior to chromosone separation makes them an ideal candidate for mediating a signal of some sort, which would cause the coordinated breakage of sister chromatids. In the axons of nerve cells, the MTs are arranged in bundles, parallel to the axon [56]. These groups of MTs span the entire length of the axon and might serve to carry signals from the cell body to the nerve terminus or vice versa. No mechanism for this sort of direct feedback is known. We demonstrate here that the MT may be able to conduct a current along its length through a process of electron hopping between binding sites on each dimer.

The MT is made up of a protein called tubulin. Each subunit contains α-tubulin and β-tubulin monomers joined together to form a dimer. The dimers are connected end to end to form a protofilament. These protofilaments, usually 13 in number, are wrapped up to form a hollow tube, the MT. The dimers are themselves 5 nm in diameter and have a length of about 8 nm. A MT has an outer diameter of 25 nm and an inner diameter of 15 nm (see Figure 18.2).

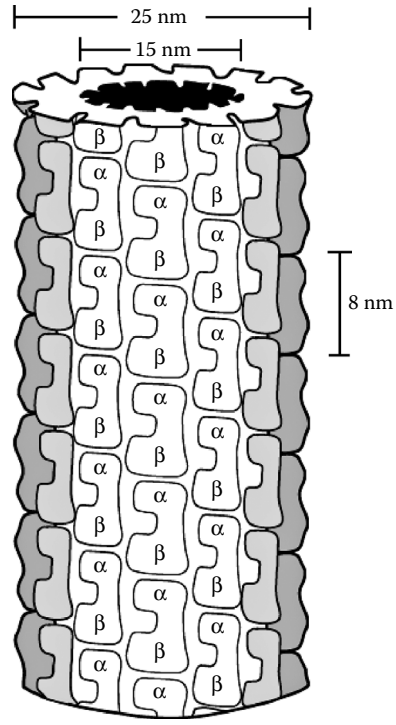

FIGURE 18.2 Structure of a typical microtubule demonstrating how it is formed by a special arrangement of tubulin dimers.

The tubulin dimer of which the MT is composed has at least two different conformational states [58]. That is, while the amino-acid chain of the protein remains fixed, its three-dimensional shape may change. It is believed that these conformational changes are the result of hydrolysis and an associated charge movement from one binding site within the molecule to another. It is precisely this charge movement that may lead to the conduction through the polymer.

One may take a semi-classical view of the movement of electrons along the protofilament. We ignore the fact that the protofilament is nearly one-dimensional and consider its *bulk* properties. Assuming two conduction electrons for each tubulin dimer, the conduction electron density is

$$\begin{aligned} n_0 &= 2/(8nm \times 5nm \times 5nm) \\ &= 1.0 \times 10^{19}/cm^3. \end{aligned} \tag{18.4}$$

In comparison with other materials, this value is slightly higher than typical semi-conductor concentrations, usually $10^{13} - 10^{17}/cm^3$, but is much less than typical metals, which have a conduction electron density of $10^{22} - 10^{23}/cm^3$. However, the electrons are expected to have relatively low mobilities unless they are excited from the ground state configuration. The excitation energy is a function of both the number of electrons within the protofilament and its size. Suppose that the mobility of excited electrons is at least similar to the mobility of electrons within semiconductors, such as Si where the electron mobility, μ_e, is about 1300 $cm^2\ V^{-1}\ s^{-1}$. The electrical conductivity σ is given in a semi-classical model by the well-known formula

$$\sigma = ne\mu_e \tag{18.5}$$

where e is the electron charge and n is the conduction electron density given by

$$n = n_0 e^{-\Delta/\kappa T} \tag{18.6}$$

where n_0 represents the total number of electrons. If we assume that the gap between valence and conduction bands, Δ, is about 0.40 eV, then at physiological temperature, some of the carriers will be excited and should be available to conduct. Applying the preceding formula (18.6), a conductivity of about 10^{-2} (in SI units) is expected for the protofilament.

$$\sigma \sim (10^{25} e^{-0.40/0/026})(1.6 \times 10^{-19})(0.13) \sim 0.04\Omega^{-1} m^{-1} \tag{18.7}$$

However, if the hybridization of electronic orbitals lowers the gap to a value closer to zero, the expected conductivity would be significantly higher:

$$\sigma \sim (10^{25})(1.6 \times 10^{-19})(0.13) \sim 2 \times 10^5 \Omega^{-1} m^{-1} \tag{18.8}$$

These values should be compared to values in excess of 10^8 for copper and other good conductors, and 10^7 for lesser conductors and semi-metals. Typical semi-conductors such as Si and Ge have intrinsic conductivities of $10^{-3} - 10^{+1}$ at room temperature, but when heavily doped, the conductivity may rise to between 10^4 and 10^5.

In order to model the MT as a semiconductor, the individual tubulin dimer must first be physically analyzed. The $\alpha\beta$-tubulin dimer is comprised of about 890 amino acids which represents about 13000 nuclei. A gross simplification which we introduce is to treat each monomer as having an effective site energy for electronic binding. Fluctuations of the site energy on scales less than the monomer spacing are therefore washed out. It is convenient to model this system as two quantum wells separated by a potential barrier. The two wells represent two binding sites for an electron, which may hop between the monomers, resulting in the change of molecular conformation. We can estimate the relevant parameters of the well depth and the well width from kinetic studies and with a knowledge of the molecule's overall geometry. Once the bound states and their energies are known for this system, this knowledge may be applied to a

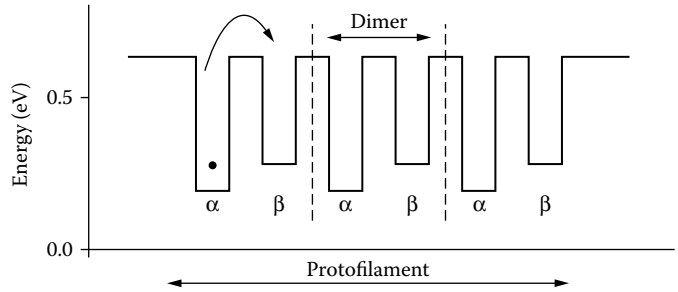

FIGURE 18.3 A one-dimensional chain of quantum wells representing the energy profile along a MT protofilament where the α and β monomers have alternating site energies.

second-quantization scheme. This procedure allows us to make progress without specifically requiring us to solve for the wavefunction of the system.

A 1D chain of quantum double wells is pictured in Figure 18.3. For simplicity, we are initially making each binding site have the same energy. If this is related to GTP hydrolysis, they may differ by about 0.17 eV (4 kcal/mol) [59]. This is roughly the quantity of energy stored in the lattice when GTP is hydrolyzed to GDP [13,60]. The barrier height between dimers has been estimated from kinetic data. The bond strength must be somewhat larger than the hydrolysis energy delivered to the lattice or else hydrolysis of the dimers would cause immediate disassembly. Hopping along the protofilament by electrons presumably has an energy comparable to this binding energy. We have estimated 0.4 eV for intra-dimer hopping and 1.0 eV for the inter-dimer hopping. What may be varied in the model, is the central barrier which must be overcome for each tubulin dimer to change conformation. If it is nearly as large as the barrier to electron movement between dimers, then the protofilament will look like a chain of single quantum wells rather than double quantum wells because the difference between the α and β monomers will not be distinguished. However, if the central barrier is too small, the chain will again look like a series of single quantum wells since the effect of the barrier would be negligible. The depth of the deeper well, f_1, has been selected as 0.4 eV initially. Given the value, we assumed a 25% difference in well depths. If f_1 is much larger, the dimer nature of the protofilament is lost because the wells are effectively the same depth.

The results for the single electron eigenstates of a double quantum-well may be found using a transfer matrix method for the time-independent 1D Schrodinger equation in each interval in which the piece-wise constant potential is defined as

$$\hat{H}\psi = \frac{\hat{p}^2}{2m}\psi + \hat{V}\psi = E\psi \tag{18.9}$$

The oscillatory solution

$$\psi(x) = A\cos(kx) + B\sin(kx) \tag{18.10}$$

applies to $E > V$ where

$$k = a\sqrt{2m(E-V)}/\hbar \tag{18.11}$$

while for $E < V$, the solutions are exponentially damped

$$\psi(x) = Ae^{\kappa x} + Be^{-\kappa x} \tag{18.12}$$

where

$$k = \sqrt{2m(V-E)}/\hbar \tag{18.13}$$

Now, matching conditions for the wave function and its derivative are applied at each interface. This gives a 2×2 matrix relating the coefficients in the wave function expansion according to

$$\begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = \begin{pmatrix} {}^{2,1}M_{11} & {}^{2,1}M_{12} \\ {}^{2,1}M_{21} & {}^{2,1}M_{22} \end{pmatrix} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} \tag{18.14}$$

In the preceding equation, the superscript to the left of the M denotes which coefficients are being linked. The subscripts indicate the matrix element. In an iterated fashion, one eventually arrives at the following:

$$\begin{pmatrix} A_n \\ B_n \end{pmatrix} = \begin{pmatrix} {}^{n,1}M_{11} & {}^{n,1}M_{12} \\ {}^{n,1}M_{21} & {}^{n,1}M_{22} \end{pmatrix} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} \tag{18.15}$$

Now, for bound states $A_1 = B_n = 0$ so that the wavefunction decays outside the region of the quantum wells:

$$B_n = 0 \quad \Rightarrow \quad {}^{n,1}M_{22} = 0 \tag{18.16}$$

Given the choices for our quantum double well (width, $a = 2$ nm; and height, $V = 1.0$ eV), one finds that there are two bound states for this dimer problem. As the number of dimers is increased, one resorts to numerical analysis. In Figure 18.4, the energy of the two bound states is plotted as the energy of the central barrier is varied. The lowest energy state is the symmetric wavefunction, which increases in energy sharply as the central barrier is increased. The second bound state is the antisymmetric wavefunction it has a node within the barrier, hence its energy increases only marginally.

The energy calculation for a sequence of n such dimers leads to the development of bands as hybrid orbitals develop across the polymer. Roughly speaking, one band is of hybridized symmetric orbitals and the higher lying band of hybridized antisymmetric orbitals. The separation of the two bands and the spread of each individual band determine the values of the parameters which shall be used in the tight-binding Hubbard model used to model the polymer.

The second-quantized Hamiltonian for a many-electron multidimer system becomes

$$\hat{H} = \sum_{i,\sigma} \epsilon_i \hat{c}^{\dagger}_{i\sigma} \hat{c}_{i\sigma} + \sum_{i \neq j,\sigma} t_{ij} \hat{c}^{\dagger}_{i\sigma} \hat{c}_{j\sigma} \tag{18.17}$$

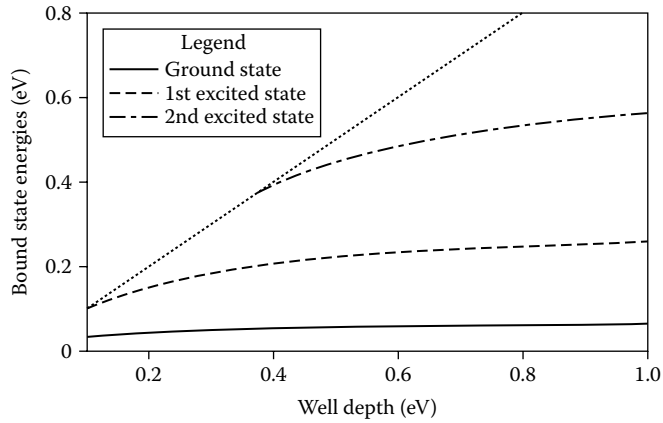

FIGURE 18.4 Variation of the bound state energies with the depth of the double quantum wells, $f_1 = f_2$. The straight line indicates where the bound state energy is equal to the well depth.

where the operators $\hat{c}^{\dagger}_{i\sigma}$ and $\hat{c}_{i\sigma}$ are the usual fermion creation and annihilation operators, and where i runs from 1 to $2n$ representing the two sites on each of the n dimers. The ϵ_i represent the potential energy at each site and the kinetic terms t_{ij} account for hopping from one site to another. There are two different kinds of interactions depending on whether an electron hops within a dimer, or between dimers. Hence, this kinetic parameter has two different values along the chain. Since there are no interactions between the states with $+\frac{1}{2}$ spin and those with $-\frac{1}{2}$ spin, the state space may be divided into two identical subspaces labeled by the electron spin. In each of these subspaces, the matrix corresponding to this chain of dimers is tri-diagonal and may be diagonalized to determine the itinerant eigenstates of the system. The coefficient t_d which represents the movement of an electron within a dimer causes the eigenstates to be split into two bands by an amount, $2t_d$. Within each of these bands, the coefficient t_l of the inter-dimer hopping, causes these two single electron bands to broaden each to about $2t_l$. Now, although the preceding description is qualitative, clearly whenever $t_d \sim t_l$, these bands will overlap and transitions between the states will be important.

Considering the band formation in the quantum well formulation, we can assign values to t_d and t_l. The two bands are separated by about 0.40 eV, so $t_d \sim 0.20$ eV, and using the bottom band to estimate t_l it widens until it is about 0.10 eV thick, so $t_l \sim 0.05$ eV.

The Hubbard model is the simplest second quantized model to capture all of the essential features of a real system of interacting particles [82]. In this model, electrons are the fundamental excitations. All states may be built up from the vacuum using the fermion creation operators. Once the number of sites is selected, n, and the number of electrons is determined, e, there are

$$\binom{2n}{e} = \frac{2n!}{e!(2n-e)!} \tag{18.18}$$

distinct electronic states. These states are built up by applying in normal order each of the combinations of e-electron states.

The second quantized Hamiltonian for the Hubbard model with electron–electron interactions is conventionally written as

$$\hat{H} = \sum_{i,\sigma} \epsilon_i \hat{c}^{\dagger}_{i\sigma} \hat{c}_{i\sigma} + \sum_{i \neq j,\sigma} t_{ij} \hat{c}^{\dagger}_{i\sigma} \hat{c}_{j\sigma} + \sum_{i} U_i \hat{c}^{\dagger}_{i\uparrow} \hat{c}_{i\uparrow} \hat{c}^{\dagger}_{i\downarrow} \hat{c}_{i\downarrow} \tag{18.19}$$

The last term accounts for electron–electron repulsion now that we have gone to a many electron system. In our simple model, this is limited to an onsite interaction. To this point, we have made each of the site energies equivalent ($\epsilon_i = \epsilon, \forall i$). In what follows, $U = 2.0$ eV which is the energy associated with two bare electrons lying about 0.7 nm apart. This choice seems reasonable within a well of width 2.0 nm. We try to solve the problem by considering the electron–electron term as a perturbation to study how it affects the electronic states of the dimer. The Hamiltonian in the absence of the final U-term may be diagonalized by the following unitary transformation:

$$\alpha^{\dagger}_{1'\sigma} = \frac{1}{\sqrt{2}}(c^{\dagger}_{1\sigma} + c^{\dagger}_{2\sigma}) \tag{18.20}$$

$$\alpha^{\dagger}_{1'\sigma} = \frac{1}{2\sqrt{2}}(c^{\dagger}_{1\sigma} - c^{\dagger}_{2\sigma}) \tag{18.21}$$

The linear combination of operators is simple because we have made the site energies ϵ_1 and ϵ_2 equal. These new operators are easily shown to obey the usual anticommutation relations for fermions and are said to be in the itinerant or distributed electron basis. The Hamiltonian may now be rewritten in terms of these new operators, as

$$\hat{H} = \sum_{\sigma}(\epsilon + t)\alpha^{\dagger}_{1\sigma}\alpha_{1\sigma} + \sum_{\sigma}(\epsilon - t)\alpha^{\dagger}_{2\sigma}\alpha_{2\sigma} + \frac{1}{2}\sum_{\sigma \neq \sigma'} V_{ijlm}\alpha^{\dagger}_{i\sigma}\alpha^{\dagger}_{j\sigma'}\alpha_{l\sigma'}\alpha_{m\sigma} \tag{18.22}$$

the vacuum state is represented by $|\Omega>$. Acting with our Hamiltonian on this basis gives us the matrix form of the Hamiltonian:

$$\hat{H} = \begin{pmatrix} 2(\epsilon+t)+\frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} & \frac{(U_2-U_1)}{4} & 0 & \frac{(U_1+U_2)}{4} \\ 0 & 2\epsilon & 0 & 0 & 0 & 0 \\ \frac{(U_1-U_2)}{4} & 0 & 2\epsilon+\frac{(U_1+U_2)}{4} & -\frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} \\ \frac{(U_2-U_1)}{4} & 0 & -\frac{(U_1+U_2)}{4} & 2\epsilon+\frac{(U_1+U_2)}{4} & 0 & \frac{(U_2-U_1)}{4} \\ 0 & 0 & 0 & 0 & 2\epsilon & 0 \\ \frac{(U_1+U_2)}{4} & 0 & \frac{(U_1-U_2)}{4} & \frac{(U_2-U_1)}{4} & 0 & 2(\epsilon-t)+\frac{(U_1+U_2)}{4} \end{pmatrix}$$

The Hamiltonian is then diagnolized in order to determine its eigenstates. In the absence of the Coulomb repulsion ($U = 0$), the electrons are localized on the $2'$ site with energy $2(\epsilon - t)$, the gap to the first excited state being $2t$. However, as U is increased, the effect of the Coulomb interaction raises the energy of the ground state relative to the excited singlet states, which do not feel the Coulomb repulsion. Consequently, the gap between the ground state and the first excited state is actually reduced through the introduction, as shown in Figure 18.5. Thus, when conductivity is being considered, it is important to bear in mind that the gap is reduced by the presence of the electron–electron interactions.

To this point, we have made each of the site energies equivalent, ($\epsilon_i = \epsilon$), and the electron repulsion the same at all sites ($U_i = U$). The lone complication lies within the kinetic term, where the hopping parameter will depend on the two sites between which the electron hops. However, since we first consider the MT protofilament, it shall initially be a constant as well, $t = 0.4$ eV, where the choice comes from the separation of the energy bands in the 1D Schrödinger picture.

Since the Hamiltonian conserves both the particle number and the overall spin of each state, we are free to work in subspaces enumerated by the spin of the states it contains. This reduces the problem slightly since it is possible to consider individually the spin $+1$, spin 0, and spin -1 systems separately in a two-electron system. In addition, the symmetry implies that the spin $+1$ and spin -1 systems have the same conductive properties. We also find that the ground state is always a state consisting of the lowest possible total spin.

When the inter-dimer hopping term is small relative to the intra-dimer hopping term $t_{inter} < t_{intra}$, the form of the ground state is independent of the number of dimers. In each case, the ground state is a linear combination of singlet states on each dimer. The singlet states are those where two electrons are

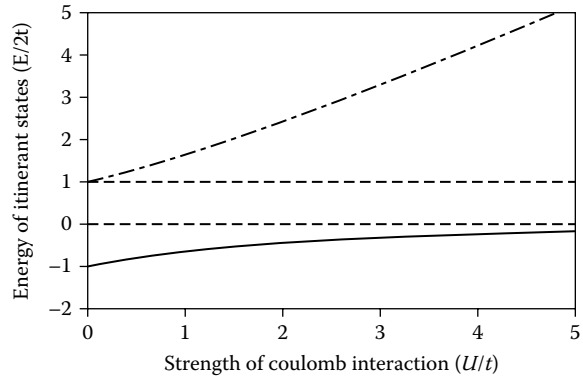

FIGURE 18.5 Energy of the itinerant states as a function of U/t with the energy plotted in units of $2t$.

paired on an individual binding site, or where the state consists of the anti-symmetric combination of an up-electron and a down-electron on neighboring binding sites of the dimer. When the inter-dimer hopping parameter is increased, the density of states becomes more uniform between the ground state and the highest energy eigenstate. With the gap between the ground state and the first excited state of the system becoming diminished. Since the hopping term within a dimer is largest, the system prefers to have two electrons with the same spin within the same dimer in the ground state.

For electronic conductivity, the band formation importantly depends upon the hopping parameter between dimers. When this parameter is small relative to the intra-dimer hopping, $t_{inter}/t_{intra} \sim 0.1$, there remains a rather large gap between the ground state and the first excited state of about $2t_{intra}$ which is reduced as the repulsion term increases. However, when the hopping between dimers is equal to the hopping within dimers, $t_{inter} \sim t_{intra}$, the gap is minimized. In the event that $t_{inter} > t_{intra}$, we would effectively have to relabel the dimers and would then return to the picture where $t_{inter} < t_{intra}$.

Kubo was the first to derive formulae for the electrical conductivity in solids, and his derivation is applied to our case in the present section [77]. In the Coulomb gauge, we write the vector potential for a uniform electric field along the direction of the chain, $A(t)$, as

$$A(t) = \frac{cE(t)}{-i\omega} e^{i\omega t}, \tag{18.23}$$

Adding a field-coupling term to the Hubbard Hamiltonian and using a canonical transformation gives [91]

$$\hat{H}'_0 = -t \sum_{i\sigma} [\hat{c}^\dagger_{i\sigma} \hat{c}_{i+1\sigma} e^{-ieA(t)/c} + \hat{c}^\dagger_{i\sigma} \hat{c}_{i-1\sigma} e^{ieA(t)/c}]. \tag{18.24}$$

where a is the lattice spacing and c is the speed of light. Expanding to second order in the vector potential, we find

$$\hat{H}_A = \frac{A}{c} \hat{j} - e \frac{A^2}{c^2} a^2 \hat{H}_0, \tag{18.25}$$

where

$$\hat{j} = i\mathrm{Eat} \sum_{i\sigma} (\hat{c}^\dagger_{i\sigma} \hat{c}_{i+1\sigma} - \hat{c}^\dagger_{i\sigma} \hat{c}_{i-1\sigma}). \tag{18.26}$$

So, the energy of the original system is corrected to this order and the interaction term is proportional to the current.

Suppose a time-dependent external electric field is applied to a solid:

$$E^{\mathrm{ext}}_\alpha(r,t) = \Xi^{\mathrm{ext}}_\alpha e^{iq\cdot r - i\omega t}, \tag{18.27}$$

where α represents the Cartesian coordinate directions. In a linear response theory, the induced current is proportional to the applied electric field:

$$J_\alpha(r,t) = \sum_\beta \sigma'_{\alpha\beta}(q,\omega) \Xi^{\mathrm{ext}}_\beta e^{iq\cdot r - \omega t}, \tag{18.28}$$

where $\sigma'_{\alpha\beta}$ is a parameter relating the observed current density to the applied field's direction, its periodicity, and frequency. However, the symbol appearing in (18.28) is not the conductivity we seek. Rather, we want the conductivity which represents the response to the total electric field in the solid, a quantity that can be measured. This conductivity takes into account all of the currents, induced by the external fields, that

create their own electric fields. Thus, we seek $\sigma_{\alpha\beta}$ that relates the macroscopic electric field to the currents of the system.

$$J_\alpha(r,t) = \sum_\beta \sigma_{\alpha\beta}(q,\omega) E_\beta e^{iq\cdot r - i\omega t} \tag{18.29}$$

$$E_\alpha(r,t) = \Xi_\alpha e^{iq\cdot r - i\omega t} \tag{18.30}$$

$$\sigma_{\alpha\beta} = Re(\sigma_{\alpha\beta}) + iIm(\sigma_{\alpha\beta}) \tag{18.31}$$

We write the Hamiltonian of the system as $\hat{H} + \hat{H}'$ where the latter term contains the electric field, which we shall introduce as a time-dependent perturbation. The evolution of the operators is given as follows [30]:

$$\hat{j}(x,t) = e^{i\hat{H}t}\hat{j}(x)e^{-i\hat{H}t}. \tag{18.32}$$

where $\hat{H}$ is the unperturbed Hamiltonian. Thus, the interaction picture is adopted. The Kubo formula for electrical conductivity gives the result in terms of a current–current correlation function:

$$\sigma_{\alpha\beta}(q,w) = \frac{1}{\omega}\int_0^\infty dt e^{i\omega t} < \Omega|\hat{j}^\dagger_\alpha(q,t)\hat{j}_\beta(q,0) - \hat{j}_\beta(q,0)\hat{j}^\dagger_\alpha(q,t)|\Omega > + i\frac{n_0 e^2}{m\omega}\delta_{\alpha\beta} \tag{18.33}$$

where $|\Omega>$ is the ground state of the system, which has not been perturbed by the electric field. The first term in (18.33) is known as the incoherent contribution to the conductivity. Now, we use (18.32) in the preceding equation and use the fact that the basis we are using is that of the eigenstates. Consequently, with proper normalization the new expression for the real part of the conductivity is [90]

$$\sigma(\omega) = \frac{\pi}{Z}\frac{(1-e^{-\beta\omega})}{\omega}\sum_{n,m} e^{-\beta E_m}| < n|\hat{j}_\alpha|m > |^2\delta[\omega - (E_n - E_m)] \tag{18.34}$$

The DC conductivity is calculated by a procedure [90,91], which employs the sum rule

$$\int_0^\infty \sigma'(\omega)d\omega = -\frac{\pi e^2}{2}a^2 < K > \tag{18.35}$$

where

$$\sigma'(\omega) = D\delta(\omega) + \sigma_{kubo}(\omega) \tag{18.36}$$

and $< K >$ is the expectation value of the kinetic energy term of the Hamiltonian. The strategy of computing $\sigma(\omega)$, and subsequently the Drude contribution, at either zero or finite temperature is reasonably straight forward. The first step is to construct the matrix corresponding to the Hamiltonian [Equation (18.19)] in a subspace which is defined by the geometry of the lattice, the number of electrons, and the total electron spin. This leads to serious computational difficulties since for a moderately sized lattice of say ten dimers and eight electrons of arbitrary spin, the corresponding space is about 77 million states. A matrix of dimension 77 million square has about 5.9×10^{15} elements. Obviously, working on a moderately sized lattice, we are restricted to a low concentration of electrons. Due to electron-hole symmetry, we are also able to study the nearly filled situation. It is useful to keep in mind the relationship

$$\lambda = \frac{1240nm\cdot eV}{\text{Energy}}. \tag{18.37}$$

So that in the plots following, the visible light range is between 1.75 eV and 3.10 eV. Energies larger than this range correspond to ultraviolet, and those smaller to infrared wavelengths. Since cells respond to light in the near-infrared [4], and centrioles comprised of MTs are proposed to be the site of light detection [5], absorption in this energy range is of great interest to cell biology. These energies should also be compared

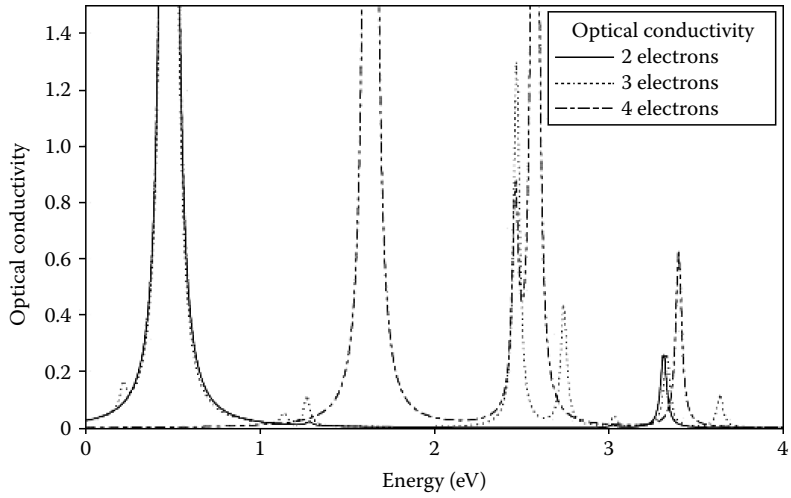

FIGURE 18.6 Optical conductivity of the two dimer system with two, three, and four electrons.

to the energy available from ATP and GTP hydrolysis, which are 0.49 eV and 0.22 eV, respectively. These values provide limits for the interactions of chemical energy in the conduction process.

At zero temperature, the linear polymer results are summarized concisely by saying that there is no DC conductivity that agrees with the previous modeling of Hubbard systems [44].

The following results for the 1D chain of tubulin dimers represent the AC conductivity. There are peaks in $\sigma(\omega)$, also known as the optical conductivity, which correspond to excitations between electronic states of the polymer. Electronic excitation results in electron redistribution and hence the development of a current. We have selected $\epsilon = 0.02$ eV to present our results, which is roughly kT and is smaller than the three energy scales in the Hubbard model, t, U, and $4t^2/U$ [82] so we expect to be able to pick out features corresponding to specific transitions in the predicted optical spectra.

We shall begin with two dimers and $t = 0.4$ eV, $U = 2.0$ eV, and equal site energy on the α and β monomer sites. This system can support up to eight electrons. The results for these systems are presented in Figure 18.6. The predicted spectra for the two and three electron cases are quite similar. The differences include a new but small peak in the three electron spectrum at an energy just below the major peak, and variations in the detail of the absorption band centered about 2.6 eV. However, the qualitative similarity of the two spectra is remarkable in terms of band locations. Contrast these two cases with the four-electron system that corresponds to half-filling. The difference is that the peak in the optical conductivity spectrum increases dramatically from about 0.48 eV to 1.64 eV. This change indicates how the half-filled case is special. The ground state in this system largely consists of electrons spread out to minimize the Coulombic energy. Exciting this system by moving any particular electron will come at the cost of greatly increasing the electron–electron repulsion and, consequently, the location of the required excitation energy corresponds roughly to U.

As the length of the polymer is increased, results remain qualitatively similar. In the three-dimer structure, results are shown for the conductivity in Figure 18.7(a) and for the integrated conductivity in Figure 18.7(b). Once again, the spectra are quite similar for all fillings aside from the half-filled case which consists of six electrons. The shift of the conductivity to higher energies can be clearly seen as the filling fraction increases towards half filling. We now present results where the broadening parameter, ϵ, and the temperature have been varied to see the effect that they have on the results. Figure 18.8 demonstrates that as the width is decreased, the spectrum becomes sharper. Note how the two peaks in this simple spectrum that occur near 2.5 eV are successively blended into a band as the ϵ is increased. Peaks represent transitions from one specific electron configuration to another and are weighted with the associated conductivity.

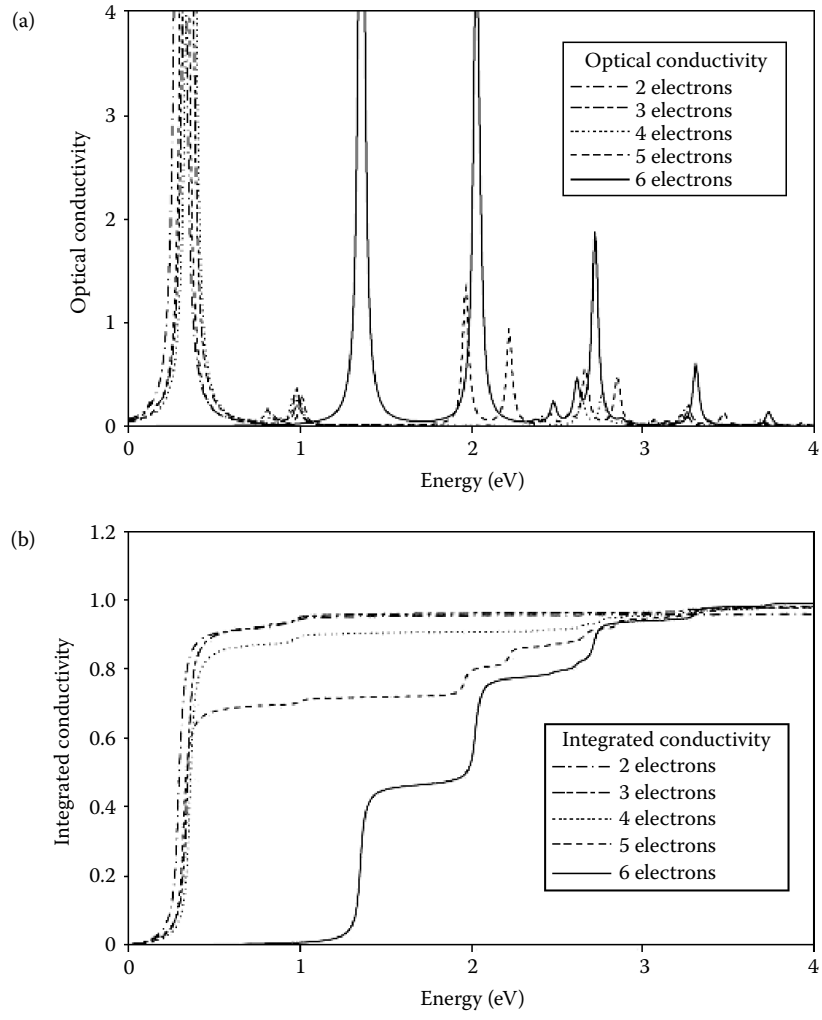

FIGURE 18.7 (a) Optical conductivity of the three-dimer system from two electrons through half filling. (b) Integrated optical conductivity of the three-dimer system shows that indeed the protofilament is an insulator. The gap for excitation of the half-filled polymer is seen easily here.

The effect of changing the temperature is to excite electron configurations other than the ground state. Consequently, transitions from one excited state to another can now contribute to the conductivity. Figure 18.9 shows how this often reduces the gap to conduction: all the major peaks in the 300 K spectrum shift slightly towards lower energies in the 3000 K spectrum, but many more features develop as well as states that previously did not contribute to conductivity may make transitions to excited states. Physiological temperature of 300 K ($kT = 0.026$ eV) is small relative to the system's energy scales, consequently lowering the temperature further causes very little change to the spectrum.

If the α-tubulin and β-tubulin sites have different energies, then the MT A and B lattices can be distinguished. The effect of this change on the optical spectrum seems to be small when individual protofilaments are considered. In addition, the sum rule shows that protofilaments remain insulators. There are a few parameters we can consider individually and which can be compared as the size of the system changes: the threshold to conductivity, and the expectation value of the kinetic energy operator. The threshold to conductivity is simply the location of the first absorption peak in the optical spectrum.

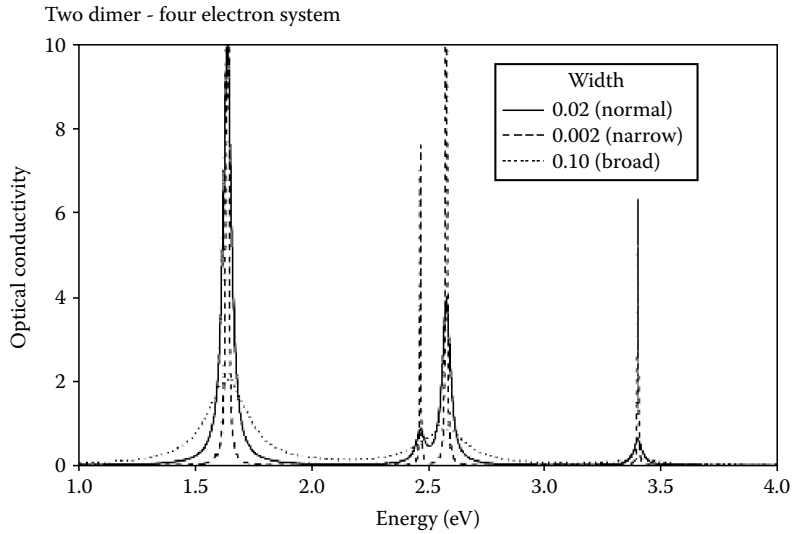

FIGURE 18.8 Optical conductivity spectrum variation with the broadening parameter.

It is a decreasing function of the polymer length. Starting at 0.48 eV for the two-dimer system, it seems to drop a little faster than $1/n$ for systems consisting of n dimers and containing two electrons. The fitted value in Figure 18.10 varies $\alpha 1/n^{1.4}$. Extrapolating to larger values of n, this gap appears certain to fall into the range where these excited states could be thermally excited. The protofilament then develops a finite DC conductivity at finite temperature. It is interesting that although the first peak does move towards zero, the fraction of the conductivity it contains is gradually diminished. Some of the conduction continues to reside in a peak located close to t in the energy spectrum. In the 2D lattice, there is a phase transition in the dimensionality. DC conduction becomes possible even at zero temperature. However, we shall still be concerned about the boundary conditions since calculations are being performed on a small lattice.

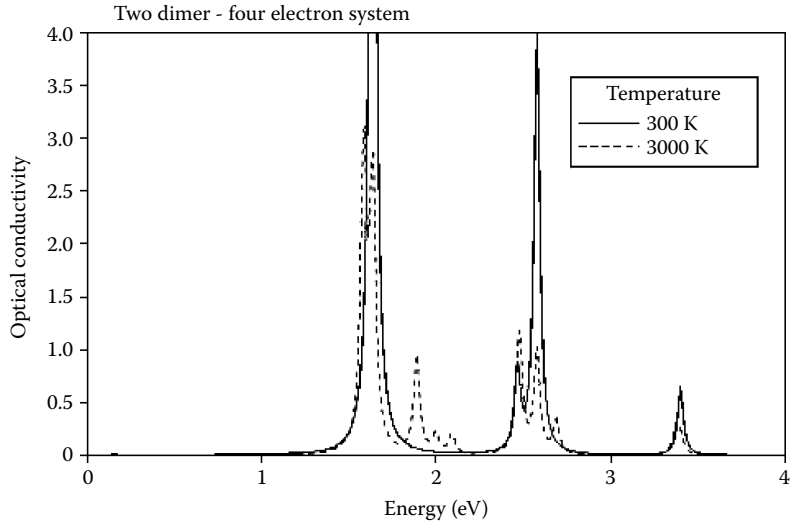

FIGURE 18.9 The variation of the optical conductivity spectrum with temperature is shown.

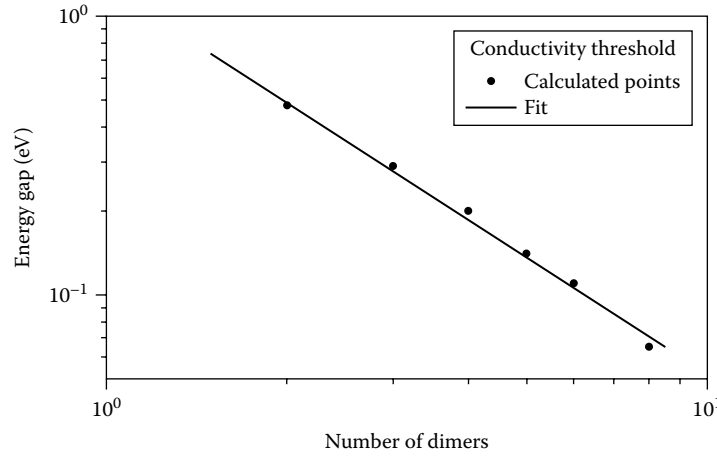

FIGURE 18.10 Threshold to conduction as a function of protofilament length.

Consider the kinetic energy/electron that has been calculated in a Hubbard model with our parameters for t and U and with either one, two or three protofilaments. Figure 18.11 demonstrates how the kinetic energy of each electron approaches the limit of $2t$ or 0.80 eV as the size of the system increases. We can easily see that for more than about 20 electron sites, the average kinetic energy of each electron starts to approach the infinite limit and we expect that the results obtained from our model should converge to the long protofilament limit in a similar manner. In particular, we are considering 28 electron sites in our MT model, which span three protofilaments. While this is not the ideal situation, the boundary conditions are not expected to create huge effects in our results. We are also using open boundary conditions since they minimize the boundary effects when compared with a variety of periodic boundary conditions.

The unit cells depicted in Figure 18.12 are the basis for the calculations. In the A lattice used for the calculations, the α-dimers connect to β-dimers along the $\bar{3}$-start helix, both within the lattice and at the seam when the MT is wrapped up. In the B lattice, the connections are $\alpha - \alpha$ or $\beta - \beta$ along the $\bar{3}$-start helix and never $\alpha - \beta$. For comparison, calculations have also been carried out with a flat tubulin sheet, specifically an A lattice MT lacking periodic boundary conditions in the lateral direction. This simulates the

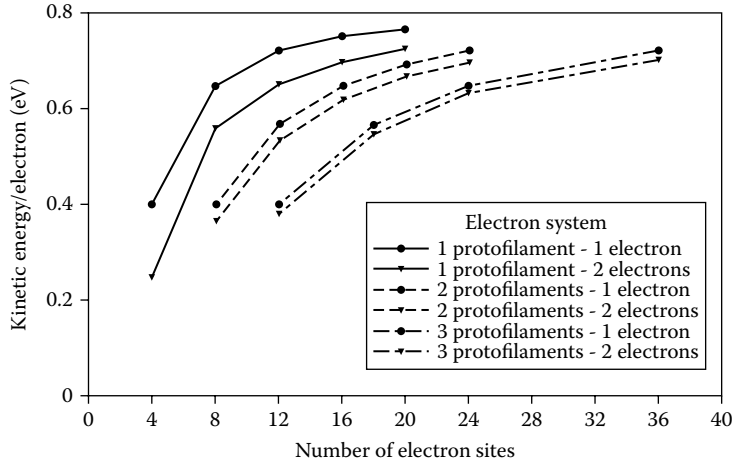

FIGURE 18.11 Kinetic energy per electron as a function of system size.

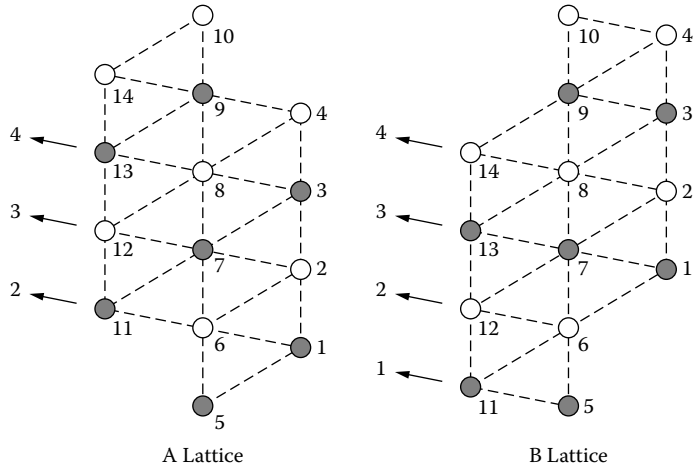

FIGURE 18.12 Lattice unit cells for conductivity calculations. The unit cell on the left corresponds to the MT A lattice, while that on the right corresponds to the MT B lattice.

MT when it has been unwrapped. We recall that the MT lattice is triangular and has three distinct hopping directions. Since protofilaments are strongly bound together along their length but relatively weakly bound to other protofilaments, one also expects the hopping parameter to be much smaller when an electron moves between protofilaments. The calculations have been carried out with the same parameters as in the one-dimensional case, $U = 2.00$ eV, $t = 0.40$ eV along the protofilaments and the site energies have been set equal to zero for all sites. The value of the hopping parameter along the $\bar{3}$-start helix is called t_ℓ (left) and that along the 8-start helix that connects diagonally from a monomer in a direction up and to the right is called t_r (right).

We consider first the results of the MT lattice which has not rolled up to form a tube but is that of a tubulin sheet where $t_r = 0$ and only the value of t_l is varied (see Figure 18.13). Since $t_r = 0$, the nature of the lattice remains rectangular to this point. When $t_l = 0$, this particular system is equivalent to individual protofilaments. The two peaks in the optical spectrum arise from the fact that the protofilaments have different lengths. The absorption peaks of 0.22 eV and 0.40 eV correspond roughly to those of the two-dimer and three-dimer, two electron cases discussed earlier in the chapter. The difference here is that the two electrons are spread over three protofilaments and consequently the effect of the electron repulsion is reduced. However, as t_l is increased from zero, the entire lattice becomes accessible and the protofilament character of the optical spectrum is lost. The two peaks of the t_l spectrum coalesce into a single peak with a large activation energy. A second but smaller absorption peak forms just above 0.50 eV. In the plot of the integrated conductivity, we can see that there is also a smaller peak at 0.16 eV when $t_l = 0.10$ eV. The source of this peak is an absorption for conduction along the direction of t_l. When t_l is increased to 0.40 eV, this peak occurs at 0.61 eV. Thus, this peak seems to occur at roughly $1.5t_l$. The activation energy for conduction along the protofilament axis also increases but is not as sensitive to t_l. Finally, examination of the integrated conductivity demonstrates that the total absorption combines such that the Drude weight remains zero.

The results in Figure 18.14 show a difference between an individual protofilament and a tubulin sheet. The behavior here is inconsistent with that of an insulator since the Drude weight is non-zero. In the optical conductivity, we find that the largest peak occurs at the same location in all directions but with different weightings. The first line traces the results for $t_r = 0.00$ eV and has peaks at 0.38 eV and 0.61 eV. Once the third hopping direction is allowed, the peak absorption is raised slightly to 0.43 eV for $t_r = 0.10$ eV and a smaller peak forms at 0.74 eV. The lower peak consists mainly of hopping along the protofilament while the second peak consists largely of hopping along the t_l direction, which also corresponds to a large

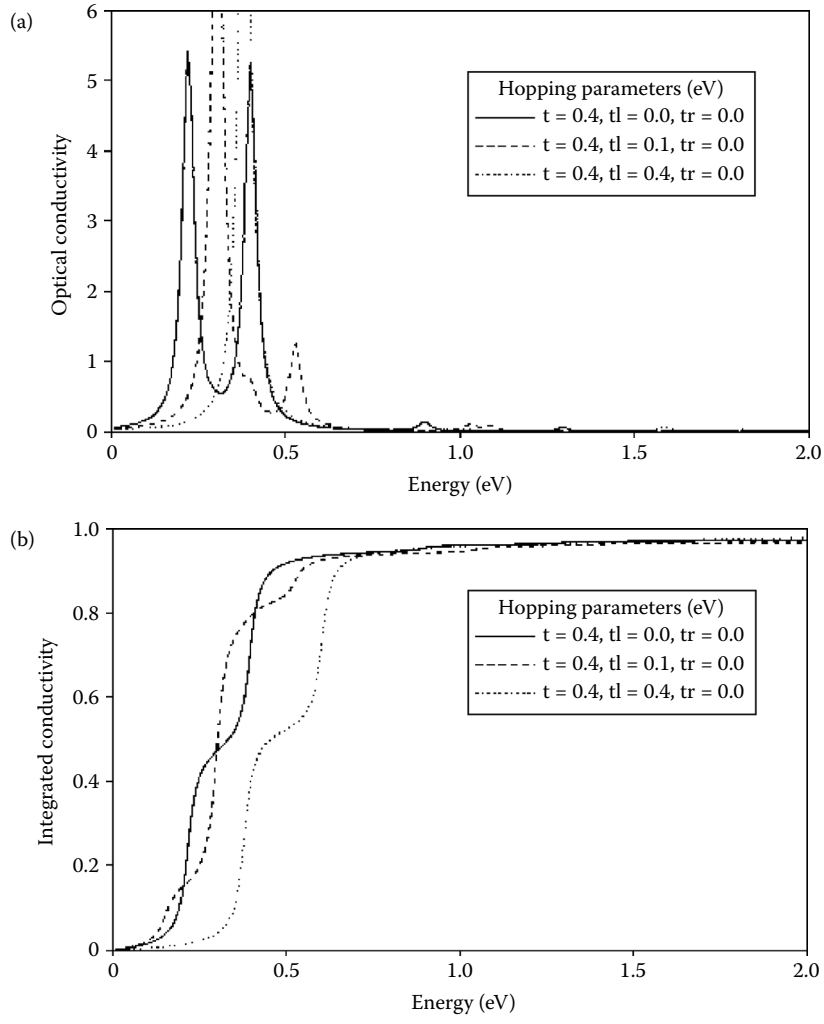

FIGURE 18.13 (a) Optical conductivity along the protofilament axis of the tubulin sheet consisting of a 14-site lattice with two electrons while $t_r = 0$ and t_l is varied. (b) Integrated conductivity of the tubulin sheet with two electrons while $t_r = 0$ and t_l is varied.

hopping parameter. Once t_r is raised to 0.40 eV so that it has the same magnitude as the other hopping parameters, there is only a single peak at 0.70 eV.

The effect of applying the MT A lattice boundary conditions to our system is shown in Figure 18.15, where we see that changing only t_l to a finite quantity while still maintaining t_r as zero is sufficient to result in a non-zero Drude weight. Thus, the periodic boundary conditions in the lateral direction seem to act in a manner similar to the additional hopping directions of the unwrapped lattice. When the kinetic parameters between protofilaments are set to zero, the optical conductivity spectrum shows there are two large absorption peaks at about 0.23 eV and 0.40 eV. As t_l increased, these peaks move higher in energy and the second peak becomes smaller in integrated weight. Eventually, once $t_l = t$, there is a single large peak near 0.47 eV. Introduction of the third hopping direction serves only to raise further the absorption peak, up to 0.70 eV in the case where the hopping parameter is 0.40 eV in all directions.

From Figure 18.15 one can see that more conduction results in the B lattice for a small t_l, such as 0.1 eV, than in the MT A lattice, by comparing it with Figure 18.16. However, even the positioning of absorption

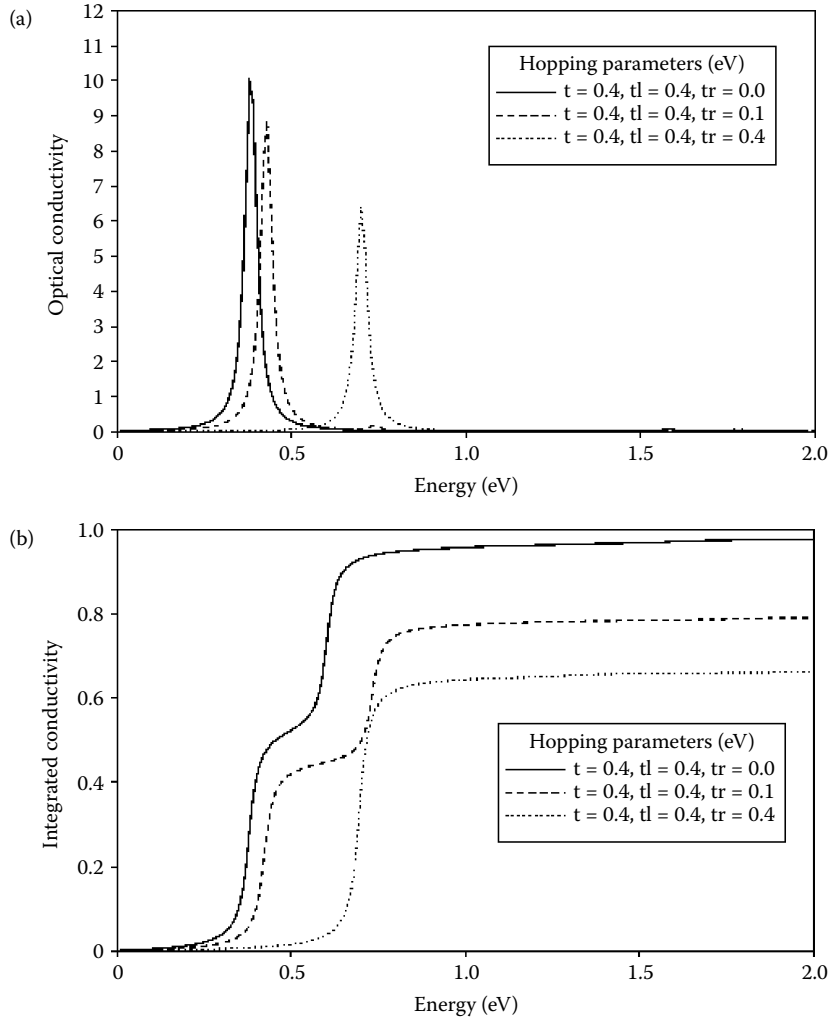

FIGURE 18.14 (a) Optical conductivity along the protofilament axis of the unwrapped 14-site lattice with two electrons while $t_l = 0.4$ and t_r is varied. (b) Integrated conductivity of the unwrapped 14-site lattice with two electrons while $t_l = 0.4$ and t_r is varied.

peaks is similar in the two lattices. Again, it is sufficient for only one of t_l or t_r to be non-zero for the Drude weight to be finite.

Finally, we compare the MT A and B lattices with the unwrapped tubulin sheet as well as with individual protofilaments of tubulin dimers. There is an interesting geometrical interpretation to the results, which shows that the MT A and MT B lattices have identical conduction properties when $t_l = t_r$. This is because in our calculations we have considered all monomers to have the same site energy. Consequently, the B lattice can be viewed as an A lattice with the opposite helicity but the same structure. The sign of the system's helicity does not affect the conduction properties along the major axis. The unwrapped MT lattice is not as good a conductor since some of the hopping freedom has been removed from the lattice but does remain conducting, provided that both t_l and t_r are non-zero.

If we consider the case where one of t_l or t_r is quite small, however, the wrapping of the lattice is much more important. As discussed earlier, the unwrapped tubulin sheet is an insulator while the MT A and B lattices may carry electrons. This observation is especially interesting given that MTs have been observed to zip up and essentially change their structure from a tube to that of a sheet *in vivo*.

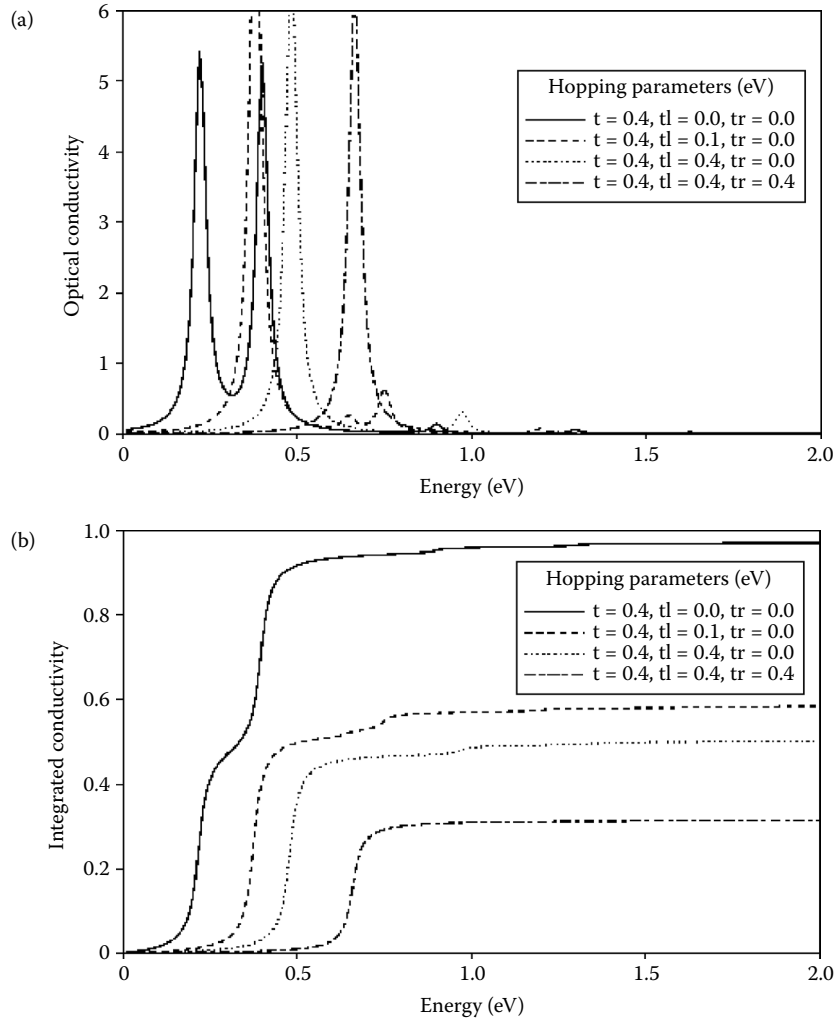

FIGURE 18.15 (a) Optical conductivity along the protofilament direction of the 14-site MT B lattice with two electrons. (b) Integrated conductivity of the 14-site MT B with two electrons shows a non-zero weight for finite t_l.

Our calculations based on the Hubbard model of electron hopping show that the MT is not an insulator, but that instead its conductivity depends on the lattice geometry and whether the MT is wrapped up or not. How well or poorly does one expect the MT to conduct relative to known semi-conductors? Referring back to Equations (18.35) and (18.36), the DC conductivity of the MT is simply given by D as

$$\frac{D}{2} = -\frac{\pi e^2}{2} a^2 < K > - \int_0^\infty \sigma_{kubo}(\omega) d\omega. \tag{18.38}$$

In this equation, the constants can be factored, and what remains is the fraction that can be read from the graphs presented earlier. The Kubo fraction (KF) is the limit of the integral as the frequency tends to infinity.

$$\frac{D}{2} = -\frac{\pi e^2}{2} a^2 < K > (1 - KF). \tag{18.39}$$

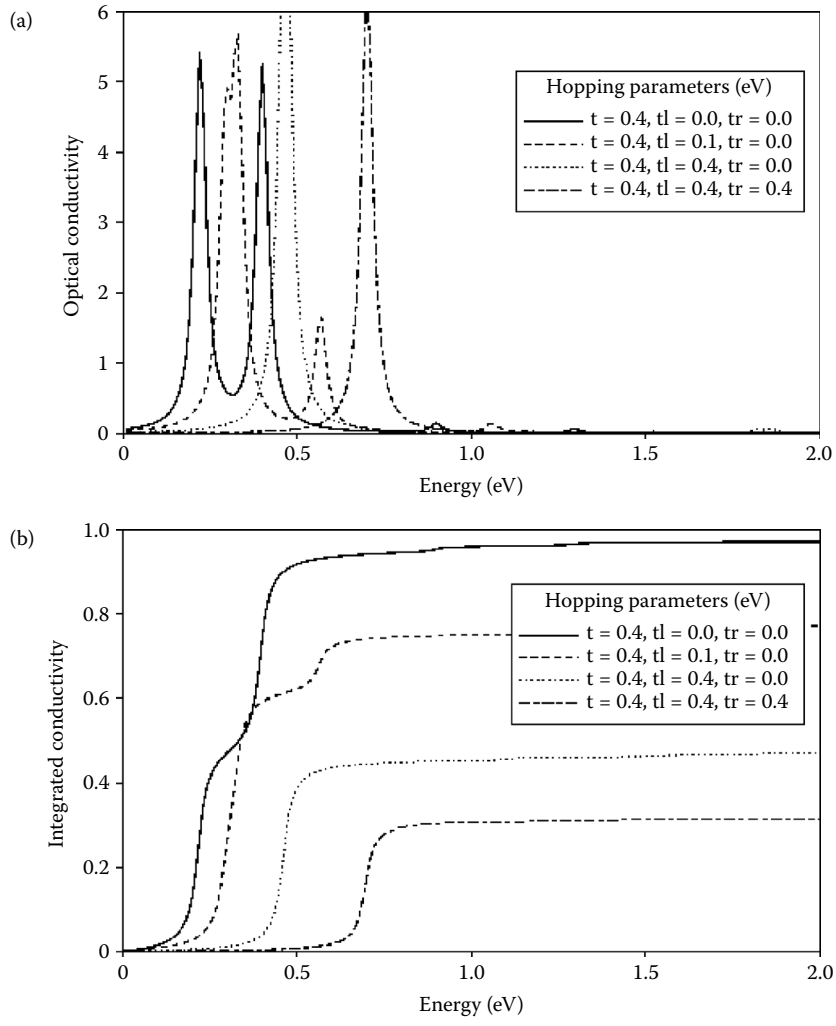

FIGURE 18.16 (a) Optical conductivity along the protofilament direction of the 14-site MT A lattice with two electrons. (b) Integrated conductivity of the 14-site MT A lattice with two electrons shows a non-zero Drude weight for finite t_1.

By returning constants of the system so that the dimensionality of D is correct, we find

$$D = -\frac{\pi n e^2 a^2}{\hbar} \frac{< K >}{t} (1 - KF). \tag{18.40}$$

Finally, we are in a position to predict the conductivity of individual MTs of varying lattice types. For the following calculations, the electron density has been taken to be of two electrons within the lattice of 14 dimers and corresponds to a density of $1.8 \times 10^{18}/cm^3$. Thus, the results must assume that the conductivity remains constant as the length of the polymer is extended, provided the degree of filling remains the same.

The values in Table 18.1 should be compared with the conductivity of metals, such as copper ($6 \times 10^7\ \Omega m^{-1}$) and iron ($1 \times 10^7\ \Omega m^{-1}$). Indeed the values can also be compared to the intrinsic semiconductors germanium ($2.5\ \Omega m^{-1}$) and silicon ($4 \times 10^{-4}\ \Omega m^{-1}$). Given these comparisons, the MT may indeed be quite a good semi-conductor given our assumptions. What is particularly interesting is the

TABLE 18.1 Calculated Conductivity and Resistance of a 1-μm Polymer Composed of Tubulin Dimers

Tubulin Structure	Conductivity ($\Omega^{-1}m^{-1}$)	Resistance
Individual Protofilament	Non-Conducting	
Tubulin sheet ($t_1 = t_r = 0.04\ eV$)	9.4×10^3	$418k\,\Omega$
Tubulin sheet ($t_l = t_r = 0.1\ eV$)	2.0×10^4	$195k\,\Omega$
Tubulin sheet ($t_1 = t_r = 0.4\ eV$)	6.3×10^4	$62k\,\Omega$
MT (A lattice, $t_l = t_r = 0.04\ eV$)	1.8×10^4	$219k\,\Omega$
MT (A lattice, $t_l = t_r = 0.1\ eV$)	4.5×10^4	$87k\,\Omega$
MT (A lattice, $t_l = t_r = 0.4\ eV$)	1.6×10^5	$25k\,\Omega$
MT (B lattice, $t_l = t_r = 0.04\ eV$)	1.9×10^4	$211k\,\Omega$
MT (B lattice, $t_l = t_r = 0.1\ eV$)	4.7×10^4	$84k\,\Omega$
MT (B lattice, $t_l = t_r = 0.4\ eV$)	1.6×10^5	$24k\,\Omega$

way the conduction properties depend on the lattice and the particular boundary conditions. The situation can be compared to carbon nanotubes which have a similar size and structure to MTs. In addition, theoretical consideration of nanotube structure predicts that the conduction properties depend on the boundary conditions. In the case of nanotubes, this means the way in which the graphene sheet is wrapped up to form the nanotube. It is quite interesting that particular sets of boundary conditions produce a semi-conducting nanotube while the appropriate choice of wrapping the nanotube gives rise to metallic conduction [31].

The ability to change from an insulator to a conductor by a simple geometrical change could be biologically relevant even without observing a single electron to be conducted along the MT since it is the conductivity property that affects the way the cell views and responds to external electromagnetic fields. Specifically, the reflectivity of MTs to electromagnetic fields is high when they are conducting, and, consequently, they could act to direct infrared signals to the interior of the centrosome. Since the centrioles are maintained at right angles to each other, the cell would be able to determine the location in latitude and longitude of a light source if the MTs are conducting [4,5]. Peaks in the AC conductivity are all at energies significantly above the thermal activation threshold so no conductivity is expected along a darkened MT, but photoconduction in the infrared-visible range is possible. Therefore, it is possible this photo-activated conduction has functional repercussions. In addition to the intrinsic semiconducting behavior of MTs, and possibly AFs, these protein filaments possess very intensely active cable properties when immersed in an ionic buffer solution. In the next section, we discuss the ionic conductivity effects of AFs.

18.6 Actin Filaments Support Nonlinear Ionic Waves

Several experiments [12,83] indicate the possibility of ionic wave generation along AFs. As the condensed cloud of counter-ions separates the filament core from the rest of the ions in the bulk solution, we expect it to act as a dielectric medium between the two. It has both resistive and capacitive components associated with each monomer that makes up the AF. Ion flow is expected to occur at a radial distance from the surface of the filament approximately equal to the Bjerrum length. An inductive component is proposed to emerge due to the actin's double-stranded helical structure that induces the ionic flow in a solenoidal manner. Due to the presence of the sheath of counter-ions around the AF, these polymers act as biological "electrical wires" [83], and have been modeled as nonlinear inhomogeneous transmission lines propagating nonlinear dispersive solitary waves. Recently, Lader *et al.* [78] applied an input voltage pulse with an amplitude of approximately 200 mV and a duration of 800 μs to an AF, and measured electrical signals at the opposite end of the AF, indicating that AFs support ionic waves in the form of axial nonlinear currents. In an earlier experiment [83], the wave patterns observed in electrically stimulated single AFs were remarkably similar to recorded solitary waveforms for electrically stimulated nonlinear transmission lines [85]. Considering the AFs highly nonlinear complex physical structure and the thermal fluctuations of the counter-ionic

cloud [105], the observation of soliton-like ionic waves is consistent with the idea of AFs functioning as biological transmission lines.

The electro-conductive medium is a condensed cloud of ions surrounding the polymer and separated from it due to the thermal fluctuations in the solution. The distance beyond which thermal fluctuations are stronger than the electrostatic attractions or repulsions between charges in solution is defined as the so-called Bjerrum length, λ_B. With the dielectric constant of the medium denoted by ε, the Bjerrum length is given by

$$\frac{e^2}{4\pi\varepsilon\varepsilon_0\lambda_B} = k_B T \tag{18.41}$$

for a given temperature T in Kelvin. Here e is the electronic charge, ε the dielectric constant, ε_0 the permittivity of the vacuum, and k_B is Boltzmann's constant. For a temperature of 293 K, we find that $k_B = 7.13 \times 10^{-10} m$. Counter-ion condensation occurs when the mean distance between charges, b, is such that $\lambda_B B/b = S > 1$. Each actin monomer carries an excess of 14 negative charges in vacuum, and accounting for events such as protonation of histidines, and assuming there to be 3 histidines per actin monomer, there exist 11 fundamental charges per actin subunit [143]. Assuming an average of 370 monomers per μm, we find there is approximately $4e/nm$. Thus, we expect a linear charge spacing of $b = 2.5 \times 10^{-10} m$ so $S = 2.85$. As the effective charge, q_{eff}, or renormalized rod charge is the bare value divided by S, we find $q_{eff} = 3.93e/monomer$. Consequently, it can be shown that approximately 99% of the counter-ion population is predominantly constrained within a radius of $8nm$ [110] around the polymer's radial axis [158]. Significant ionic movements within this "tightly bound" ionic cloud are therefore allowed along the length of the actin, provided that it is shielded from the bulk solution [104,107].

The physical significance of each of the components of the electrical network, and additional details, are described in [148]. For actin in solution, a key feature is that the positively charged end assembles more quickly than the negatively charged end [135]. This results in an asymmetry in the charges at the ends of the filaments and F-actin's electric polarization. Actin monomers arrange themselves head to head to form actin dimers resulting in an alternating distribution of electric dipole moments along the length of the filament [73]. We assume, therefore, that there is a helical distribution of ions winding around the filament at approximately one Bjerrum length. This corresponds to a solenoid in which a fluctuating current flows as a result of voltage gradient between the two ends.

The capacitive element of the electric circuit is obtained following the observation of oppositely charged layers surrounding the filament surface. We envisage the protein surface's negative charge to be distributed homogeneously on a cylinder defining the filament surface. Furthermore, positive counter-ionic charges in the bulk are expected to form another cylinder at a radius greater than the AF itself, approximately one Bjerrum length, λ_B, away from the actin surface, which includes the condensed ions. The permittivity, ε_0, is given by $\varepsilon = \varepsilon_0\varepsilon_r$ where ε_r is the relative permittivity which we take to be that of water, i.e., $\varepsilon_r = 80$. We take the length of an actin monomer typically as $a = 5.4\ nm$ and the radius of the actin filament, r_{actin}, to be $r_{actin} = 2.5\ nm$ [14]. The next step is to consider a cylindrical Gaussian surface of length a whose radius is r such that $r_{actin} < r < r_{actin} + \lambda_B$.

Applying of Gauss's law for the total charge enclosed in the cylinder, we have the following expression for the capacitance

$$C_0 = \frac{2\pi\varepsilon a}{ln(\frac{r_{actin}+\lambda_B}{r_{actin}})} \tag{18.42}$$

With the parameters given previously, we estimate the capacitance per monomer is $C_0 = 96 \times 10^{-6}\ pF$. The resistive part is obtained from Ohm's law. Taking into account the potential difference and the current I, the magnitude of the resistance, $R = V/I$, for an actin filament is given by

$$R = \frac{\rho ln(\frac{r_{actin}+\lambda_B}{r_{actin}})}{2\pi l} \tag{18.43}$$

where ρ is the resistivity. Typically, for K^+ and Na^+, intracellular ionic concentrations are 0.15 M and 0.02 M, respectively [147]. Kohlrausch's law states that the molar conductance of a salt solution is the sum of the conductivities of the ions comprising the salt solution. Thus

$$\sigma = \Lambda_0^{K^+} c_{K^+} + \Lambda_0^{Na^+} c_{Na^+} = 1.21(\Omega m)^{-1} \tag{18.44}$$

Using this with $\rho = \sigma^{-1}$, the resistance estimate becomes $R = 6.11\ M\Omega$, which is much lower than pure water since $R_{water} = 1.8x10^6\ M\Omega$.

To describe the properties of the whole filament, we simply connect n subcircuits, as described earlier, to obtain an effective resistance, inductance, and capacitance, respectively, such that:

$$R_{eff} = \left(\sum_{i=1}^{n} \frac{1}{R_{2,i}} \right)^{-1} + \sum_{i=1}^{n} R_{1,i} \tag{18.45}$$

$$L_{eff} = \sum_{i=1}^{n} L_i \tag{18.46}$$

and

$$C_{eff} = \sum_{i=1}^{n} C_{0,i} \tag{18.47}$$

where $R_{1,i} = 6.11 \times 10^6\ \Omega$, $R_{2,i} = 0.9x10^6\ \Omega$ such that $R_{1,i} = 7R_{2,i}$. Note that we have used $R_{1,i} = R_1$, $R_{2,i} = R_2$, $L_i = L$, and $C_{0,i} = C_0$. For a 1 μm of the AF, we find

$$R_{eff} = 1.2 \times 10^9\ \Omega \tag{18.48}$$

$$L_{eff} = 340 \times 10^{-12}\ H \tag{18.49}$$

$$C_{eff} = 0.02 \times 10^{-12}\ F \tag{18.50}$$

This solenoidal flow geometry leads to an equivalent electrical element possessing self-inductance. From Faraday's law, we can derive an effective inductance for the actin filament in solution by

$$L = \frac{\mu N^2 A}{l} \tag{18.51}$$

where l is the length of the F-actin and A is the cross-sectional area of the effective coil given by

$$A = \pi (r_{actin} + \lambda_B)^2 \tag{18.52}$$

The number of turns is approximated by simply working out how many ions could be lined up along the length of a monomer. We would then be approximating the helical turns as circular rings lined up along the axis of the F-actin. We also take the hydration shell of the ions into account in our calculation. The hydration shell is then the group of water molecules oriented around an ion. It can be shown that $L = 1.7pH$ for the length of the monomer.

The electrical model of the AF is an application of Kirchhoff's laws to one section of the effective electrical circuit that is coupled to neighboring monomers. Taking the continuum limit [148] for a large number of monomers along an AF, we derive the following equation which describes the spatio-temporal

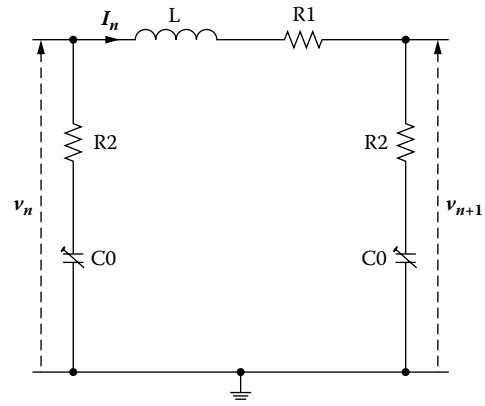

FIGURE 18.17 An equivalent electrical circuit for a segment of an actin filament.

behavior of the potential along the AF:

$$LC_0\frac{\partial^2 V}{\partial t^2} = a^2(\partial_{xx}V) + R_2C_0\frac{\partial[a^2(\partial_{xx}V)]}{\partial t} - R_1C_0\frac{\partial V}{\partial t} + R_1C_0 2bV\frac{\partial V}{\partial t} \tag{18.53}$$

Motivated by this picture, physical properties of the ionic distribution along a short stretch of the polymer (the average pitch 35 to 40 nm) have been modeled by Tuszynski *et al.*, [148] as an electrical circuit with non linear components (see Figure 18.17). The main elements of the circuit are: (a) a non linear capacitor associated with the spatial charge distribution between the ions located in the outer and inner regions of the polymer; (b) an inductance due to the helical geometry of the filament; and (c) a resistor due to the viscosity imposed by the solution.

From Kirchhoff's laws, one can derive an equation governing the propagation of voltage along the filament (see [148]). One of the key aspects in this model is the nonlinearity of the associated capacitance [86,150] that eventually gives rise to the self-focusing of the ionic waves. The equations developed for the model originate from the application of Kirchhoff's laws to the RLC resonant circuit of a model actin monomer in a filament. Perhaps the most important finding is the existence of the traveling wave, which describes a moving transition region between a high and low ionic concentration due to the corresponding inter-monomeric voltage gradient. The velocity of propagation was estimated to range between 1 and 100 ms^{-1} depending on the characteristic properties of the electrical circuit model. It is noteworthy that these values overlap with action potential velocities in excitable tissues [55].

Analysis of the model described earlier reveals the possibility of stationary waves in time that may lead to the establishment of spatial periodic patterns of ionic concentration. As mentioned previously, Lader *et al.* [78] applied an input voltage pulse with an amplitude of approximately 200 mV and a duration of 800 μs to an AF, and measured electrical signals at the opposite end of the AF, indicating that AFs support ionic waves in the form of axial nonlinear currents. In an earlier experiment [83], the wave patterns observed in electrically stimulated single AFs were similar to recorded solitary waveforms for electrically stimulated nonlinear transmission lines [85]. Considering the AFs highly nonlinear physical structure and thermal fluctuations of the counter-ionic cloud [105], the observation of soliton-like ionic waves is consistent with the idea of AFs functioning as biological transmission lines.

This section only provides an indication as to a realistic model of actin that can support soliton-like ionic traveling waves. Modeling relies on data constrained by experimental conditions, and/or assumptions made, including the charge density, which is calculated based on the net surface charges of actin. It should also be considered that soliton velocity is directly proportional to the magnitude of the stimulus, which in a biological setting has not been formally described. Actin interacts with a number of ion channels of different ionic permeability and conductance. Thus, it is expected that channel opening, single channel

currents, and other channel properties, including the resting potential of the cell, may significantly modify the amplitude and velocity of the soliton-supported waves. This should correlate with the velocity of the traveling waves along channel-coupled filaments. Other parameters that may play a role in this type of electrodynamic interaction are the local ionic gradients and the regulatory role of actin binding proteins, which can help "focus" the conductive medium, or otherwise impair wave velocity. The physical significance of each of the components of the electrical network (see Figure 18.17) and additional details, are described in [148]. MTs differ from AFs in several respects. One of the key differences is the presence of peptide chains called C-termini that protrude from their surface. In the following section, we outline their role in ionic wave conductivity along MTs.

18.7 Long-Range Spatio-Temporal Ionic Waves Along Microtubules

MTs are long hollow cylinders made of $\alpha\beta$-tubulin dimers [33], as described in Section 18.5. Recently, it has become apparent that neurons utilize MTs in cognitive processing. Both kinesin and MAP2 that associate with MTs have been implicated in learning and memory [69,154]. Dendritic MTs are implicated in particular, and it is highly probable that the precisely coordinated transport of critical proteins and mRNAs to the post-synaptic density via kinesin along MT tracks in dendrites is necessary for learning, as well as for LTP [70].

The following molecular dynamics (MD) simulation results focus on the C-termini of neighboring tubulins, whose biophysical properties have a significant influence on the transport of material to activated synapses. This affects cytoskeletal signal transduction and processing as well as synaptic functioning related to LTP. Using MD modeling we calculated conformation states of the C-termini protruding from the outer surfaces of MTs and strongly interacting with other proteins, such as MAP2 and kinesin [124]. To elucidate the biophysical properties of C-termini and gain insight into the role they play in the functioning of dendrites, we developed a quantitative computational model based on the currently available biophysical and biochemical data regarding the key macromolecular structures involved, including tubulin, their C-termini, and associated MAP2. In the proposed model of the C-termini microtubular network, the tubulin dimer is considered to be the basic unit. Each dimer is decorated with two C-termini that may either extend outwardly from the surface of the protofilament or bind to it in one of a few possible configurations.

The most dynamic structural elements of the system (i.e., its elastic and electric degrees of freedom) are envisaged as conformational states of the C-termini. Each state of the unbound C-terminus evolves so as to minimize the overall interaction energy of the system. The negatively charged C-termini interact with (a) the dimer's surface, (b) neighboring C-termini and (c) adjacent MAPs. While the surface of the dimer is highly negatively charged overall, it has positive charge regions that attract the C-termini causing them to bend and bind in a "downward" state. The energy difference between the two major metastable states is relatively small, on the order of a few $k_B T$ [112].

To simplify our calculations, we first used a bead-spring model representing the C-terminus as a sequence of beads with flexible connections. We have accounted for the electric field exerted by the dimer, the external field generated by the environment, and various short-range interactions within the simulated C-terminus, including interactions between the beads (i.e., Lennard–Jones potential, angular forces, etc.).

A simplified model of the interaction between MAP2 and its ionic environment via counter-ions was used to investigate the ability of MAP2 to function as a "wave-guide" that transfers the conformational change in a C-terminus state to an adjacent MT (see Figure 18.18). A perturbation applied to the counter-ions at one end of the MAP2 drives them out of equilibrium and initiates a wave that travels along the MAP2 (for details see [112]). Figure 18.18 (right) depicts the main result for a localized perturbation applied for a few picoseconds to the counter-ions near the binding site of MAP2. Wave propagation along the chain of $N = 50$ counter-ions is shown as a counter-ion displacement parallel to MAP2, u_i, where i denotes the i^{th} counter-ion. This perturbation along MAP2 propagates almost as a "kink" whose phase velocity has been found to be $v_{ph} \approx 2nm \cdot ps^{-1}$.

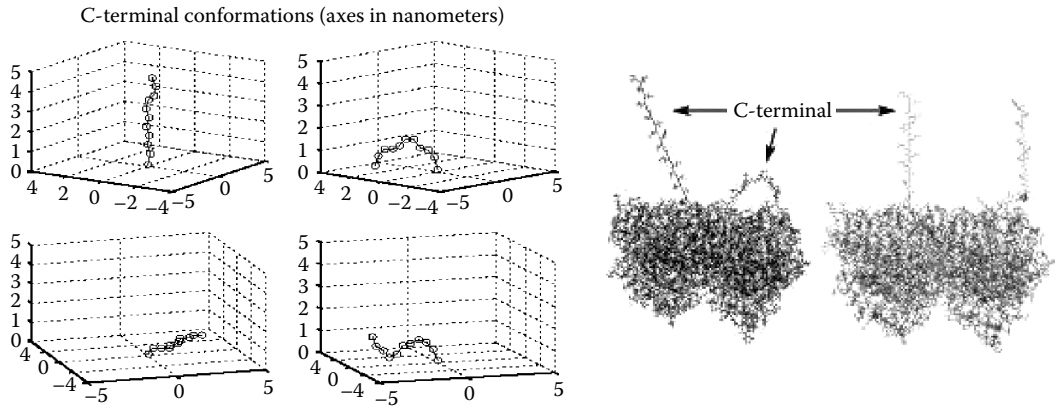

FIGURE 18.18 Examples of the conformational states of the C-termini in a tubulin dimer (right) and results from bead-spring model simulations (left).

Our simulations indicate the ability of an ionic wave to trigger a coupled wave of C-termini state changes from their upright to downward orientations. Four examples of "up" and "down" states of the C-termini obtained through bead-spring model simulations are shown in Figure 18.18 (left) and results from molecular dynamics simulations for an actual tubulin dimer are shown in Figure 18.18 (right). Calculations of the energy minimized positions of the individual beads representing the amino acids of the C-terminus in two equivalent forms reveal that the probability of the down position, which includes all cases of full or partial attachment, is 15%. This means that the system has two major states with a strong bias towards the stretched-up state.

In the remainder of this section, we present an MD simulation study of the interaction between MTs and MAP2, followed by preliminary experimental results of ionic wave conduction by MTs.

A simplified model of the interaction between MAP2 and its ionic environment via counter-ions was used to investigate the ability of MAP2 to function as a "biological wire" that transfers the conformational change in a C-terminus state to an adjacent MT (see Figure 18.19).

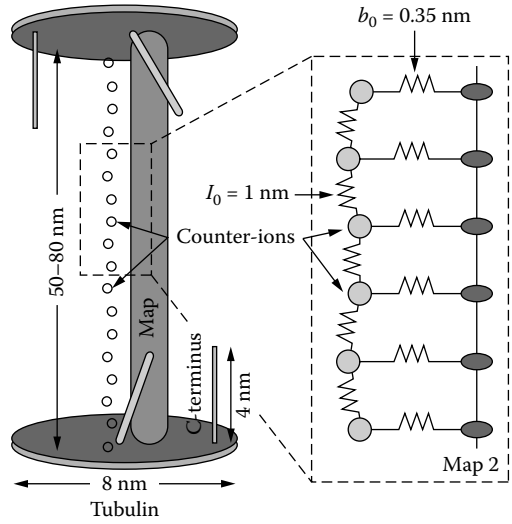

FIGURE 18.19 An illustration of a MT C-terminus conformational change transfer process. Ionic waves travel along an adjacent MAP via local perturbations to the bounded counter-ions.

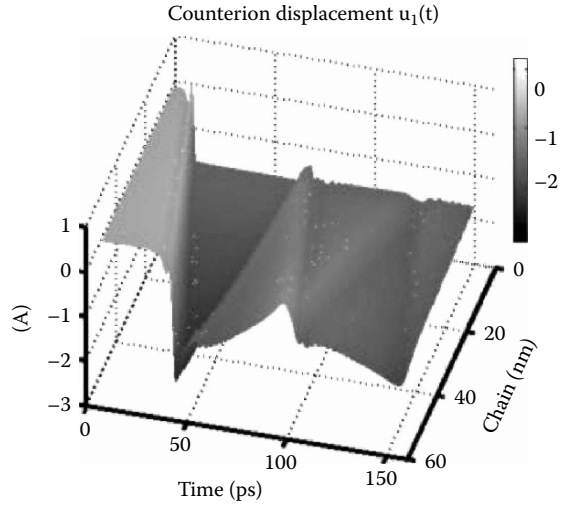

FIGURE 18.20 Propagation of a localized perturbation applied to counter-ions near the binding site of a MAP2.

A perturbation applied to the counter-ions at one end of the MAP2 drives them out of equilibrium and initiates a wave that travels along the MAP2 [112]. Figure 18.20 depicts the main result for a localized perturbation applied for a few picoseconds to the counter-ions near the binding site of a MAP2. Wave propagation along the chain of counter-ions is demonstrated as counter-ions displacement parallel to MAP2.

To validate the proposed model, we have conducted experiments on electro-stimulation of MTs in a solution. A detailed description of the experiment and its results has been published elsewhere [113]. Here we only describe the main aspects of the work on this phenomenon. Figure 18.21 depicts the experimental setup used. Isolated taxol-stabilized MTs have been shown to be able to amplify an electric signal applied to them through a micropipette. The input signal was of 5 to 10 msec duration, with amplitude in the range of $\pm$200 mV. The signal that arrived at the other end of the MT was more than twice as high as the signal recorded in a control experiment where the same two pipettes were immersed in a solution with no MT making contact to them. The calculated conductivity of MTs was found to be on the order of 10 nS, indicating a high level of ionic conductivity along an MT. By comparison, for a typical ion channel, the corresponding value ranges between 5 and 200 pS.

The results of the MD modeling previously described raise the possibility of transmitting electrostatic perturbations collectively among neighboring C-termini, and from C-termini on one MT to those C-termini on another MT via MAP2. The importance of collective conformational states of C-termini and of transmitting perturbations among the C-termini as a novel information processing mechanism operating at a subneuronal level is clear. MAP2 and kinesin bind near to the C-termini on tubulin and the electrostatic properties of C-termini affect this binding [2,145]. Hence the conformational states of the C-termini must

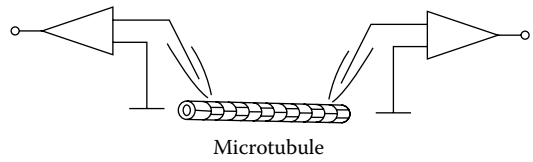

FIGURE 18.21 Schematic representation of the experimental set-up used for the measurements of a MTs ionic conductivity. The MT is attached to two micropipettes that are connected to signal amplifiers.

at some point be taken into account in order to understand neural processing that depends on transport of synaptic proteins inside of neurons. Kim and Lisman [71] have shown that inhibition of MT motor proteins reduces an AMPA receptor-mediated response in hippocampal slice. This means that a labile pool of AMPA-receptors depends on MT dynamics, and MT-bound motors determine the amplitudes of excitatory postsynaptic currents (EPSC). A walking kinesin carries with it a protein or an mRNA molecule. Since kinesin binds to a MT on a C-terminus, as it steps on it, it brings the C-terminus to the MT surface and makes it ineffective in binding for the next kinesin over a period of time that it takes the C-terminus to unbind and protrude outside. From this we can deduce that long stretches of C-termini in the upright position are going to be most efficient at transporting kinesin and kinesin cargo while C-termini that lie flat are expected to be most efficient at detaching kinesin. Thus, in considering the trafficking of many kinesins, collective electrostatic effects of C-termini become crucially important. Collective states that correspond to transport strategies that will send optimal numbers of kinesin molecules to synaptic zones are likely to occur when synapses are activated (e.g., when synapses are generating EPSCs). One type of kinesin cargo associated with learning and memory is the NMDA receptor, which is well known to be associated with LTP. The PSD might be expected to require replenishment of NMDA receptors at a later time than AMPA receptors are replenished (see [71]). Kinesin protein (specifically KIF17) actively transports NMDA receptor 2B subunits (NR2B) to the region of the PSD [52]. Once NR2B is in the vicinity of an active synapse it dissociates from kinesin and then becomes associated with the PSD, presumably using actin transport as an intermediary step. Hence, kinesin-mediated transport of NMDA receptors along MTs has a built-in negative feedback mechanism: whenever too many NMDA receptors are transported to the synaptic site (often located on a spine head), then those NMDA receptors can initiate proteolytic breakdown of MAP2. The latter event would be expected to reduce further transport of NMDA receptors to the synaptic site. The signal transduction molecule CaMKII is also critical for learning and LTP. Similar to the NMDA receptor, CaMKII is transported to active synapses via a kinesin-mediated transport mechanism. However, it appears to be the mRNA for CaMKII to a larger extent than the protein that is transported to spines, since dendrites are enriched with polyribosomes and CaMKII mRNA [140]. Ribosomes are redistributed from dendrites to spines with LTP [106]. Local translation of CaMKIIα in dendrites appears to be necessary for the late phase of LTP: fear conditioning and spatial memory [98]. Moreover, changes in synaptic efficacy are often accompanied by changes in morphology; reorganization of underlying MTs is a fundamental factors for these morphological changes. Having discussed the individual properties and roles played by AFs and MTs in subcellular conduction processes, we now turn to an integrated view of their functioning within a cell. The next several sections discuss this issue in depth.

18.8 Dendritic Cytoskeleton Information Processing Model

Our current hypothesis states that the cytoskeletal biopolymers constitute the backbone for ionic wave propagation that interacts with, and regulates, dendritic membrane components, such as ion channels to effectively control synaptic connections. Figure 18.22 depicts a portion of the dendritic shaft where MTs are decorated by C-termini and interconnected by MAP2 (thick line). Connections between MTs and AFs are shown as well as two types of synaptic bindings. On the upper left side, actin bundles bind to the post-synaptic density (PSD) of a spineless synapse. On the lower right side, a spiny synapse is shown, where actin bundles enter the spine neck and bind to the PSD, which at the other end, is connected to the MTN.

We envision a mechanism in which a direct regulation of ion channels and thus synaptic strength by AFs and associated cytoskeletal structures controls and modifies the electrical response of the neuron. In this picture, MTs arranged in networks of mixed polarity receive signals in the form of electric perturbations, from synapses via AFs connected to MTs by MAP2 [122], or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT [108]. As discussed next, the MTN may be viewed as a high-dimensional dynamic system where the main degrees of freedom are related to the conformational state of the C-termini. The input signals perturb the current state of the system that continues to evolve. Hypothetical integration of the preceding ideas is outlined as follows. Electrical signals arrive at the PSD

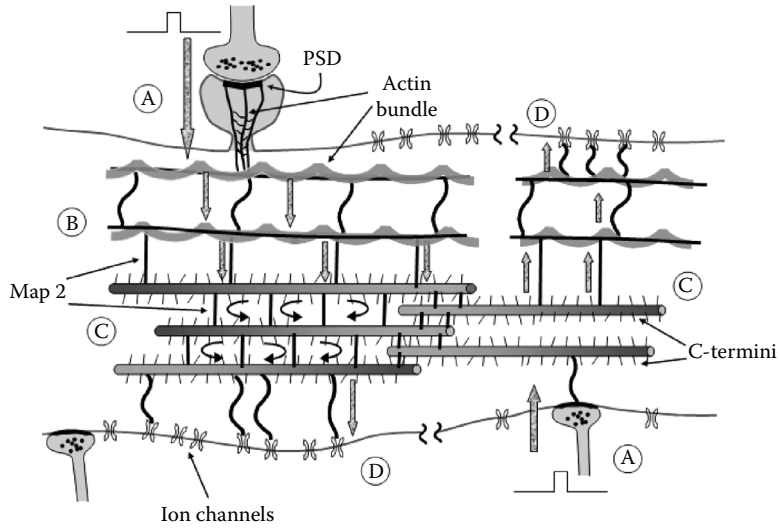

FIGURE 18.22 A scheme of the dendritic shaft with MTs arranged in networks of mixed polarity that receive signals in the form of electric perturbations from synapses via AFs connected to MTs by MAP2, or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT. A spiny synapse is depicted in the bottom right where an actin bundle enters the spine neck.

via synaptic transmission, which in turn elicits ion waves along the associated AFs at the synaptic spine. These dendritic input signals propagate in the form of ionic waves through AFs to the MTN where they serve as input signals. The MTN, operating as a large high-dimensional state machine, evolves these input states, e.g., by dynamically changing C-termini conformation. The output from the MTN is the state of the system that may propagate via AFs to remote ion-channels. These output functions are assumed to regulate the temporal gating state of voltage-sensitive channels. This process subsequently regulates the membrane conductive properties and controls the axon hillock behavior by changing the rate, distribution, and topology of open/close channels. The overall functions of the dendrite and neuron can thus be regulated in this manner.

The attractiveness of the concept that the cytosol, with its cytoskeletal structures, may behave as a large dynamical system is clear since it provides a means for real-time computation without the need for stable attractor states. Moreover, the output is relatively insensitive to small variations in either the MTN (cytoskeletal networks) or the input patterns. It should be noted that the temporal system's state evolves continuously, even without external inputs. Recent perturbations, however, have a long-term effect on the MTN trajectories, i.e., there is a memory effect inherent to this system (not to be mistaken with synaptic LTP, which has a much longer time scale). The output from the MTN may converge at or near ion channels to regulate their temporal behavior. The issue of adaptation requires a feedback mechanism that will, at least locally, enable the change of the output function. In the context of neuronal function, with a focus on processivity, synaptic strengthening, LTP, and memory enhancement, the output function may simply reflect an effect of the MTN on synaptic channel function, such that the desired state of the channel appears to have a higher probability of being open/close upon the presentation of the associated input pattern. One possibility is a Hebbian-based response where more frequent activity of certain subdomains of the MTN output states gives rise to a higher/lower density of AFs connecting to corresponding channels.

We now explain how this integrative view may serve as a regulatory (adaptive) mechanism. The input level denoted by A in Figure 18.22 is associated with external electric perturbations passing through membranes, mainly synaptic inputs arriving from other neurons. These signals arrive at the cytoskeleton and directly affect MTNs, and/or actin filaments (bundles), in spiny synapses. However, the actin cytoskeleton is responsible for the propagation of signals to the MTN (see level B). These propagated signals (level C)

are in turn used as inputs to the MTN, viewed as a dynamic system. We further propose that the MTN generates diverse phase space trajectories in response to different input vectors. The requirements from such a system are not too restrictive since the output-state is not an attractor of the system. In other words, information processing at this level is not necessarily based on attractor dynamics but rather on real-time computations. This proposition relies on the observed ability of the MTN to propagate signals and on the specific topological features of MTNs in dendrites, in which shorter MTs of mixed polarity are interconnected by MAP2s. The output from the MTN would be a function of the evolved state vector in certain areas accessed by actin filaments and/or directly linked to ion channels (see both possibilities at level D). These output signals may modify the temporal channel activity, either by directly arriving from the MTN to the channels, or mediated by actin filaments. Hence, the channel-based synaptic membrane conductance is regulated, in particular in the axon hillock region, which is, in most cases, responsible for the generation of action potentials.

The idea that a nonspecific high-dimensional dynamical system may serve as a reservoir of trajectories in the context of liquid state machines (LSMs), has recently been suggested as an explanation for the existence of microcircuits in the brain [87]. The basic structure of an LSM is an excitable medium (hence "liquid") and an output function that maps the current liquid state. The liquid must be sufficiently complex and dynamic to guarantee a universal computational power. This is sufficient to ensure that different input vectors lead to separate trajectories. A network of spiking neurons and a recurrent neural network has been used as a "liquid", whereas the output (readout) function has been implemented by simple perceptrons, threshold functions, or even linear regression functions. Clearly, simpler readout functions restrict the ability of the whole system to capture complex nonlinear dependencies.

18.9 The Inter-Relation Between the Neural Cytoskeleton and the Membrane

Usually, F-actin and microtubular cytoskeletal networks are thought to fulfill separate, independent cellular roles. Highly dynamic actin networks are known for their role in cell motility, in particular the spreading of the leading edge and contraction. The more stable MT cytoskeleton is best known for its importance in cell division and organelle trafficking. However, recent studies provide a more unified role, ascribing important roles to the actin cytoskeleton in cell division and trafficking and important roles for MTs in the generation and plasticity of cellular morphology. Coordination between the actin- and MT- based cytoskeletons has been recently observed during cellular migration and morphogenesis, processes that share some similarities with neurite initiation [28]. A direct physical association between both cytoskeletons has been suggested, because MTs often preferentially grow along actin bundles and transiently target actin-rich adhesion complexes. In neurons, certain plakins and neuron-specific MAPs, like MAP1B and MAP2, may play a role in linking MTs and AFs, helping in the transition from an undifferentiated state to neurite-bearing morphology.

MAP1B and MAP2 are both known to interact with actin in vitro [20,109,128,134,146]. It is likely that by crosslinking, MAP2 and/or MAP1B associated with both cytoskeletons could be involved in guidance of MTs along AF bundles. Alternatively, MAPs could shuttle from MTs to actin and could alter F-actin behavior by actively crosslinking AFs.

Little is known, however, about interactions between neuronal ion channels and the cytoskeleton. Recently, whole-cell and single channel recordings showed that acute disruption of endogenous AFs with cytochalasin D activated voltage-gated K^+ currents in these cells, which was largely prevented by intracellular perfusion with the AF-stabilizer agent, phalloidin. Interestingly, the direct addition of actin to excised, inside-out patches activated, and/or increased single K^+ channels. Thus, acute changes in actin-based cytoskeleton dynamics regulate voltage-gated ion channel activity in bipolar neurons. This may be indicative of a more general and quite appealing mechanism by which cytoskeletal structures control feedback mechanisms in neuronal channels.

Recent theoretical and experimental studies of the electrical properties of AFs and MTs in solution revealed their capability to act as biopolymer wires [83,148]. This means that these protein polymer

filaments are capable of conducting nonlinear ionic waves and even amplifying the signal with respect to the conducting solution [112]. We conjecture a mechanism in which a direct regulation of ion channels and thus synaptic strength by AFs and associated cytoskeletal structures controls and modifies the electrical response of the neuron. According to this scenario (see Figure 18.22), MTs arranged in networks of mixed polarity receive signals in the form of electric perturbations from synapses via AFs connected to MTs by MAP2 [122], or via direct MT connections to postsynaptic density proteins by molecules such as CRIPT [108]. These signals propagate in the form of ionic waves. Specific physical properties of the propagating ionic waves will be discussed in sections that follow.

18.10 Relationship to Cognitive Functions

Transport of proteins and receptors in neurons is likely to have an electromagnetic basis to the extent that this function is possibly a result of MT computation. The perspective advanced in this chapter is that a specific fingerprint defined by a particular electromagnetic state of a microtubular array potentially corresponds to a unique unit of cognition (e.g., a basic visual parameter). Recently, it has been shown that visual components can be represented musically [23]; hence, the idea that one common type of energy underlies divergent perceptual and cognitive processes appears likely. Activation of one electromagnetic fingerprint could, in turn, activate another electromagnetic fingerprint, irrespective of sensory input. Moreover, the subjective feels of this widespread pattern of electromagnetic energy can be specified according to those key physical properties of MTs that influence the transport of proteins to synapses. Factors influencing kinesin-mediated transport include the protein conformation of tubulin and the nature of the C-termini (see [112,136]).

Not only is the conformational state of tubulin critical to effective transport, motor proteins appear to alter albeit temporarily, the conformation of tubulin. Kinesin binding and that of MAP, tau, significantly alter the direction of the protruding protofilament ridges along MTs, which in turn influences their further binding abilities [127]. More than mere local adaptation to binding, MTs may alter their conformation ahead of kinesin processivity [76], supporting the notion of long-range cooperative effects between tubulin dimers located along longitudinal protofilaments of MTs. These biochemical relationships have consequences for electromagnetic fields. The dipole moment of tubulin depends on its configuration in the MT [53,97]. Thus, electromagnetic fields among MTs could, in theory, be induced or inhibited by synaptic inputs that affect the protein conformation of tubulin directly or through alterations in kinesin or MAP binding. Synaptic effects upon MTs could be mediated through ionic currents, by propagation via actin filaments [148], or by signal transduction cascades resulting in the phosphorylation of MAPs [126].

Due to lengthwise electric dipoles of tubulin dimers, information in the form of traveling waves propagated along microtubular tracks can, in principle, be transmitted between synapses with high fidelity (see [149]). MAP2 bridges keep microtubular arrays within the dendritic core parallel and antiparallel by aligning portions of polarized MTs. The antiparallel alignment of MTs, which specifically occurs in dendrites, would severely attenuate any electromagnetic field generated by MTs. However, during enhanced kinesin-mediated transport, as is likely to occur with heightened synaptic activity, MAP2 bound to the MT would be perturbed and may even temporarily detach from the MT. A similar phenomenon might also occur due to dynein-mediated transport, which occurs largely in the opposite direction to that of kinesin-mediated transport. Assuming that at least some MAP2 stays attached to the antiparallel MTs, keeping the dendritic array intact, any net unidirectional transport along the MT array should increase the strength of the electromagnetic field associated with the fingerprint and should further result in the spread of that electromagnetic field to adjacent MTs. Once a sufficient number of MTs were engaged in dynamically sending and receiving complementary electromagnetic energies, whole neuronal compartments (e.g., dendrites) might be expected to interact. Due to the parallel/antiparallel arrangement of MTs in cortical dendrites and the ability of electromagnetic fields to pass from one dendrite to adjacent dendrites, information could, in principle, pass between neurons when such electromagnetic fields were sufficiently amplified as a result of changes in the binding of MAPs or kinesin.

While it is true that there are some 100 billion neurons and some 100 trillion synapses in the human cerebral cortex, so too does each sensory field afford the luxury of extremely high resolution. The fovea of the retina, for example, contains roughly 1 million receptor cells that relay information to the cerebral cortex, diverging to eventually drive the synaptic activity of at least 1 billion cortical cells. Although the mammalian cortex has many neurons, and even more synapses, its connectivity can be readily grasped by one recurrent theme: repetitive high-resolution topographic representation. Despite this simple organizational plan, cells in cortical areas, in particular cells in higher sensory or association areas, inexplicably show correlated responses during cognitive tasks. Experience alters the basic structure of dendrites, and as a consequence, it should also alter any electromagnetic fields generated by MTs as a result of transport proteins moving along them. As described earlier, a rearrangement of the cytoskeleton occurs during early development, with learning, and with neurodegeneration underlying dementia.

Although models of changes in synaptic efficacy, e.g., long-term potentiation or depression (LTP or LTD), offer great potential as memory mechanisms (see [93]), one often overlooked problem is that large numbers of synapses are affected in concert. If only a few synapses are changed with each memory, then the entire cortical system would have a near unlimited capacity, but if many synapses participate in each memory, as seems to be the case for LTP, then there could be a serious saturation effect. This relates back to the topographic organization of the cerebral cortex. Strictly synaptic models (electrochemical) suggest that complex neural networks increase synaptic weights (i.e., neurons that fire together wire together). Nonetheless, visual cortical regions, for example, do not have massively random interconnections among all parts of the visuotopic map, thereby making many of the changes in synaptic efficacy necessary for encoding complex perceptual features impossible.

The biophysical properties of MTs are just beginning to be understood at molecular and atomic levels, and recent empirical evidence suggests interesting effects occur between MTs under certain experimentally induced conditions. Two groups, one led by Watt Webb at Cornell and another led by Paul Campagnola and William Mohler at the University of Connecticut, observed that MTs give rise to intense second-harmonic generation: a frequency doubling upon exposure to a sapphire laser in the 880-nm range. (Other frequencies were partially effective.) MTs were one of the few biological materials having electric dipoles that constructively interfered with the dipoles of neighboring MTs [11,29]. This occurred for parallel MTs in axons, but not for antiparallel MTs in dendrites. Could such a phenomenon be expected to occur with natural learning or upon exposure to oscillatory input, an LTP-inducing tetanus or various pharmacological agents? To the extent that these induce electromagnetic energy, it is conceivable. In addition to being sensitive to electromagnetic radiation, MTs may themselves produce this kind of energy. Second-harmonic generation by MTs is consistent with their ferroelectric properties. In second-harmonic generation, the most strongly enhanced wavelength is 880-nm, supporting the frequently overlooked reports of electromagnetic signaling by cells. Guenther Albrecht-Buehler [5] observed electromagnetic energy in the near infrared region overlapping the 880 nm value that was generated by centrioles for the purpose of cell-to-cell communication, leading him to suggest that: "... one of the functions of MTs may be to play the role of cellular 'nerves'." Infrared light in this range of wavelengths also induces cell aggregation [6]. Since frequency (and hence wavelength) determines the long-range effect of dielectric polarization of a given MT, one would expect this effect to be length-dependent. The distance between MTs was shown to be critical in second-harmonic generation by MTs.

18.11 The Potential for Bioelectronic Applications and Neuromorphic Computing

Traditionally, biologists viewed the cell as a "fluid mosaic bag" containing enzymes, organelles, etc. Recent work has focused on finding the proteins that come together in this cellular "soup" and proceed to effect a change corresponding to a particular biological function. Through the molecular-level analysis of these protein-protein interactions, recent work in various labs has proceeded to build a model of "systems biology," in which these biochemical reactions that have been individually characterized can be brought together to form a cohesive whole, a synergistic dynamics network. From this knowledge, we hope to extract

useful information that will affect fields as diverse as nanotechnology, biotechnology, and materials science. Inside each cell, there is an elaborate network that serves a multitude of functions. It is an intracellular "highway" that provides a roadway for motor proteins to carry cargo and travel along in their journey to extend axonal length, for example. It controls synapses, and dendrite outgrowth. It is responsible for pulling the chromosomes apart during mitosis, for cell motility, etc.

As man-made engineered systems become more and more miniaturized, the push to build "nano-machinery" is driving physicists and engineers towards biomimetics, (i.e., the branch of engineering that mimics biological materials). This is highly feasible and much progress has been made in this area. However, due to the limitations inherent in trying to build mechanical devices on such a small scale, there is still much to learn. It is conceivable that through our better understanding of the cell's individual functional and structural components we will be able to advance medicine and technology beyond even our wildest dreams. One area that may undergo a major paradigm shift as a result of it is computer engineering.

As we enter into the 21st century, the dawn of the exciting new world of computational biotechnology is upon us and we are poised for a new generation of computers that do not have to be told what to do, but have the power to learn on their own. The development of a biological computer that is fast, small, and evolvable is no longer considered science fiction. Scientists are combining biological materials with the latest silicon-based technology in an effort to give us not only electronic devices that are smaller, but are also more flexible in terms of structure and function.

Ironically, our brain can serve as proof of concept. Many scientists now believe that individual neurons display wiring patterns and communication powers that resemble a human computer, and therefore may provide the framework for the design of a biological computer. The brain is composed of 10 billion neurons, each of which may be communicating with 1000 others. The neuron transmits electric signals along its arms, or 'axons'. Inside each axon a parallel architecture of microtubules is interconnected with other proteins, not unlike the parallel computer's wiring. In fact, the structure of microtubules may have evolved towards optimal computational efficiency. The piezoelectric properties of these protein filaments allow them to bend as a result of electric fields or currents which makes them ideal candidates as regulators of synaptic plasticity, a mechanism that could explain the popular principle of "use it or lose it." Thus, seldom used synaptic connections would be switched off in favor of more active ones. Biologist Guenter Albrecht-Buehler [3] demonstrated that cells perceive their environment through a tiny organelle called the centriole, composed of microtubules that were shown to interact with electromagnetic radiation. To further display that microtubules themselves can be conductive, the German biotechnology group, led by Eberhard Unger [41,42] succesfully conducted required experiments and is now working on building nanoelectronic components using these and other proteins. Simultaneously, ideas of combining biological and silicon-based materials in hybrid arrangements are gaining more and more support for future bioelectronic applications. Work is underway at various labs around the world to develop a biological chip. The main objective is to design nanoelectronic components using hybrid protein–silicon structures with arrays of proteins as biological oscillators that can be stimulated by electrodes or acoustic couplers. This will provide an analog circuit with rich dynamics.

DNA computers are unlikely to become stand alone competitors for electronic computers. But digital memory in the form of DNA and proteins is a real possibility with exquisitely efficient editing machines that navigate through the cell, cutting and pasting molecular data into the stuff of life. Beyond that, the innate intelligence built into DNA molecules could help fabricate tiny, complex structures: in essence, using computer logic not to crunch numbers but to build things, an idea conceived of by Caltech's Winfree and Rothemund [123]. A single test tube of DNA tiles could perform about 10 trillion additions per second (about a million times faster than an electronic computer). Interfacing DNA or protein-based hybrid structures with living cells will enable a host of medical and technological applications including non-invasive diagnostic and therapeutic medical applications and computational devices.

One major component of this framework is a protein-based subcellular structure called a microtubule, to which we have devoted a large portion of this chapter. Microtubules are composed of 13 protofilaments, arranged in a spiral pattern, and each protofilament is composed of subunits of tubulin. Each tubulin possesses one of two conformational states: either both monomers can align, or one monomer can shift

30° relative to the vertical axis. Based on the conformation an individual tubulin exists in at a given moment, the conformation of its nearest neighbors can be altered as well. This conformational change can be transmitted throughout the microtubule in a similar manner as patterns are transmitted through cellular automata programs. In addition, as we argued earlier in this chapter, tubulin can have several electronic states as well as dipolar states, some of which can be conceivably linked to the conformations of C-termini and the counter-ion clouds around them. The idea that we could input an electric, chemical, or mechanical signal and generate another one at the output end of the system brings computing or information processing to mind. We believe that ordered protein arrays can function as a programmable processor or even a computer either inside cells such as neurons or as nano-scale devices.

Nanotechnology could and should take advantage of biology in a completely novel manner, (i.e., instead of building materials that mimic biological components, we could use the components themselves). In the case of microtubules and tubulin, rather than purify it from traditional sources such as cow or pig brains, tubulin can be readily cloned into an expression vector, and purified from bacteria in mass quantities. Then, purified tubulin of a predetermined sequence (and thus with desirable biophysical and biochemical characteristics) can be routinely polymerized to form microtubules with specific structural and functional properties. Following that, the microtubules produced could be stabilized in a polymer gel capable of undergoing a phase transition at a particular value of the control parameter such as temperature, applied pressure, pH, or ionic concentration. This would then trigger a signal that would initiate computational processes carried out by individual microtubules or their assemblies interconnected by MAPs or even connected to actin filaments in architecures that could mimic subneuronal designs. This technology could also be applied to sensors or artifical intelligence systems in building an evolvable computer. The only limitations in this endeavor are those imposed by our imagination and our ability to dream up new applications.

18.12 Discussion

Considering the abundance of MTNs and AFs in axons and dendritic trees, the findings and theoretical models described earlier may have important consequences for our understanding of the signaling and ionic transport at an intracellular level. Extensive new information (see [63]) indicates that AFs are both directly [14] and indirectly linked to ion channels in both excitable and non-excitable tissues, providing a potentially relevant electrical coupling between these current generators (i.e., channels), and intracellular transmission lines (i.e., AFs and MTs). Furthermore, both filaments are crucially involved in cell motility and, in this context, they are known to be able to rearrange their spatial configuration. In nerve cells, AFs are mainly located in the synaptic bouton region, whereas MTs are located in both dendrites and the axon. Again, it would make sense for electrical signals supported by these filaments to help trigger neurotransmitter release through a voltage-modulated membrane deformation leading to exocytosis [132]. Actin is also prominent in post-synaptic dendritic spines, and its dynamics within dendritic spines has been implicated in the post-synaptic response to synaptic transmission. Kaech *et al.*, [65] have shown that general anesthetics inhibit this actin mediated response. Among the functional roles of actin in neurons, we mention in passing glutamate receptor channels, which are implicated in long-term potentiation. It is therefore reasonable to expect ionic wave propagation along AFs and MTs to lead to a broad range of physiological effects.

In summary, this chapter broadly described the physical conditions that enable cytoskeletal polymers such as AFs and MTs to act as electrical transmission lines for ion flows along their lengths and along MAP-mediated interconnections between adjacent filaments. In the case of AFs, we propose a model in which each protein subunit is equivalent to an electric circuit oscillator. The physical parameters used in the model were evaluated based on the molecular properties of the polymer. Using the general conductivity rules that apply to electrical circuits we analyzed the properties of ionic waves that propagate along AFs and compared these values to those observed in earlier experiments. In the context of the role played by MTs in neurons, we described the dynamics of C-termini states. We discussed both individual MTs and their networks, including the interactions with ions and signal transmission via MAPs. Recent experiments

on ionic conductivity along AFs and MTs show the validity of the basic assumptions postulated in our models. In light of these results, we conjectured a new dendritic signaling mechanism that involves ion waves along protein filaments which may travel without significant decay over tens of microns, potentially affecting the function of synapses and ion channels.

We proposed a new model for information processing in dendrites based on electrical signaling involving the cytoskeleton. This model predicts that the dendritic cytoskeleton, including MTs and AFs plays an active role in computations affecting neuronal function. These cytoskeletal filaments are affected by, and regulate, ion channel activity. A molecular dynamics description of the C-termini protruding from the surface of a MT has revealed the existence of several conformational states, which lead to collective dynamical properties of the neuronal cytoskeleton. These collective states of the C-termini on MTs have been shown to have a significant effect on the ionic condensation and ion cloud propagation with physical similarities to those recently found in actin-filaments. We have been able to then provide an integrated view of these phenomena in a bottom-up scheme that demonstrates how ionic wave propagation along cytoskeletal structures may impact channel functions, and thus neuronal computational capabilities.

The possibility of an evolvable, dynamic, and responsive electrical circuitry within the cell provided by actin and MT filaments could be of enormous consequence to our understanding of the way cells operate internally and interact with their environment. In particular, it would cast an entirely new light on cell differentiation, cell division, and cell–cell communication. While an integrated theory of this type of behavior is far from being constructed, its individual elements are gradually taking shape.

Communicated by Peter G. Wolynes, University of California at San Diego, La Jolla, CA, July 5, 2001 (received for review May 8, 2001)

Evaluation of the electrostatic properties of biomolecules has become a standard practice in molecular biophysics. Foremost among the models used to elucidate the electrostatic potential is the Poisson-Boltzmann equation; however, existing methods for solving this equation have limited the scope of accurate electrostatic calculations to relatively small biomolecular systems. Here we present the application of numerical methods to enable the trivially parallel solution of the Poisson-Boltzmann equation for supramolecular structures that are orders of magnitude larger in size. As a demonstration of this methodology, electrostatic potentials have been calculated for large microtubule and ribosome structures. The results point to the likely role of electrostatics in a variety of activities of these structures.

The importance of electrostatic modeling to biophysics is well established; electrostatics have been shown to influence various aspects of nearly all biochemical reactions. Advances in NMR, x-ray, and cryo-electron microscopy techniques for structure elucidation have drastically increased the size and number of biomolecules and molecular complexes for which coordinates are available. However, although the biophysical community continues to examine macromolecular systems of increasing scale, the computational evaluation of electrostatic properties for these systems is limited by methodology that can handle only relatively small systems, typically consisting of fewer than 50,000 atoms. Despite these limitations, such computational methods have been immensely useful in analyses of the stability, dynamics, and association of proteins, nucleic acids, and their ligands (1–3). Here we describe algorithms that open the way to similar analyses of much larger subcellular structures.

One of the most widespread models for the evaluation of electrostatic properties is the Poisson-Boltzmann equation (PBE) (4, 5)

$$-\nabla\cdot\varepsilon(x)\nabla\phi(x) + \bar{\kappa}^2(x)\sinh\phi(x) = f(x), \qquad [1]$$

a second-order nonlinear elliptic partial differential equation that relates the electrostatic potential (ϕ) to the dielectric properties of the solute and solvent (ε), the ionic strength of the solution and the accessibility of ions to the solute interior ($\bar{\kappa}^2$), and the distribution of solute atomic partial charges (f). To expedite solution of the equation, this nonlinear PBE is often approximated by the linearized PBE (LPBE) by assuming $sinh\phi(x) \approx \phi(x)$. Several numerical techniques have been used to solve the nonlinear PBE and LPBE, including boundary element (6–8), finite element (9–11), and finite difference (12–14) algorithms. However, despite the variety of solution methods, none of these techniques has been satisfactorily applied to large molecular structures at the scales currently accessible to modern biophysical methods. To accommodate arbitrarily large biomolecules, algorithms for solving the PBE must be both efficient and amenable to implementation on a parallel platform in a scalable fashion, requirements that current methods have been unable to satisfy. Although boundary element LPBE solvers provide an efficient representation of the problem domain, they are not useful for the nonlinear problem and have not been applied to the PBE on parallel platforms. Similarly, adaptive finite element methods have shown some success in parallel evaluation of both the LPBE and nonlinear PBE (15), but limitations in current solver technology and difficulty with efficient representation of the biomolecular data prohibits their practical application to large biomolecular systems. Finally, unlike the boundary and finite element techniques, finite difference methods have the advantage of very efficient multilevel solvers (12, 16) and applicability to both the linear and nonlinear forms of the PBE; however, existing parallel finite difference algorithms often require costly interprocessor communication that limits both the nature and scale of their execution on parallel platforms (17–21) [see especially Van de Velde (19) for reviews of the various methods].

Multigrid Solution Through Parallel Focusing

Recently, a new algorithm (Bank-Holst) was described for the parallel adaptive finite element solution of elliptic partial differential equations with negligible interprocess communication (22). Unlike finite difference methods, which use a fixed resolution of the problem domain, adaptive finite element techniques generate very accurate solutions of these equations by locally enriching the basis set in regions of high error through refinement of the domain discretization. The first step in the Bank-Holst parallel finite element algorithm is the solution of the equation over the entire problem domain using a coarse resolution basis set by each processor. This solution is then used, in conjunction with an *a posteriori* error estimator, to partition the problem domain into P subdomains, which are assigned to the P processors of a parallel computer. The algorithm is load balanced by equidistributing *a posteriori* error estimates across the subdomains. Each processor then solves the partial differential equation over the global mesh, but confines its adaptive refinement to the local subdomain and a small surrounding overlap region. This procedure results in a very accurate representation of the solution over the local subdomain. After all processors have completed their local adaptive solution of the equation, a global solution is constructed by the piecewise assembly of the solutions in each subdomain. It can be rigorously shown that the piecewise-assembled solution is as accurate as the solution to the problem on a single global mesh (23). Because each processor performs all of its computational work independently, the Bank-Holst algorithm requires very little interprocess communication and exhibits excellent parallel scaling. Unfortunately, although this algorithm works well for adaptive techniques, such as finite elements, it is not directly applicable to the fixed-resolution finite difference methods that currently offer the most efficient solution of the PBE for large molecular systems. However, by combining the Bank-Holst method with

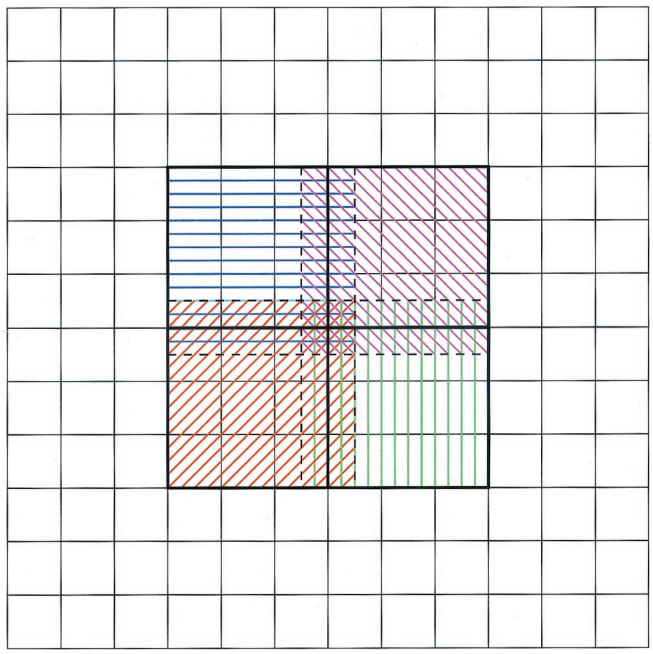

Fig. 1. Parallel focusing subdomains for four processors on simple two-dimensional mesh. Parallel computations occur on subset (hashed areas) of global mesh. Each processor performs calculations over a domain (colored hashed patterns) that combines a unique partition (inside heavy, black lines) with an overlap region (between heavy black lines and dashed lines).

other techniques, we have been able to extend this algorithm to finite difference solvers.

Electrostatic "focusing" is a popular technique in finite difference methods for generating accurate solutions to the PBE in subsets of the problem domain, such as a binding or titratable sites within a protein (4, 14). Like the Bank-Holst method, the first step in electrostatic focusing is the calculation of a low-accuracy solution on a coarse finite difference mesh spanning the entire problem domain. This coarse solution is then used to define the boundary conditions for a much more accurate calculation on a finer discretization of the desired subdomain. As noted previously (22), this focusing technique is superficially related to the Bank-Holst algorithm, where the local enrichment of a coarse, global solution has been replaced by a the solution of a fine, local multigrid problem using the solution from a coarse, global problem for boundary conditions.

We have combined standard focusing techniques and the Bank-Holst algorithm into a "parallel focusing" method for the solution of the PBE. Unlike previous parallel algorithms for solving the PBE, this method has excellent parallel complexity, permitting the treatment of very large biomolecular systems on massively parallel computational platforms. Furthermore, the finite difference discretization on a regular mesh allows for fast solution by certain highly efficient multigrid solvers (12). The algorithm is summarized below:

Given the problem data and P processors of a parallel machine:

(i) Each processor $i = 1...,P$ (a) obtains a coarse solution of the PBE over the global domain, (b) heuristically subdivides the global domain into P subdomains ($\Omega_1...,\Omega_P$), which are assigned to processors 1...,P, (c) assigns boundary conditions to its subdomain Ω_i using the coarse global solution, and (d) solves the PBE on subdomain Ω_i.

(ii) A master processor collects observable data (free energy, etc.) from the other processors and controls I/O.

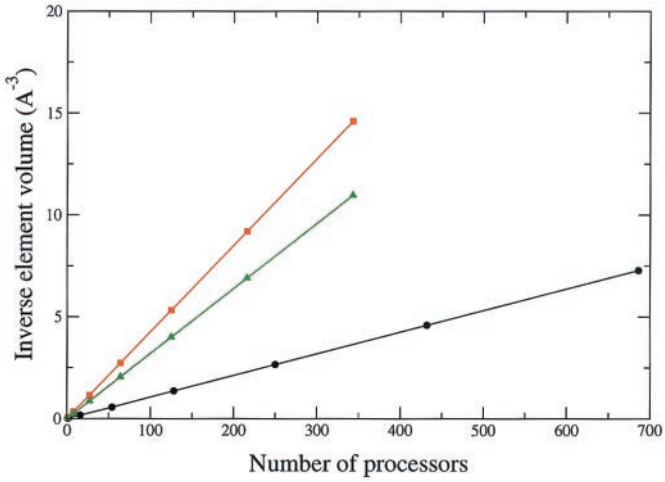

Fig. 2. Scaling of the parallel focusing algorithm to solve the LPBE for the microtubule (black line), 50S ribosome subunit (green line), and 30S ribosome subunit (red line) systems on the NPACI IBM Blue Horizon supercomputer. As discussed in the text, the inverse element volume (a measure of the mesh resolution) is a linear function of the number of processors, $v(P)^{-1} = (h_{xhyhz})^{-1} = cP$, where c = 0.011, 0.043, and 0.032 Å^{-3}/processor for the microtubule, 30S, and 50S systems, respectively.

This parallel focusing algorithm begins with each processor independently solving a coarse global problem. The per-processor subdomains are chosen in a heuristic fashion as outlined in Fig. 1. Like standard focusing calculations, only a subset of the global mesh surrounding the area of interest is used for the parallel calculations. This subset is partitioned into P approximately equal subdomains, which are distributed among the processors. Each processor then performs a fine-scale finite difference calculation over this subdomain and an overlap region that usually spans about 5–10% of the neighboring subdomains. The overlap regions are included to compensate for inaccuracies in the boundary conditions derived from the global coarse solution; however, these regions are not used to assemble the fine-scale global solution and do not contribute to calculations of observables such as forces and energies. After the fine-scale calculations are complete, a master processor accumulates the desired data from the other processes and controls I/O of the solution. Like the Bank-Holst algorithm, each process computes independently on both the global coarse problem and its subdomain. These independent computations result in an algorithm that requires negligible interprocess communication and offers excellent parallel performance.

Because of its low communication requirements, this parallel focusing algorithm can be used on parallel platforms ranging from low-bandwidth networks of workstations to high-performance supercomputers. Because step d of the parallel focusing algorithm typically dominates the overall computation, this algorithm provides excellent time complexity with respect to the number of processors. Most importantly for Poisson-Boltzmann calculations on large molecules, the mesh resolution increases linearly with the number of processors.** This linear behavior has been observed on calculations involving hundreds of processors; Fig. 2 shows the scaling results for calculations on the biomolecular systems discussed below. The parallel focusing algorithm was tested on up to 700 processors and shows linear

**For example, let $v(P) = h_x(P)h_y(P)h_z(P)$ be the volume of a grid element in a P-processor calculation with $100f$% overlap on a $n_x \times n_y \times n_z$ mesh with spacings $h_x(P),h_y(P),h_z(P)$ over a problem domain of volume V. One measure of the mesh resolution is the inverse element volume, which behaves as $v(P)^{-1} \sim (1 - 2f)^3P(n_x - 1)(n_y - 1)(n_x - 1)/V$, which is linear in P.

(*b*) Same view of microtubule with electrostatic potential isocontours at +1 kT/e (blue) and −1 kT/e (red). Potential calculated as in Fig. 3.

scaling over the entire range. The implications of the improved performance available through this parallel algorithm are discussed in more detail in the next section.

Parallel focusing has been implemented as an extension (23) of the APBS (Adaptive Poisson-Boltzmann Solver) software package (9) by using the PMG multigrid library to assemble and solve the PBE algebraic systems (12, 16). The parallel routines have been implemented by using MALOC, a portable hardware abstraction layer library (23), which allows interprocess communication through a variety of methods.

The following sections describe the application of the parallel focusing techniques to very large biomolecular systems whose electrostatic properties were unattainable by using traditional methods for solving the PBE. Specifically, we examine two important cellular components: a million-atom microtubule fragment and the large and small subunits of the ribosome.

Electrostatic Properties of Microtubules

Within every eukaryotic cell is a complex system of proteins and filaments called the cytoskeleton. The largest structures within the cytoskeleton are microtubules, cylindrical polymers formed from the protein tubulin. Microtubules perform many functions within the cell, from providing basic structure to cell division and transport, and many of these roles involve electrostatic interactions. The recent solution of the structure of tubulin (24) has allowed us to construct a working model of a microtubule containing 90 tubulin dimers. This structure contains more than 1.25 million atoms [the negatively charged C termini of both the α and β subunits were not resolved in the tubulin structure (24) and have not been rebuilt in our microtubule structure], and the structure has dimensions of ≈300 Å × 300 Å × 600 Å. The LPBE was solved at 0.54-Å mesh spacing by using 686 processors of the National Partnership for Advanced Computational Infrastructure (NPACI) Blue Horizon supercomputer. Blue Horizon is a massively parallel IBM RS6000 supercomputer consisting of 1,152 375-MHz Power3 processors distributed among 144 eight-way symmetric multiprocessing nodes. These nodes are connected with the IBM Colony switch, which delivers 350 MB/sec peak message-passing interface performance with 17-ms latency. Following the parallel focusing algorithm, each processor solved the LPBE on a coarse 97^3 global mesh, as well as a finer 97^3 spanning a subset of the overall domain. The global solution was obtained in less than 1 h. This system provides an excellent example of the improved performance available through the parallel focusing method. A sequential PBE solver treating the same system at a similar resolution would discretize the problem on a 1,111 × 555 × 555 mesh, requiring more than 350 times more memory and time to solve.

Although more work is presently underway to elucidate the implications of electrostatics on microtubule structure and function, Fig. 3 shows some early results. The most obvious feature is the overall negative electrostatic potential of the microtubule with smaller regions of positive potential. This large negative potential likely plays a significant role in the interaction with microtubule-associated proteins, motor proteins such as kinesin and dynein, and other microtubules. Fig. 3 *b* and *c* also exhibits dramatic differences between the + end (β tubulin monomer exposed) and − end (α tubulin monomer exposed) of the microtubule, which, as has been shown for actin filaments (3), may contribute to differences in the polymerization properties (25) and relative stabilities of the two ends. Fig. 4 shows a microtubule inner surface in cross-section. The binding regions of compounds such as vinblastine, colchicine, and taxol (26) are shown in Fig. 4*a*, while electrostatic isocontours are shown, for the same view, in Fig. 4*b*. Qualitative examination of the electrostatic data shows interesting variations in the drug binding

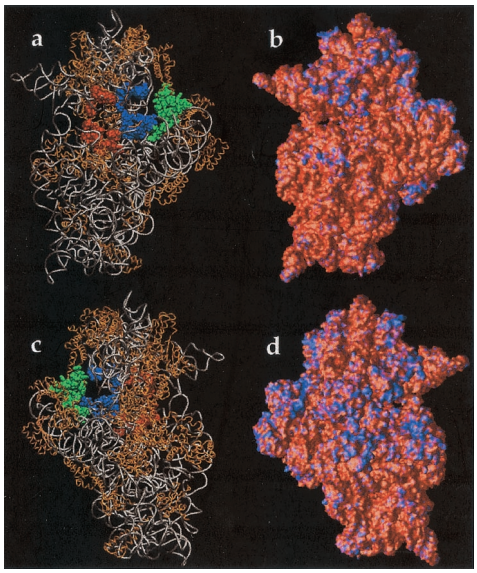

Fig. 5. Electrostatic properties of the 30S ribosomal subunit. Potential obtained by solution of the LPBE at 150 mM ionic strength with a solute dielectric of 2 and a solvent dielectric of 78.5 by using the 30S structure from the 1FJG Protein Data Bank entry (29, 34). (*a*) Front view (face that contacts the 50S subunit) of the 30S backbone with protein shown in gold; nucleic acids shown in silver. Selected components of the A-site (16S residues 525–535, 955–965, 1055–1060, 1490–1493; S12 residues 45–49) are shown in red, components of the P-site (16S residues 789–791, 925–927, 965–967, 1229–1230, 1338–1341, 1399–1403, 1497–1499; S9 residues 124–128; S13 residues 122–126) are shown in blue, and components of the E-site (16S residues 691–695, 792–797; S7 residues 80–90, 150–170; S11 residues 45–60) are shown in green. (*b*) Front view of the electrostatic potential mapped on the 30S molecular surface; a blue color indicates regions of positive potential ($> +2.6$ kT/e) whereas red depicts negative potential (< -2.6 kT/e) values. (*c*) Back view (opposite the 50S-binding face) of the 30S backbone. (*d*) Back view of the electrostatic potential mapped on the 30S molecular surface.

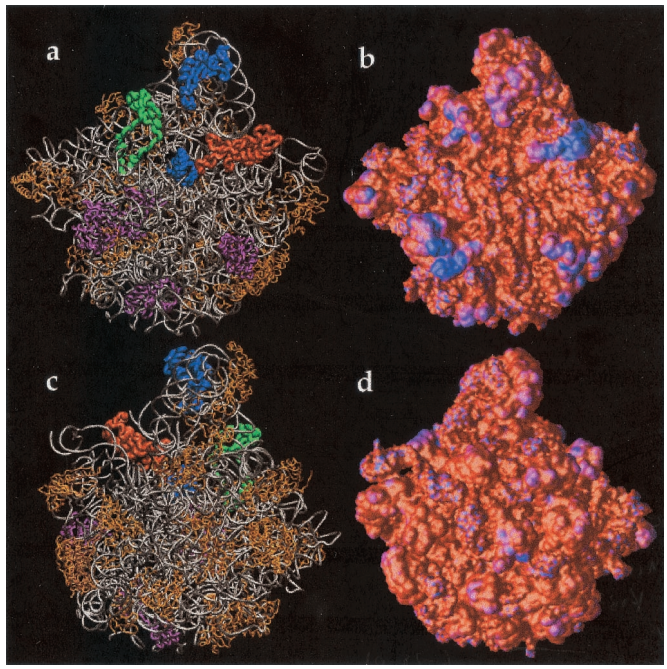

Fig. 6. Electrostatic properties of the 50S ribosomal subunit. Potential obtained by solution of the LPBE at 150 mM ionic strength with a solute dielectric of 2 and a solvent dielectric of 78.5 by using the 50S structure from the 1FFK Protein Data Bank entry (27). (*a*) Front view (face that contacts the 30S subunit) of the 50S backbone with protein component (L10e) of the A-site shown as green tube, protein component (L5) of the P-site shown as gold tube, nucleic P-loop portion of P-site shown as gold spheres, protein component (L44e) of E-site shown as white tube, various protein components (L2, L14, L19) of 50S-30S interface shown in purple. Remaining protein components are shown in gold and nucleic acid components in silver. (*b*) Front view of the electrostatic potential mapped on the 50S molecular surface; a blue color indicates regions of positive potential (>0 kT/e) whereas red depicts negative potential values (< -9.6 kT/e). (*c*) Back view (opposite the 30S-binding face) of the 50S backbone. (*d*) Back view of the electrostatic potential mapped on the 50S molecular surface.

regions; however, much more work needs to be done to quantitatively elucidate contribution of electrostatics to the interaction of these pharmaceuticals with microtubules.

The microtubule also provides a good example for examining the improved performance of this parallel algorithm with respect to sequential solvers.

Electrostatic Properties of the Ribosome

Ribosomes are macromolecular complexes responsible for the translation of the mRNA into protein. These complexes consist of two subunits: the large 50S subunit and the small 30S subunit, both of which are composed of RNA and protein constituents. During translation, the large and small subunits associate to form an active ribosome. Recently, high-resolution structures of the 50S subunit from *Haloarcula marismortui* (27) and the 30S subunit from *Thermus thermophilus* (28, 29) were solved by x-ray crystallography. These structures present a unique opportunity to examine the electrostatic potential of large ribonucleoprotein complexes.

The protonated 30S structure consists of more than 88,000 atoms and roughly spans a 200-Å-long cubic box. Using APBS on 343 processors of the NPACI Blue Horizon, LPBE was solved to give the electrostatic potential of the small ribosomal subunit at 0.41-Å resolution. Calculations also were performed on the protonated 50S subunit structure, which consisted of 94,854 atoms[††] and has similar dimensions to the 30S subunit. The electrostatic potential of the large subunit was obtained at 0.45-Å resolution by using APBS to solve the LPBE on 343 processors of the Blue Horizon. Both systems were solved by using the parallel focusing algorithm: each processor first solved a coarse problem defined by a 97^3 mesh covering the entire problem domain, and the solved the LPBE on a 97^3 mesh covering the particular subset of the global problem. Examination of the electrostatic potential mapped to the molecular surfaces of the 30S (Fig. 5) and 50S (Fig. 6) reveals large areas of negative potential with smaller regions of positive potential corresponding to some of the proteins implicated in binding of the 30S and 50S subunits to form the active ribosomal complex (27, 29–31). Not surprisingly, the potential surface maps between the two subunits exhibit qualitative electrostatic complementarity. Despite the fact that the 30S and 50S structures are from distinct species that thrive in very different environments, such comparisons of electrostatic potential are not unwarranted. Formation of active ribosomal complexes has been observed by using subunits from different species (32, 33), indicating some evolutionary conservation of the elements involved in subunit association.

Fig. 5 *b* and *d* shows the electrostatic potential mapped to the 30S subunit molecular surface. As evidenced by the 30S structure (Fig. 5 *a* and *c*), regions of positive potential typically correspond to protein components of the small subunit or cocrystallized counterions. Of particular interest is the active site of the 30S subunit, shown in Fig. 5 *a* and *b*. There are interesting variations in the electrostatic potential near regions of antibiotic

[††]The 50S Protein Data Bank coordinate file (1FFK) (27) contained only Cα coordinates for the protein constituents. Therefore, each protein residue was simply represented by its Cα atom, which was assigned the total charge of the residue and a radius of 4.0 Å.

binding (34) and the A, P, and E tRNA binding sites (29, 34). For example, the codon binding sites and "platform region" (protuberance on the right side of Fig. 5 *a* and *b*) are surrounded by regions of positive potential, which could help stabilize complexes of the ribosome with mRNA and tRNA. However, more quantitative calculations will be needed to fully explore these hypotheses.

The electrostatic potential of the 50S subunit is shown in Fig. 6 *b* and *d*. Like the small subunit, the electrostatic surface potential is largely negative, with scattered regions of positive potential typically associated with ribosomal proteins. Some of the most interesting aspects of this data set are the regions of positive potential on the 50S "crown" (see upper protuberance in Fig. 6 *a* and *b*), which correspond to proteins of the large subunit involved in tRNA binding. Specifically, these positive regions are due to proteins L44e, L5, and L10e (see Fig. 6*a*), which have been implicated in tRNA binding to the 50S subunit (35), and contribute large regions of positive potential to the molecular surface in the upper portions of the A, P, and E tRNA binding sites. Furthermore, the P-loop (shown as blue spheres in Fig. 6*a*), an important component of the 50S P-site (35, 36), shows significant positive surface potential due to a nearby Mg^{2+} ion. These areas of positive potential may provide stabilizing interactions with mRNA or tRNA bound to the ribosomal complex during translation. However, as with the 30S calculations, more detailed work is required to accurately resolve the role of electrostatics in tRNA and mRNA binding to the 50S subunit.

Conclusions

We have described the combination of standard finite difference focusing techniques and the Bank-Holst algorithm into a parallel focusing method to facilitate the solution of the PBE for nanoscale systems. Unlike previous multiprocessor algorithms for solving the PBE, this method has excellent parallel complexity that permits the solution of these problems on massively parallel computational platforms. Furthermore, the finite difference discretization on a regular mesh allows for fast solution by highly efficient multigrid solvers. This algorithm has been implemented in the APBS software by using the PMG multigrid solver and tested on the NPACI IBM Blue Horizon supercomputer.

Using these methods for the parallel multigrid solution of elliptic differential equations, the electrostatic properties of very large biomolecular assemblages are now amenable to computation. This technique relies on the efficient solution of the PBE combined with parallel focusing techniques to solve these large problems in a variety of distributed computational environments. Solution of the LPBE for the 1.2 million-atom microtubule system provided electrostatic potential data, which revealed interesting features near drug binding sites and provided possible insight into stability differences at the + and − ends of the microtubule. Such detailed electrostatic information will be central to future studies that examine the possible collective effects involved in the formation of structural defects and the stabilizing effects of taxol binding to the interior of microtubules. Likewise, application of this methodology to ribosome systems elucidated intriguing electrostatic properties of the ribosomal active site, which will provide the starting point for investigation of the stabilization of the tRNA- and mRNA-ribosome complexes during translation and the rational design of novel antibiotics. Finally, the ability to determine the contribution of electrostatics to the forces and energies of nanoscale systems should extend the scale of implicit solvent dynamics methods to much larger macromolecular complexes.

Communicated by Peter G. Wolynes, University of California at San Diego, La Jolla, CA, July 5, 2001 (received for review May 8, 2001)

Evaluation of the electrostatic properties of biomolecules has become a standard practice in molecular biophysics. Foremost among the models used to elucidate the electrostatic potential is the Poisson-Boltzmann equation; however, existing methods for solving this equation have limited the scope of accurate electrostatic calculations to relatively small biomolecular systems. Here we present the application of numerical methods to enable the trivially parallel solution of the Poisson-Boltzmann equation for supramolecular structures that are orders of magnitude larger in size. As a demonstration of this methodology, electrostatic potentials have been calculated for large microtubule and ribosome structures. The results point to the likely role of electrostatics in a variety of activities of these structures.

The importance of electrostatic modeling to biophysics is well established; electrostatics have been shown to influence various aspects of nearly all biochemical reactions. Advances in NMR, x-ray, and cryo-electron microscopy techniques for structure elucidation have drastically increased the size and number of biomolecules and molecular complexes for which coordinates are available. However, although the biophysical community continues to examine macromolecular systems of increasing scale, the computational evaluation of electrostatic properties for these systems is limited by methodology that can handle only relatively small systems, typically consisting of fewer than 50,000 atoms. Despite these limitations, such computational methods have been immensely useful in analyses of the stability, dynamics, and association of proteins, nucleic acids, and their ligands (1–3). Here we describe algorithms that open the way to similar analyses of much larger subcellular structures.

One of the most widespread models for the evaluation of electrostatic properties is the Poisson-Boltzmann equation (PBE) (4, 5)

$$-\nabla\cdot\varepsilon(x)\nabla\phi(x) + \bar{\kappa}^2(x)\sinh\phi(x) = f(x), \qquad [1]$$

a second-order nonlinear elliptic partial differential equation that relates the electrostatic potential (ϕ) to the dielectric properties of the solute and solvent (ε), the ionic strength of the solution and the accessibility of ions to the solute interior ($\bar{\kappa}^2$), and the distribution of solute atomic partial charges (f). To expedite solution of the equation, this nonlinear PBE is often approximated by the linearized PBE (LPBE) by assuming $sinh\phi(x) \approx \phi(x)$. Several numerical techniques have been used to solve the nonlinear PBE and LPBE, including boundary element (6–8), finite element (9–11), and finite difference (12–14) algorithms. However, despite the variety of solution methods, none of these techniques has been satisfactorily applied to large molecular structures at the scales currently accessible to modern biophysical methods. To accommodate arbitrarily large biomolecules, algorithms for solving the PBE must be both efficient and amenable to implementation on a parallel platform in a scalable fashion, requirements that current methods have been unable to satisfy. Although boundary element LPBE solvers provide an efficient representation of the problem domain, they are not useful for the nonlinear problem and have not been applied to the PBE on parallel platforms. Similarly, adaptive finite element methods have shown some success in parallel evaluation of both the LPBE and nonlinear PBE (15), but limitations in current solver technology and difficulty with efficient representation of the biomolecular data prohibits their practical application to large biomolecular systems. Finally, unlike the boundary and finite element techniques, finite difference methods have the advantage of very efficient multilevel solvers (12, 16) and applicability to both the linear and nonlinear forms of the PBE; however, existing parallel finite difference algorithms often require costly interprocessor communication that limits both the nature and scale of their execution on parallel platforms (17–21) [see especially Van de Velde (19) for reviews of the various methods].

Multigrid Solution Through Parallel Focusing

Recently, a new algorithm (Bank-Holst) was described for the parallel adaptive finite element solution of elliptic partial differential equations with negligible interprocess communication (22). Unlike finite difference methods, which use a fixed resolution of the problem domain, adaptive finite element techniques generate very accurate solutions of these equations by locally enriching the basis set in regions of high error through refinement of the domain discretization. The first step in the Bank-Holst parallel finite element algorithm is the solution of the equation over the entire problem domain using a coarse resolution basis set by each processor. This solution is then used, in conjunction with an *a posteriori* error estimator, to partition the problem domain into P subdomains, which are assigned to the P processors of a parallel computer. The algorithm is load balanced by equidistributing *a posteriori* error estimates across the subdomains. Each processor then solves the partial differential equation over the global mesh, but confines its adaptive refinement to the local subdomain and a small surrounding overlap region. This procedure results in a very accurate representation of the solution over the local subdomain. After all processors have completed their local adaptive solution of the equation, a global solution is constructed by the piecewise assembly of the solutions in each subdomain. It can be rigorously shown that the piecewise-assembled solution is as accurate as the solution to the problem on a single global mesh (23). Because each processor performs all of its computational work independently, the Bank-Holst algorithm requires very little interprocess communication and exhibits excellent parallel scaling. Unfortunately, although this algorithm works well for adaptive techniques, such as finite elements, it is not directly applicable to the fixed-resolution finite difference methods that currently offer the most efficient solution of the PBE for large molecular systems. However, by combining the Bank-Holst method with

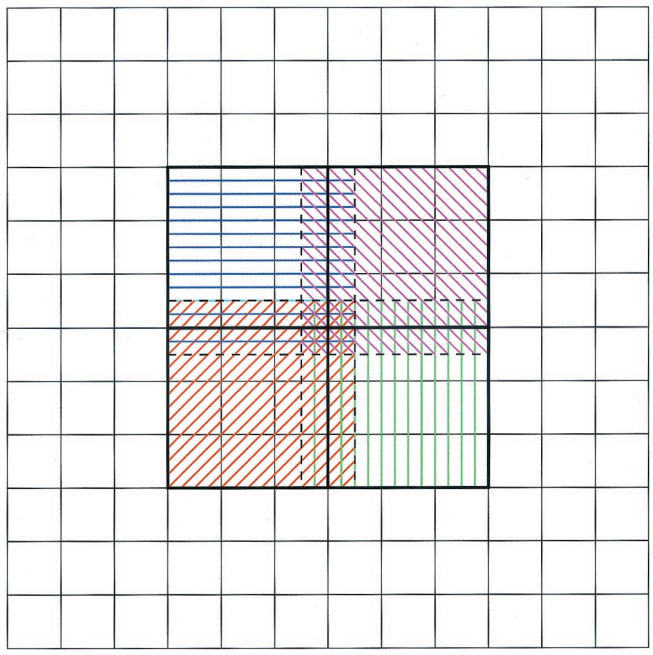

Fig. 1. Parallel focusing subdomains for four processors on simple two-dimensional mesh. Parallel computations occur on subset (hashed areas) of global mesh. Each processor performs calculations over a domain (colored hashed patterns) that combines a unique partition (inside heavy, black lines) with an overlap region (between heavy black lines and dashed lines).

other techniques, we have been able to extend this algorithm to finite difference solvers.

Electrostatic "focusing" is a popular technique in finite difference methods for generating accurate solutions to the PBE in subsets of the problem domain, such as a binding or titratable sites within a protein (4, 14). Like the Bank-Holst method, the first step in electrostatic focusing is the calculation of a low-accuracy solution on a coarse finite difference mesh spanning the entire problem domain. This coarse solution is then used to define the boundary conditions for a much more accurate calculation on a finer discretization of the desired subdomain. As noted previously (22), this focusing technique is superficially related to the Bank-Holst algorithm, where the local enrichment of a coarse, global solution has been replaced by a the solution of a fine, local multigrid problem using the solution from a coarse, global problem for boundary conditions.

We have combined standard focusing techniques and the Bank-Holst algorithm into a "parallel focusing" method for the solution of the PBE. Unlike previous parallel algorithms for solving the PBE, this method has excellent parallel complexity, permitting the treatment of very large biomolecular systems on massively parallel computational platforms. Furthermore, the finite difference discretization on a regular mesh allows for fast solution by certain highly efficient multigrid solvers (12). The algorithm is summarized below:

Given the problem data and P processors of a parallel machine:

(i) Each processor $i = 1...,P$ (a) obtains a coarse solution of the PBE over the global domain, (b) heuristically subdivides the global domain into P subdomains ($\Omega_1...,\Omega_P$), which are assigned to processors 1...,P, (c) assigns boundary conditions to its subdomain Ω_i using the coarse global solution, and (d) solves the PBE on subdomain Ω_i.

(ii) A master processor collects observable data (free energy, etc.) from the other processors and controls I/O.

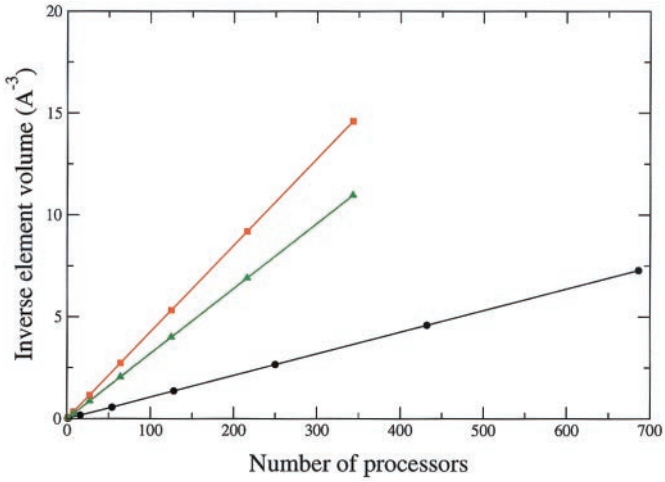

Fig. 2. Scaling of the parallel focusing algorithm to solve the LPBE for the microtubule (black line), 50S ribosome subunit (green line), and 30S ribosome subunit (red line) systems on the NPACI IBM Blue Horizon supercomputer. As discussed in the text, the inverse element volume (a measure of the mesh resolution) is a linear function of the number of processors, $v(P)^{-1} = (h_{xhyhz})^{-1} = cP$, where c = 0.011, 0.043, and 0.032 Å^{-3}/processor for the microtubule, 30S, and 50S systems, respectively.

This parallel focusing algorithm begins with each processor independently solving a coarse global problem. The per-processor subdomains are chosen in a heuristic fashion as outlined in Fig. 1. Like standard focusing calculations, only a subset of the global mesh surrounding the area of interest is used for the parallel calculations. This subset is partitioned into P approximately equal subdomains, which are distributed among the processors. Each processor then performs a fine-scale finite difference calculation over this subdomain and an overlap region that usually spans about 5–10% of the neighboring subdomains. The overlap regions are included to compensate for inaccuracies in the boundary conditions derived from the global coarse solution; however, these regions are not used to assemble the fine-scale global solution and do not contribute to calculations of observables such as forces and energies. After the fine-scale calculations are complete, a master processor accumulates the desired data from the other processes and controls I/O of the solution. Like the Bank-Holst algorithm, each process computes independently on both the global coarse problem and its subdomain. These independent computations result in an algorithm that requires negligible interprocess communication and offers excellent parallel performance.

Because of its low communication requirements, this parallel focusing algorithm can be used on parallel platforms ranging from low-bandwidth networks of workstations to high-performance supercomputers. Because step d of the parallel focusing algorithm typically dominates the overall computation, this algorithm provides excellent time complexity with respect to the number of processors. Most importantly for Poisson-Boltzmann calculations on large molecules, the mesh resolution increases linearly with the number of processors.** This linear behavior has been observed on calculations involving hundreds of processors; Fig. 2 shows the scaling results for calculations on the biomolecular systems discussed below. The parallel focusing algorithm was tested on up to 700 processors and shows linear

**For example, let $v(P) = h_x(P)h_y(P)h_z(P)$ be the volume of a grid element in a P-processor calculation with $100f$% overlap on a $n_x \times n_y \times n_z$ mesh with spacings $h_x(P),h_y(P),h_z(P)$ over a problem domain of volume V. One measure of the mesh resolution is the inverse element volume, which behaves as $v(P)^{-1} \sim (1 - 2f)^3P(n_x - 1)(n_y - 1)(n_x - 1)/V$, which is linear in P.

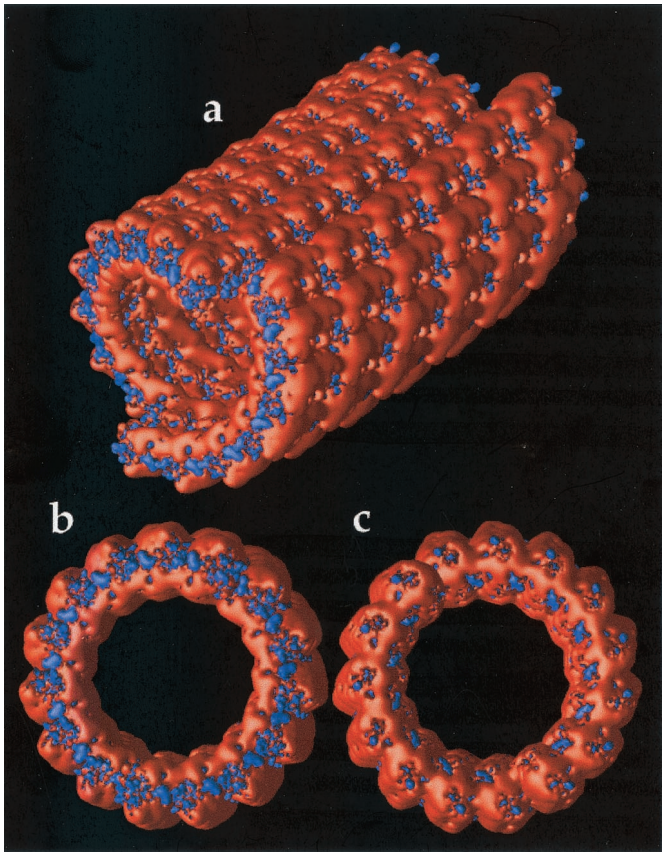

Fig. 3. Electrostatic properties of the microtubule exterior. Potential isocontours are shown at +1 kT/e (blue) and −1 kT/e (red) and obtained by solution of the LPBE at 150 mM ionic strength with a solute dielectric of 2 and a solvent dielectric of 78.5. (*a*) Exterior view of entire microtubule with − end (α tubulin monomer exposed) forward. (*b*) View of − end. (*c*) View of + end of microtubule (β tubulin monomer exposed).

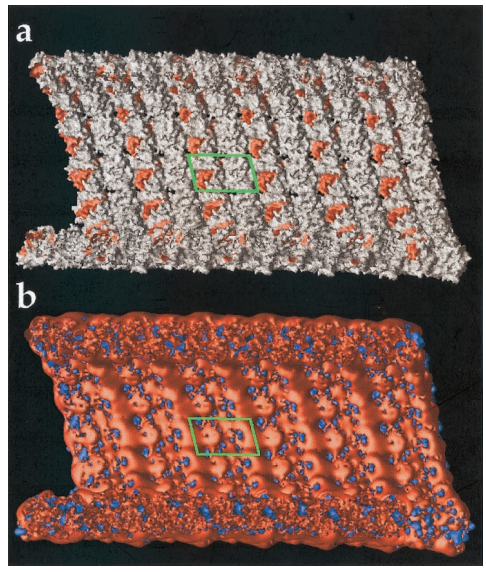

Fig. 4. Electrostatic properties of microtubule interior. Cross-section view with − end to the left and tubulin dimer outlined by green box. (*a*) View of microtubule molecular surface with regions implicated in vinblastine, colchicine, and taxol binding shown in red. (*b*) Same view of microtubule with electrostatic potential isocontours at +1 kT/e (blue) and −1 kT/e (red). Potential calculated as in Fig. 3.

scaling over the entire range. The implications of the improved performance available through this parallel algorithm are discussed in more detail in the next section.

Parallel focusing has been implemented as an extension (23) of the APBS (Adaptive Poisson-Boltzmann Solver) software package (9) by using the PMG multigrid library to assemble and solve the PBE algebraic systems (12, 16). The parallel routines have been implemented by using MALOC, a portable hardware abstraction layer library (23), which allows interprocess communication through a variety of methods.

The following sections describe the application of the parallel focusing techniques to very large biomolecular systems whose electrostatic properties were unattainable by using traditional methods for solving the PBE. Specifically, we examine two important cellular components: a million-atom microtubule fragment and the large and small subunits of the ribosome.

Electrostatic Properties of Microtubules

Within every eukaryotic cell is a complex system of proteins and filaments called the cytoskeleton. The largest structures within the cytoskeleton are microtubules, cylindrical polymers formed from the protein tubulin. Microtubules perform many functions within the cell, from providing basic structure to cell division and transport, and many of these roles involve electrostatic interactions. The recent solution of the structure of tubulin (24) has allowed us to construct a working model of a microtubule containing 90 tubulin dimers. This structure contains more than 1.25 million atoms [the negatively charged C termini of both the α and β subunits were not resolved in the tubulin structure (24) and have not been rebuilt in our microtubule structure], and the structure has dimensions of ≈300 Å × 300 Å × 600 Å. The LPBE was solved at 0.54-Å mesh spacing by using 686 processors of the National Partnership for Advanced Computational Infrastructure (NPACI) Blue Horizon supercomputer. Blue Horizon is a massively parallel IBM RS6000 supercomputer consisting of 1,152 375-MHz Power3 processors distributed among 144 eight-way symmetric multiprocessing nodes. These nodes are connected with the IBM Colony switch, which delivers 350 MB/sec peak message-passing interface performance with 17-ms latency. Following the parallel focusing algorithm, each processor solved the LPBE on a coarse 97^3 global mesh, as well as a finer 97^3 spanning a subset of the overall domain. The global solution was obtained in less than 1 h. This system provides an excellent example of the improved performance available through the parallel focusing method. A sequential PBE solver treating the same system at a similar resolution would discretize the problem on a 1,111 × 555 × 555 mesh, requiring more than 350 times more memory and time to solve.

Although more work is presently underway to elucidate the implications of electrostatics on microtubule structure and function, Fig. 3 shows some early results. The most obvious feature is the overall negative electrostatic potential of the microtubule with smaller regions of positive potential. This large negative potential likely plays a significant role in the interaction with microtubule-associated proteins, motor proteins such as kinesin and dynein, and other microtubules. Fig. 3 *b* and *c* also exhibits dramatic differences between the + end (β tubulin monomer exposed) and − end (α tubulin monomer exposed) of the microtubule, which, as has been shown for actin filaments (3), may contribute to differences in the polymerization properties (25) and relative stabilities of the two ends. Fig. 4 shows a microtubule inner surface in cross-section. The binding regions of compounds such as vinblastine, colchicine, and taxol (26) are shown in Fig. 4*a*, while electrostatic isocontours are shown, for the same view, in Fig. 4*b*. Qualitative examination of the electrostatic data shows interesting variations in the drug binding

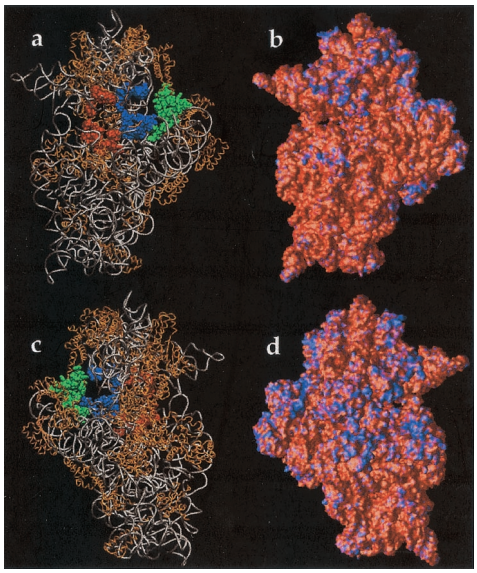

Fig. 5. Electrostatic properties of the 30S ribosomal subunit. Potential obtained by solution of the LPBE at 150 mM ionic strength with a solute dielectric of 2 and a solvent dielectric of 78.5 by using the 30S structure from the 1FJG Protein Data Bank entry (29, 34). (*a*) Front view (face that contacts the 50S subunit) of the 30S backbone with protein shown in gold; nucleic acids shown in silver. Selected components of the A-site (16S residues 525–535, 955–965, 1055–1060, 1490–1493; S12 residues 45–49) are shown in red, components of the P-site (16S residues 789–791, 925–927, 965–967, 1229–1230, 1338–1341, 1399–1403, 1497–1499; S9 residues 124–128; S13 residues 122–126) are shown in blue, and components of the E-site (16S residues 691–695, 792–797; S7 residues 80–90, 150–170; S11 residues 45–60) are shown in green. (*b*) Front view of the electrostatic potential mapped on the 30S molecular surface; a blue color indicates regions of positive potential ($> +2.6$ kT/e) whereas red depicts negative potential (< -2.6 kT/e) values. (*c*) Back view (opposite the 50S-binding face) of the 30S backbone. (*d*) Back view of the electrostatic potential mapped on the 30S molecular surface.

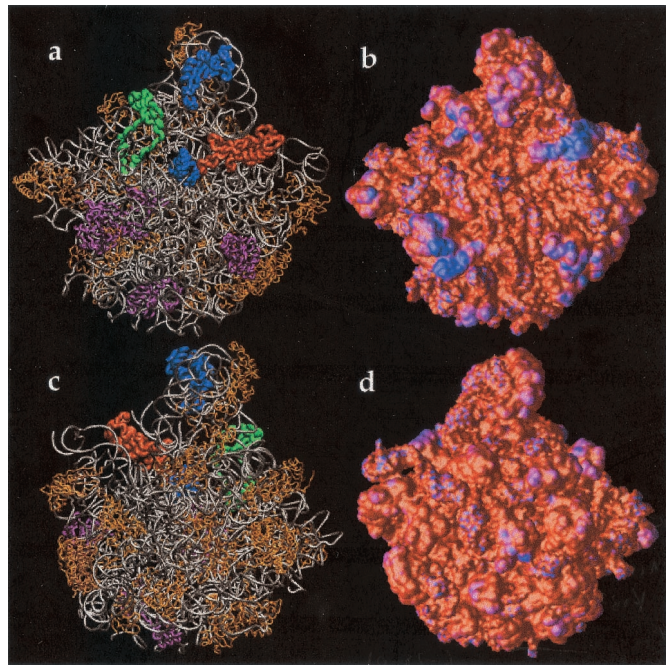

Fig. 6. Electrostatic properties of the 50S ribosomal subunit. Potential obtained by solution of the LPBE at 150 mM ionic strength with a solute dielectric of 2 and a solvent dielectric of 78.5 by using the 50S structure from the 1FFK Protein Data Bank entry (27). (*a*) Front view (face that contacts the 30S subunit) of the 50S backbone with protein component (L10e) of the A-site shown as green tube, protein component (L5) of the P-site shown as gold tube, nucleic P-loop portion of P-site shown as gold spheres, protein component (L44e) of E-site shown as white tube, various protein components (L2, L14, L19) of 50S-30S interface shown in purple. Remaining protein components are shown in gold and nucleic acid components in silver. (*b*) Front view of the electrostatic potential mapped on the 50S molecular surface; a blue color indicates regions of positive potential (>0 kT/e) whereas red depicts negative potential values (< -9.6 kT/e). (*c*) Back view (opposite the 30S-binding face) of the 50S backbone. (*d*) Back view of the electrostatic potential mapped on the 50S molecular surface.

regions; however, much more work needs to be done to quantitatively elucidate contribution of electrostatics to the interaction of these pharmaceuticals with microtubules.

The microtubule also provides a good example for examining the improved performance of this parallel algorithm with respect to sequential solvers.

Electrostatic Properties of the Ribosome

Ribosomes are macromolecular complexes responsible for the translation of the mRNA into protein. These complexes consist of two subunits: the large 50S subunit and the small 30S subunit, both of which are composed of RNA and protein constituents. During translation, the large and small subunits associate to form an active ribosome. Recently, high-resolution structures of the 50S subunit from *Haloarcula marismortui* (27) and the 30S subunit from *Thermus thermophilus* (28, 29) were solved by x-ray crystallography. These structures present a unique opportunity to examine the electrostatic potential of large ribonucleoprotein complexes.

The protonated 30S structure consists of more than 88,000 atoms and roughly spans a 200-Å-long cubic box. Using APBS on 343 processors of the NPACI Blue Horizon, LPBE was solved to give the electrostatic potential of the small ribosomal subunit at 0.41-Å resolution. Calculations also were performed on the protonated 50S subunit structure, which consisted of 94,854 atoms[††] and has similar dimensions to the 30S subunit. The electrostatic potential of the large subunit was obtained at 0.45-Å resolution by using APBS to solve the LPBE on 343 processors of the Blue Horizon. Both systems were solved by using the parallel focusing algorithm: each processor first solved a coarse problem defined by a 97^3 mesh covering the entire problem domain, and the solved the LPBE on a 97^3 mesh covering the particular subset of the global problem. Examination of the electrostatic potential mapped to the molecular surfaces of the 30S (Fig. 5) and 50S (Fig. 6) reveals large areas of negative potential with smaller regions of positive potential corresponding to some of the proteins implicated in binding of the 30S and 50S subunits to form the active ribosomal complex (27, 29–31). Not surprisingly, the potential surface maps between the two subunits exhibit qualitative electrostatic complementarity. Despite the fact that the 30S and 50S structures are from distinct species that thrive in very different environments, such comparisons of electrostatic potential are not unwarranted. Formation of active ribosomal complexes has been observed by using subunits from different species (32, 33), indicating some evolutionary conservation of the elements involved in subunit association.

Fig. 5 *b* and *d* shows the electrostatic potential mapped to the 30S subunit molecular surface. As evidenced by the 30S structure (Fig. 5 *a* and *c*), regions of positive potential typically correspond to protein components of the small subunit or cocrystallized counterions. Of particular interest is the active site of the 30S subunit, shown in Fig. 5 *a* and *b*. There are interesting variations in the electrostatic potential near regions of antibiotic

[††]The 50S Protein Data Bank coordinate file (1FFK) (27) contained only Cα coordinates for the protein constituents. Therefore, each protein residue was simply represented by its Cα atom, which was assigned the total charge of the residue and a radius of 4.0 Å.

binding (34) and the A, P, and E tRNA binding sites (29, 34). For example, the codon binding sites and "platform region" (protuberance on the right side of Fig. 5 *a* and *b*) are surrounded by regions of positive potential, which could help stabilize complexes of the ribosome with mRNA and tRNA. However, more quantitative calculations will be needed to fully explore these hypotheses.

The electrostatic potential of the 50S subunit is shown in Fig. 6 *b* and *d*. Like the small subunit, the electrostatic surface potential is largely negative, with scattered regions of positive potential typically associated with ribosomal proteins. Some of the most interesting aspects of this data set are the regions of positive potential on the 50S "crown" (see upper protuberance in Fig. 6 *a* and *b*), which correspond to proteins of the large subunit involved in tRNA binding. Specifically, these positive regions are due to proteins L44e, L5, and L10e (see Fig. 6*a*), which have been implicated in tRNA binding to the 50S subunit (35), and contribute large regions of positive potential to the molecular surface in the upper portions of the A, P, and E tRNA binding sites. Furthermore, the P-loop (shown as blue spheres in Fig. 6*a*), an important component of the 50S P-site (35, 36), shows significant positive surface potential due to a nearby Mg^{2+} ion. These areas of positive potential may provide stabilizing interactions with mRNA or tRNA bound to the ribosomal complex during translation. However, as with the 30S calculations, more detailed work is required to accurately resolve the role of electrostatics in tRNA and mRNA binding to the 50S subunit.

Conclusions

We have described the combination of standard finite difference focusing techniques and the Bank-Holst algorithm into a parallel focusing method to facilitate the solution of the PBE for nanoscale systems. Unlike previous multiprocessor algorithms for solving the PBE, this method has excellent parallel complexity that permits the solution of these problems on massively parallel computational platforms. Furthermore, the finite difference discretization on a regular mesh allows for fast solution by highly efficient multigrid solvers. This algorithm has been implemented in the APBS software by using the PMG multigrid solver and tested on the NPACI IBM Blue Horizon supercomputer.

Using these methods for the parallel multigrid solution of elliptic differential equations, the electrostatic properties of very large biomolecular assemblages are now amenable to computation. This technique relies on the efficient solution of the PBE combined with parallel focusing techniques to solve these large problems in a variety of distributed computational environments. Solution of the LPBE for the 1.2 million-atom microtubule system provided electrostatic potential data, which revealed interesting features near drug binding sites and provided possible insight into stability differences at the + and − ends of the microtubule. Such detailed electrostatic information will be central to future studies that examine the possible collective effects involved in the formation of structural defects and the stabilizing effects of taxol binding to the interior of microtubules. Likewise, application of this methodology to ribosome systems elucidated intriguing electrostatic properties of the ribosomal active site, which will provide the starting point for investigation of the stabilization of the tRNA- and mRNA-ribosome complexes during translation and the rational design of novel antibiotics. Finally, the ability to determine the contribution of electrostatics to the forces and energies of nanoscale systems should extend the scale of implicit solvent dynamics methods to much larger macromolecular complexes.

ENHANCED ANTI-STOKES RAMAN SCATTERING FROM LIVING CELLS OF *CHLORELLA PYRENOIDOSA*

F. DRISSLER [1] and R.M. MACFARLANE
IBM Research Laboratory, San Jose, CA 95193, USA

Received 14 September 1978

The anti-Stokes/Stokes ratios for living *Chlorella pyrenoidosa* cells at 294 K considerably exceed those given by the thermal population factors $[n/(n+1)]$. We have shown that resonance enhancement in the scattered photons is mainly responsible for this, but cannot rule out that some population enhancement occurs.

Recent studies [1,2] have shown that the investigation of Raman scattering from photosynthetic systems can provide information on the chemical and structural composition of the absorbing pigments, and the molecular surroundings in which they are found. Resonances of the incident laser light with visible absorption bands of these pigments lead to an enhancement of the scattering. The use of such resonances to investigate specific molecules in heterogeneous biological systems is rahter widespread [3].

We have measured Raman spectra of active *Chlorella pyrenoidosa* cells at 294 K in an attempt to clarify questions related to the role of vibrational states in biological membranes as predicted by theoretical considerations [4–7] and as suggested by some experimental observations [8,9]. According to the theory, a non-thermal population of vibrational states can occur in living systems which should lead to enhanced anti-Stokes scattering.

We have observed enhanced anti-Stokes scattering for several modes in *Chlorella pyrenoidosa* but point out that a large part of this arises from resonances in the scattered photon channel which is different for Stokes and anti-Stokes photons. Population factors derived from our experimental data show, however, that we cannot rule out that some population enhancement occurs.

[1] On leave from the University of Stuttgart, Physikalisches Institut (Teil 3) D-(7000) Stuttgart 80, Germany.

The starting culture of *Chlorella pyrenoidosa* cells was obtained from D. Fork, Carnegie Institution, Stanford, and grown in nutrient solution as proposed by Lorenzen [10]. A CO_2–air mixture (1.5% CO_2) was bubbled through the cell culture which was illuminated with fluorescent lamps. The Raman measurements were performed with a flow arrangement as described elsewhere [11] to avoid heating the cells with the laser beam and to be able to keep them in a rather adapted state. The cell concentration was 10^7 cells/mℓ with a flow speed of 40 cm/s. White background light was available for illumination of the reservoir in order to investigate a possible relation between Raman intensities and the activity of photosynthesis. All spectra were recorded at $\sim 5\ \mathrm{cm}^{-1}$ resolution using Ar^+-laser excitation, a 1 m-double monochromator and conventional photon counting detection.

The Stokes Raman spectrum of active *Chlorella pyrenoidosa* cells at 294 K is shown in fig. 1 for a laser wavelength of 5145 Å (19 436 cm^{-1}). The main features are a few groups of sharp lines (width $\sim 10\ \mathrm{cm}^{-1}$) between 800 and 1600 cm^{-1} superimposed on a rather structureless background. The anti-Stokes Raman spectrum for this range is shown in fig. 2 for the same laser frequency and power.

The intensity ratios R of the main anti-Stokes lines with respect to their Stokes counterparts ($R = I_{as}^{19436}/I_{s}^{19436}$) deviate considerably from the thermal population factor $[n(\Omega, T)/(n(\Omega, T)+1)]$ which is

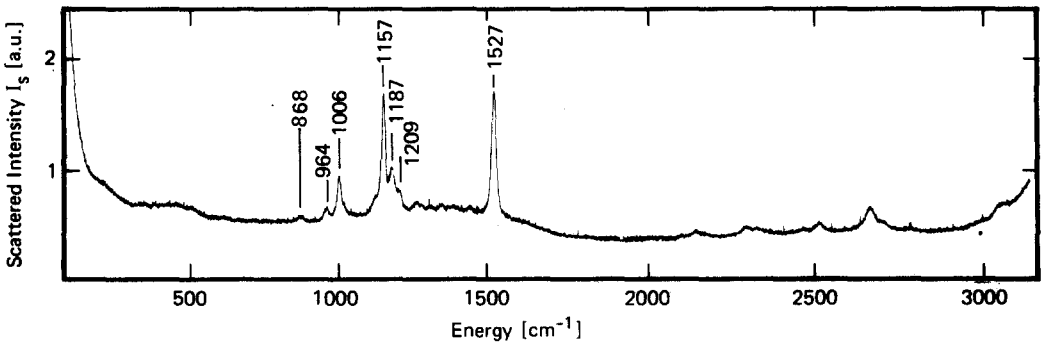

Fig. 1. Stokes Raman spectrum measured at 294 K with active cells of the green alga *Chlorella pyrenoidosa* during irradiation at 5145 Å. The bands at 868 cm^{-1}, 964 cm^{-1}, 1006 cm^{-1}, 1157 cm^{-1}, 1187 cm^{-1}, 1209 cm^{-1} and 1527 cm^{-1} are assigned to vibrational modes of carotenoid molecules [1].

given by a Planck equilibrium (Ω is the vibrational mode frequency, $T = 294$ K, see table 1, column 3). The dependence of the anti-Stokes intensity on laser power shows that local heating by the laser is not responsible for its enhancement.

As the laser wavelength was changed between 5145 Å and 4545 Å substantial changes in the scattered Stokes intensities occurred which overwhelmed the non-resonant ω^4 behaviour (fig. 3), and are attributed resonance with the absorption band of carotenoid pigments.

Furthermore, the influence of additional light (i.e., illumination of the cells in the reservoir with white light) on the intensity of the Stokes lines at 868 cm^{-1}, 1006 cm^{-1} and 1527 cm^{-1} was measured. Our preliminary results show that a reproducible increase in the intensity of those lines occurred which amounted to ~5% and which reached its maximum value approximately 60 s after light was switched on.

We concentrate our attention on the enhanced anti-Stokes/Stokes ratios R of the Raman lines at 868 cm^{-1}, 1006 cm^{-1}, 1157 cm^{-1} and 1527 cm^{-1}. These are assigned to vibrations of carotenoid molecules by Lutz [1].

The intensity ratio R for excitation at laser frequency ω is given by eq. (1):

$$R(\Omega, \omega, T) = \frac{I_{as}^{\omega}}{I_{s}^{\omega}} = a\frac{(x-\Omega)^2}{(x+\Omega)^2} P(\Omega, T), \qquad (1)$$

where a accounts for reabsorption of Stokes and anti-Stokes light, the second factor with $x = \omega - \omega_e$ expresses the resonance term, and P is the population factor which in normal thermal equilibrium is just $n/(n+1)$. Relaxing the assumption of a single resonance does not affect the essentials of our arguments.

Far from resonance both a and Ω can be neglected and R measures the population factor. On the other hand near resonance, and particularly for large Ω,

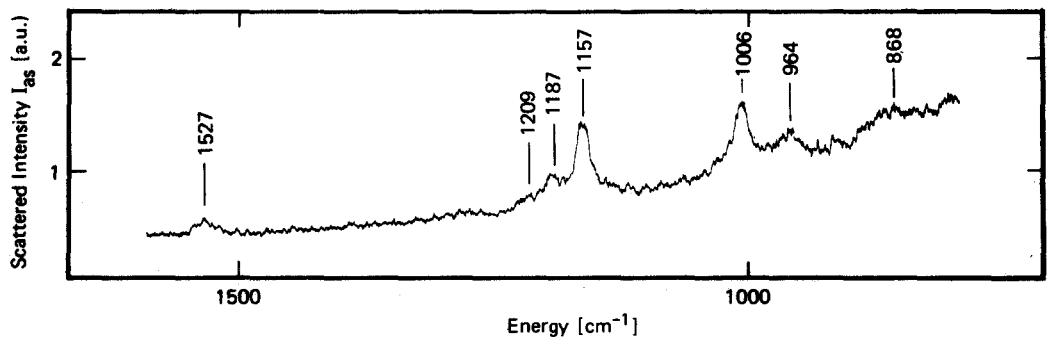

Fig. 2. Anti-Stokes spectrum between 800 and 1600 cm^{-1} measured under the same experimental conditions as the Stokes spectrum shown in fig. 1. Each Stokes shifted line has its counterpart in the anti-Stokes spectrum. The intensity ratio $I_{as}^{19436}/I_{s}^{19436}$ appears to be much larger than given by thermal population factors assuming a Planck equilibrium.

Table 1

Vibrational energy Ω (cm^{-1})	Observed ratio R $I_{as}^{19436}/I_{s}^{19436}$	Anti-Stokes enhancement $R/n(n+1)$	Res. factor $I_{s}^{19436+\Omega}/I_{s}^{19436}$ from fig. 3	$\frac{P}{n/(n+1)}$
868	0.1	10.3	4.0	2.6±0.5
1006	0.060	7.2	5.6	1.3±0.1
1157	0.020	5.3	4.1	1.3±0.1
1527	0.0024	3.5	2.7	1.3±0.2

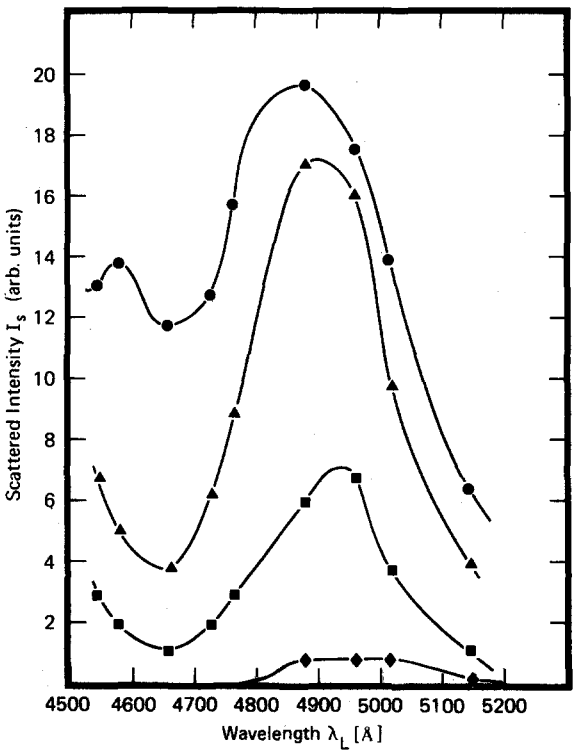

Fig. 3. Intensity dependence of the Stokes shifted bands at 868 cm^{-1} (♦), 1006 cm^{-1} (■), 1157 cm^{-1} (▲) and 1527 cm^{-1} (●) on the wavelength of the incident laser light.

R can be dominated by the frequency-dependent cross section factor. We have attempted to separate this from the population factor P by considering the ratio of Stokes intensity $I_s^{\omega+\Omega}$ (laser at $\omega+\Omega$) and anti-Stokes intensity I_{as}^{ω} (laser at ω). In this configuration it can be shown from the usual equations for Raman intensities that

$$P = I_{as}^{\omega}/I_s^{\omega+\Omega} = R(I_s^{\omega}/I_s^{\omega+\Omega}), \qquad (2)$$

is independent of resonance and reabsorption factors.

Eq. (2) can be rewritten to show the anti-Stokes enhancement as:

$$\frac{R}{n(n+1)} = \frac{I_s^{\omega+\Omega}}{I_s^{\omega}} \frac{P}{n(n+1)} . \qquad (3)$$

Table 1 shows values for the factors in eq. (3), the ratio $I_s^{\omega+\Omega}/I_s^{\omega}$ being obtained from fig. 3.

The population ratio P appears to be enhanced by factors ranging from 1.3 to 2.6 if compared with the thermal population factor $n/(n+1)$ (enhanced population factors have been suggested by refs. [4–7]).

However, the major part of the experimentally measured anti-Stokes enhancement can be explained as due to a resonance with the carotenoid absorption band at ~480 nm. This shows clearly the importance of an analysis of resonance enhancements for investigations of population effects.

We are grateful to H. Fröhlich for suggesting the experiments, and to F. Keilmann for assistance in initial measurements.

EVIDENCE FOR BOSE CONDENSATION-LIKE EXCITATION OF COHERENT MODES IN BIOLOGICAL SYSTEMS

H. FRÖHLICH

Department of Electrical Engineering, University of Salford, Salford, M5 4WT, UK

Received 4 January 1975

Experimental evidence of the action of coherent millimeter electromagnetic radiation on biological systems shows very striking effects which are strongly frequency selective at very low power supply thus indicating resonance effects. The existence of a threshold for the power supply below which no effects are found strongly supports the earlier theoretical prediction that energy supply above a critical rate will lead to excitation of polar coherent modes in the system in a manner comparable to Bose condensation.

Some time ago it was suggested that many biological systems have a branch of polar modes in the $10^{11} - 10^{12}$ s^{-1} frequency region, and that supply of energy to these modes leads to very strong (coherent) excitation of a single mode provided the rate of supply of energy, S, is larger than a critical one, S_0, i.e. $S > S_0$, [1–3]. In the formal treatment the transition from $S < S_0$ to $S > S_0$ shows great similarity with Bose condensation.

The vibrations are considered to involve regions of biological membranes, or substantial sections of giant molecules – such as proteins, DNA, etc. Coherent excitation of these modes could have very far reaching biological influences in particular in the case that the excited mode represents a giant dipole oscillation (polarisation wave with zero wave number, $k = 0$). Amongst the many consequences of such excitations are the establishment of long range and short range selective forces [4] which so far have been invoked to interpret a number of specific biological features [5, 6], but which might in very many cases be the agent which initiates positional or conformational changes from which a variety of biological effects might arise (cf also [7]).

While the vibrations with higher wave numbers may be expected to be largely – though not exclusively – longitudinal no such classification holds for the giant dipole ($k = 0$) oscillation. Furthermore the linear dimension of most of the relevant biological objects (molecules, membranes) is less than the wave length of electromagnetic radiation in the $10^{11} - 10^{12}$ s^{-1} frequency region. It follows then that radiation in resonance with the $k = 0$ frequency would be selectively absorbed by the material. The energy of excitation (cf [3] with minor modifications for the present case) would then be shared with other modes as long as $S < S_0$. Ultimately this would lead to an increase in temperature. For $S > S_0$, however, a single vibrational mode would be strongly (coherently) excited in a manner comparable to a Bose condensation. This mode may – but need not – be the mode $k = 0$ which absorbs the radiation; in this case S_0 would be relatively small.

Recently in a report of a meeting of the USSR Academy of Science (January 1973) [8] several remarkable contributions have demonstrated a striking influence of 6–7 mm coherent electromagnetic radiation on the behaviour of a variety of biological objects. The corresponding frequency of $\frac{1}{2} \times 10^{11}$ s^{-1} is close to the theoretically predicted region for such effects. while the reported biological effects represent without doubt very complex processes they exhibit two very simple common features; (i) they depend very strongly on frequency exhibiting a typical resonance behaviour, and (ii) (cf. fig. 1 of [9] and fig. 3 of [10] there exists a critical power supply $S = S_0$ below which no effects are observed and above which the observed effects are nearly independent of S.

These features strongly support the theoretical prediction of the existence of polar vibrations in the mentioned frequency region and of their biological importance when excited coherently. The crucial point here is the evidence for the existence of a threshold S_0 such that for $S > S_0$ a complete change of behaviour occurs comparable to a phase transition at $S = S_0$.

The theoretical interpretation of these results rests on the proposal that arising from the $k = 0$ resonance absorption the experimentally observed transition at $S = S_0$ consists in the coherent excitation of the polar mode mentioned above which does exhibit the required transition at $S = S_0$. This coherent excitation which is possible only when $S > S_0$ should then initiate the essential first step (e.g. selective attraction of molecules, opening of a section of a DNA complex, etc) in a possibly very complicated sequence of biological events. The time t_1, required for this first step will decrease with increasing coherent excitation, i.e. with S (provided $S > S_0$), but the time t_2 for all the subsequent processes will be independent of S. An S value will thus be reached for which $t_1 \ll t_2$ holds so that for larger S the total rate will become nearly independent of S in agreement with the observations.

It thus appears that the very simple common features discovered in experiments on a variety of biological objects find their natural interpretation in the previous theoretical predictions. It should be emphasised that the new concepts introduced there make use of a greatly simplified model. These concepts are, however, of a very general nature and permit the considerable refinements and modifications of the model which will be required for the detailed description of the observed phenomena. It is very striking to see, however, that complex biological phenomena may contain common features of very great simplicity in terms of the appropriate physical concepts.

EVIDENCE FOR NON-THERMAL EXCITATION OF ENERGY LEVELS IN ACTIVE BIOLOGICAL SYSTEMS

S.J. WEBB
Department of Physics, University of South Florida, USA

M.E. STONEHAM
College of Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S79 OWO, Canada

and

H. FRÖHLICH
Department of Physics, The University P.O. Box 147, Liverpool L69 3BX, UK

Received 2 September 1977

The ratio R of the intensities of anti Stokes and Stokes Raman shift lines of 124 cm^{-1} and of 118 cm^{-1} of active *E. coli* B was measured. For an oscillating system in therm equilibrium $R \approx 0.55$ is expected whereas we find $R \approx 1.0$. This shows that this system is excited strongly above thermal excitation in agreement with a previous theoretical conjecture [2–5].

Recent investigation of Raman effect in bacteria has demonstrated [1] that Raman shift lines below 200 cm^{-1} are found in active (metabolizing) synchronised cells whereas broad bands only are exhibited by both resting cells and nutrient solutions. These findings were considered a first step towards confirmation of the theoretical prediction [2–5] that metabolic energy may be used by biological systems to excite coherent vibrations in the region of 10^{11}–10^{12} Hz.

Details of the spectra found in [1] depend on both the type of bacteria and the type of nutrient. To show that these Raman lines represent excitations beyond thermal equilibrium requires the ratio R of the intensities of anti Stokes: Stokes lines (in an oscillating system) to lie close to $R \approx 1$ when the thermal equilibrium value $R = \exp(-h\nu/kT)$ is considerably smaller (ν = Raman shift).

We have, therefore, measured R for active cells of *E. coli* B (glucose nutrient). Experimental procedures were as in [1] except that the sensitivity setting for the Rayleigh lines was reduced by a factor 200 compared with that of the shift lines. It should also be reemphasized that the incubation temperature must be held above 25°C [6].

Figs. 1a, b, c give typical results of spectra taken 40, 50, and 60 minutes after begin of incubation. A total of eight series of such spectra was taken so far. We note that the line near 120 cm^{-1} ranges between 118 cm^{-1} and 125 cm^{-1} depending on the age of the cell. At these frequencies the thermal equilibrium value R lies between 0.55 and 0.57. Experimentally, however, we find $R = 1.01 \pm 0.10$ for 118 cm^{-1} and $R = 0.93 \pm 0.13$ for 125 cm^{-1} after averaging over the eight spectra. These values clearly are far above the thermal equilibrium values and thus constitute conclusive confirmation of the theoretical conjecture.

These excitations should be interpreted as arising from certain activities of the cell which change with its age. We note in this context the band near about 40 cm^{-1} which occurs for a short period only.

Finally the lines near 5 cm^{-1} should be noted. They might form a link with biological effects of coherent mm waves (near 2 cm^{-1}) [7].

We are grateful to Jane Montgomery for help in the experiments.

Exact solutions to the time-dependent Landau-Ginzburg model of phase transitions

J. A. Tuszyński* and R. Paul
Chemistry Department, The University of Calgary, Calgary, Alberta T2N 1N4, Canada

R. Chatterjee
Physics Department, The University of Calgary, Calgary, Alberta, T2N 1N4, Canada
(Received 20 June 1983; revised manuscript received 16 September 1983)

Using the Landau-Ginzburg Hamiltonian, which provides a phenomenological description of phase transition, we derive its Lagrangian and subsequently the Lagrange-Euler equations of motion for the order parameter. In the case of one-dimensional systems these equations appear in the form of a nonlinear Schrödinger equation and are solved exactly following the method of Hasse, using the assumption of constant envelope velocity. The resulting time-dependent solutions possess a permanent profile, and their role and range of existence are discussed. The temperature dependence of their velocities and widths is analyzed.

I. INTRODUCTION

This paper is intended to generalize the Landau-Ginzburg model of phase transitions and to investigate the resulting time-dependent solutions of the equation of motion of the order parameter η. We treat the order parameter as a complex time- and space-dependent function and utilize the Hamiltonian approach. The potential function appears as a power series up to order $2n$ in $|\eta|$. The equation of motion also includes a dissipative term. We begin by reviewing the original Landau-Ginzburg approach.

Landau[1] developed a phenomenological theory of second-order phase transitions by expanding the Gibbs free energy G of the system in a series of symmetry invariants of the low-temperature symmetry group g_0 which is also a subgroup of the high-temperature symmetry group g_1,

$$G(T,P)=G_0(T,P)\eta^2+A_4\eta^4+\cdots , \tag{1}$$

where P denotes the external field conjugated with the order parameter η and G_0 is the Gibbs free energy of the high-temperature phase. In order to obtain the desired transition at T_c Landau postulated that

$$A_2(T,P)=a(P)\epsilon , \tag{2}$$

where $\epsilon=(T-T_c)/T_c$ is the normalized temperature. The extremal value of η, $\bar{\eta}$, is found simply by minimizing G,

$$\left[\frac{\partial G}{\partial \eta}\right]_{\eta=\bar{\eta}}=0 ,$$

and using the stability conditions

$$\left[\frac{\partial^2 G}{\partial \eta^2}\right]_{\eta=\bar{\eta}}>0 ,$$

$$\bar{\eta}=\begin{cases}\pm[-(a/2A_4)\epsilon]^{1/2}, & T<T_c\\ 0, & T\geq T_c .\end{cases} \tag{3}$$

It is required that $A_4>0$ and $a>0$ for the low-temperature phase to be ordered.

When the expansion Eq. (1) is carried out to the next order,

$$G(T,P)=G_0(T,P)+a(P)\epsilon\eta^2+A_4\eta^4+A_6\eta^6+\cdots , \tag{4}$$

then $\bar{\eta}$ becomes

$$\bar{\eta}=\begin{cases}\dfrac{\pm[-A_4+(A_4^2-4aA_6\epsilon)^{1/2}]^{1/2}}{3A_6}, & T<T_c^*\\ 0, & T\geq T_c^*\end{cases} \tag{5}$$

where the new transition temperature T_c^* is

$$T_c^*=T_c+(A_4^2/4aA_6) , \tag{6}$$

and the transition may be either of second or first order depending on whether $A_4>0$ or $A_4<0$, respectively.[2]

In order to include spatial inhomogeneities of the order parameter, when these inhomogeneities are slowly varying, Ginzburg[3] added another correction to the original Landau expression,

$$G=G_0+\int(A_2\eta^2+A_4\eta^4+D\,|\,\vec{\nabla}\eta\,|^2)dV , \tag{7}$$

where the sixth-order term of Eq. (4) has been dropped and D is called the dissipation constant. Minimizing this functional with respect to η one obtains[4]

$$2(a\epsilon+2A_4\eta^2-D\nabla^2)\eta=0 , \tag{8}$$

which has two trivial, spatially homogeneous solutions [those of Eq. (5)] and one nontrivial solution (in one-dimensional systems) representing a boundary wall between two possible ordered phases of opposite signs,

$$\eta=\eta_0\tanh[x/\sqrt{2}\zeta(T)] , \tag{9}$$

where $\eta_0=\eta(x\rightarrow\infty)$ and $\zeta^2(T)\equiv D/|A_2|$. Here ζ is the coherence length. The latter solution exists only below T_c and only if $D>0$.

In order to consider time-dependent phenomena one

 ©1984 The American Physical Society

uses the Gibbs free energy G from Eq. (7) and arrives at the Langevin[5] equation (without the presence of external forces),

$$\dot{\eta}=(-2)\left[(A_2=2A_4\eta^2)\eta-D\frac{\partial^2\eta}{\partial x^2}\right], \tag{10}$$

where the constants, A_2, A_4, and D should be taken in units of the rate constant as Eq. (10) is a rate equation. This equation has been termed as "rather hopeless"[15] to be solved exactly. Therefore, a usual procedure has been to linearize it and use various approximations to perturb the linearized solution.[6] However, Parliński and Zieliński[7] discussed the first-order structural phase transitions in a recent paper and postulated two types of special solutions to Eq. (10). The Gibbs free energy they used can be represented as

$$G=G_0+\int\left[A_2\eta^2+A_{n+2}\eta^{n+2}+A_{2n+2}\eta^{2n+2}+\frac{D}{2}(\vec{\nabla}\eta)^2\right]dV, \tag{11}$$

where $n=2$ corresponds to the standard Landau functional and $n=1$ may be the case in systems where η is time reversal or space-inversion invariant. They obtained an equation of motion analogous to Eq. (10) and postulated the following solutions (which they checked by substitution). (i) A kink in the form of

$$\eta=\eta_0\{1+\exp[\delta(X-X_0-vt)]\}^{-1/n}, \tag{12}$$

where η_0 corresponds to $\bar{\eta}$ of Eq. (5), δ is the reciprocal width, and v is the velocity. (ii) A kink-antikink couple in the form of

$$\eta=\eta_0(1+\exp\{-\delta[X-X_A(t)]\})^{-1/n}\times(1+\exp\{\delta[X-X_B(t)]\})^{-1/n}. \tag{13}$$

The first solution is interpreted as an interface separating the ordered phase from the disordered one, whereas the other solution describes a nucleation center of the ordered phase. Both solutions have permanent profiles and travel with constant velocities. All of their parameters depend significantly on temperature.

It is our intention to provide a derivation of exact solutions of a generalized time-dependent Landau-Ginzburg model without restricting the order of the transition. Instead of the free Gibbs energy we will employ the Hamiltonian formalism and the order parameter will be a complex function. The resultant equation which replaces Eq. (10) is

$$-D\eta_{xx}+[2A_2+(n+2)A_{n+2}|\eta|^2+(2n+2)A_{2n+2}|\eta|^{2n}]\eta=-i\eta_t. \tag{14}$$

II. EQUATION OF MOTION

In this paper we follow the approach taken by Ma[8] and employ a block Hamiltonian for a system undergoing phase transition. The free energy of the system is therefore not used. The necessary steps leading to the final form of the equation of motion may be conveniently summarized as follows.

(1) We use the continuum approximation and include the possibility of inhomogeneities by writing an appropriate Hamiltonian H as

$$H=\int dx[(m/2)\dot{\eta}(x)^2+A_2|\eta|^2+A_{n+2}|\eta|^{n+2}+A_{2n+2}|\eta|^{2n+2}-(D/2)|\vec{\nabla}\eta|^2]\equiv\int dx\,\mathscr{H}(x), \tag{15}$$

where (x) is the Hamiltonian density.

(2) The Landau condition given by Eq. (2) is adopted.

(3) We invoke the Gaussian approximation with a probability density ρ given by

$$\rho=Z^{-1}\exp[-(\eta-\tilde{\eta})^2/kT]. \tag{16}$$

Here Z is the appropriate normalization constant and $\tilde{\eta}$ is the most probable value of η. Within this approximation $\tilde{\eta}=\bar{n}$.

(4) Assuming that the kinetic energy term in Eq. (15) can be treated as a constant we replace the block Hamiltonian by an approximate equivalent Hamiltonian expressed as

$$H=\int dx[_0+A_2\bar{\eta}^2+A_{n+2}|\bar{\eta}|^{n+2}+A_{2n+2}|\bar{\eta}|^{2n+2}-(D/2)|\vec{\nabla}\bar{\eta}|^2]. \tag{17}$$

Here $\bar{\eta}=\bar{\eta}(x)$.

(5) We express $\bar{\eta}$ as a complex function depending upon both space (x) and time (t),

$$\bar{\eta}=|\eta(x,t)|e^{i\phi(x,t)}\equiv\eta e^{i\phi}, \tag{18}$$

where for the sake of convenience we have also denoted $\eta\equiv|\bar{\eta}|$.

(6) By using the Legendre transformation we convert the Hamiltonian density (x) into a Lagrangian density $L(\eta_x,\eta_t,\eta)$. This transformation is readily carried out as follows:

$$H=L-\pi\eta_t,\quad \pi=\frac{\partial L}{\partial\eta_t}, \tag{19a}$$

$$\eta_t=\frac{\partial\eta}{\partial t},\quad \eta_x=\frac{\partial\eta}{\partial x}. \tag{19b}$$

From Eqs. (19) it is easy to see that π is the momentum density conjugate to η. The Lagrangian density resulting from these calculations has the form

$$L=(i/2)(\eta\eta_t^*-\eta^*\eta_t)(D/2)\eta_x^2-A_2|\eta|^2-A_{n+2}|\eta|^{n+2}-A_{2n+2}|\eta|^{2n+2}-_0. \tag{20}$$

(7) The standard Lagrange-Euler equations of motion may be written as

$$\frac{\partial}{\partial x}\frac{\partial L}{\partial\eta_x}+\frac{\partial}{\partial t}\frac{\partial L}{\partial\eta_t}-\frac{\partial L}{\partial\eta}=0. \tag{21}$$

(8) Substituting Eq. (20) in Eq. (21) we get

$$-D\eta_{xx}+[2A_2+(n+2)A_{n+2}|\eta|^n+(2n+2)A_{2n+2}|\eta|^{2n}]\eta=-i\eta_t. \tag{22}$$

This is our final equation of motion and is an example of the well-known nonlinear Schrödinger equation.[9] Hasse[10] has presented a method which can be adapted for the exact solution of Eq. (22). In the next section we turn our attention to this aspect of the problem.

III. SOLUTION OF THE NONLINEAR SCHRÖDINGER EQUATION

Representing the potential term in Eq. (22) by

$$W(\eta)=2A_2(n+2)A_{n+2}|\eta|^n+(2n+2)A_{2n+2}|\eta|^{2n}, \tag{23}$$

and substituting $\bar{\eta}$ from Eq. (18) into Eq. (22), we obtain

$$i(\eta_t+i\eta\phi_t)=Dn_{xx}+2iD\eta_x\phi_x+iD\eta\phi_{xx}-D\eta\phi_x^2 - W(\eta)\eta . \tag{24}$$

We may now separate the real and imaginary parts as follows.

(i) The imaginary part yields

$$\eta_t=2D\eta_x\phi_x+D\eta\phi_{xx} , \tag{25}$$

which when multiplied through by 2η transforms into

$$\frac{\partial}{\partial t}(\eta^2)=\frac{\partial}{\partial x}(\eta^2)(2D\phi_x)+\eta^2(2D\phi_{xx}) . \tag{26}$$

Introducing the quantum velocity as

$$v=-2D\phi_x \tag{27}$$

and the density as

$$\rho(x,t)=\eta^2(x,t) , \tag{28}$$

we rewrite Eq. (26) in the form of an equation of continuity,

$$\rho_t=-(\rho V)_x . \tag{29}$$

(ii) The real part yields

$$-\eta\phi_t=D\eta_{xx}-D\eta\phi_x^2-W(\eta)\eta , \tag{30}$$

which can be transformed into

$$\phi_t-W(\eta)-(1/4d)v^2+(D/\eta)\eta_{xx}=0 . \tag{31}$$

Integration of Eq. (27) yields

$$\phi(x,t)=(1/2D)\int_{x'=vt}^{x'=x}dx'v(x',t)+f(t) , \tag{32}$$

where the function $f(t)$ is selected in the manner suggested by Hasse[10] such that the expectation value of the Hamiltonian gives the energy of the wave packet. To carry out this program we interpret $(2D)^{-1}$ as the effective mass of the quasiparticle described by the Schrödinger equation, Eq. (22): $m=(2D)^{-1}$, and we write

$$\langle H\rangle=-\langle\phi_t\rangle=mv^2/2=v^2/4D . \tag{33}$$

We now assume v to be constant and set $f(t)=v^2/4Dt$ to obtain

$$\phi(x,t)=(1/2D)v(x-vt)+(v^2/4D)t , \tag{34}$$

which yields $-\phi_t=-\langle\phi_t\rangle=v^2/4D$ as required by Eq. (33). Substituting this value of ϕ_t into Eq. (31) we arrive at

$$\eta_{xx}=[(1/2D)v^2+W(\eta)]\eta/D . \tag{35}$$

Because of the assumed constancy of v, Eq. (35) can be solved exactly upon introducing a new variable: $z\equiv(\eta_x)^2$. As a result we transform Eq. (35) into

$$\frac{dz}{d\eta}=\frac{2}{D}\eta\left[\frac{1}{2D}v^2+W(\eta)\right] , \tag{36}$$

which can be written in the integral form

$$z(\eta)=\frac{2}{D}\int_0^\eta d\eta\eta\left[\frac{1}{2D}v^2+W(\eta)\right] . \tag{37}$$

By substituting the definition of W from Eq. (23) and carrying out a termwise integration over η we obtain

$$z(\eta)=c_1\eta^2+c_2\eta^{n+2}+c_3\eta^{2n+2} , \tag{38}$$

where the constants are

$$c_1=\frac{1}{D}\left[2A_2+\frac{v^2}{2D}\right] , \tag{39}$$

$$c_2=\frac{2A_{n+2}}{D} , \tag{40}$$

$$c_3=\frac{2A_{2n+2}}{D} . \tag{41}$$

We now employ the definition of z to solve for η

$$\pm(x-vt)=\int_{\eta_0}^{\eta}d\eta' z(\eta')^{-1/2} =\int_{\eta_0}^{\eta}d\eta'[\eta'(c_1+c_2\eta'^n+c_3\eta'^{2n})^{1/2}]^{-1} , \tag{42}$$

where $\eta_0=\eta(x=vt)$. Changing the integration variable to $\zeta=\eta^n$, Eq. (42) becomes

$$\pm(x-vt)=\frac{1}{n}\int_{\eta_0^n}^{\eta^n}d\zeta[\zeta(c_1+c_2\zeta+c_3\zeta)^{1/2}]^{-1} , \tag{43}$$

which upon another change of variable, $\tau=1/\zeta$ assumes the form of a standard elliptic integral,

$$\pm(x-vt)=-\frac{1}{n}\int_{\eta_0^{-n}}^{\eta^{-n}}d\tau(C_3+C_2\tau+c_1\tau^2)^{-1/2} , \tag{44}$$

whose value depends on the constants c_1, c_2, and c_3, and another constant defined as

$$\Delta=4c_3c_1-c_2^2=\frac{4}{D^2}\left[2A_{2n+2}\left[2A_2+\frac{v^2}{2D}\right]-A_{n+2}^2\right] . \tag{45}$$

Equation (44) is obtained, after a series of transformations, as a result of using the Hamiltonian, Eq. (15), to derive the equation of motion of η, Eq. (22). The latter equation has been integrated out by assuming the form of η as in Eq. (18) and keeping the velocity v constant. The variable τ is simply $\tau=\eta^{-n}$. The analytical expressions for the integral Eq. (44) are given in Appendix A. Substituting those expressions into Eq. (44) and solving for η we

obtain the following possibilities.

(i) If $c_1>0$ and $\Delta>0$, then

$$\eta(x,t)=\{(1/2c_1)\sqrt{\Delta}\sinh[x_1\mp n\sqrt{c_1}(x-vt)] -c_2/2c_1\}^{-1/n}, \tag{46}$$

where

$$x_1=\sinh^{-1}[(2c_1\eta_0^{-n}+c_2)/\sqrt{\Delta}] . \tag{47}$$

(ii) If $c_1<0$ and $\Delta<0$, then

$$\eta(x,t)=\{(1/2c_1)\sqrt{-\Delta}\sin[x_2\pm n\sqrt{-c_1}(x-vt)] -c_2/2c_1\}^{-1/n}, \tag{48}$$

where

$$X_2=\sin^{-1}[(2c_1\eta_0^{-n}+c_2)/\sqrt{-\Delta}] . \tag{49}$$

(iii) If $c_1>0$ and $\Delta=0$, then

$$\eta(x,t)=\{(1/2c_1)\exp[X_3\pm n\sqrt{c_1}(x-vt)]-c_2/2c_1\}^{-1/n}, \tag{50}$$

where

$$X_3=\ln(2c_1\eta_0^{-n}+c_2) . \tag{51}$$

(iv) If $c_1>0$ and arbitrary Δ, then

$$\eta(x,t)=\left[\frac{1+\Delta}{4c_1}\sinh[X_4\pm n\sqrt{c_1}(x-vt)] +\frac{1-\Delta}{4c_1}\cosh[X_4\pm n\sqrt{c_1}(x-vt)]-\frac{c_2}{2c_1}\right]^{-1/n}, \tag{52}$$

where

$$X_4=\ln\{2[c_1(c_1\eta_0^{-2n}+c_2\eta_0^{-n}+c_3)]^{1/2}+2c_1\eta_0^{-n}+c_2\} . \tag{53}$$

Note that Eq. (52) becomes identical to Eqs. (50) and (46) if $\Delta=0$ and 1, respectively. A special use of this solution with $\Delta=-1$ and $n=4$ is listed in Table 1 of Hasse.[10]

All the solutions given in Eqs. (46), (48), (50), and (52) are essentially waves propagating through the system with a constant velocity v and a permanent profile. These formulas determine the real part of $\bar{\eta}$ [see Eq. (18)] which is related to the envelope wave,[9] whereas the carrier wave is given by $e^{i\phi}$ where ϕ is displayed in Eq. (34). Therefore, each of these time-dependent solutions can, in general, be written as

$$\eta(x,t)=\eta_0 f[\delta_e(\Delta X_e-V_e t)]\exp[i\delta_c(\Delta X_c-v_c t)] , \tag{54}$$

where the index e refers to the envelope and c refers to the carrier properties, η_0 is the amplitude, and f is the function of the profile expressed in (i)–(iv). It is readily seen that

$$\delta_c=\frac{v}{2},\quad v_c=\frac{v}{2},\quad \delta_e=n\sqrt{c_1},\quad v_e=v . \tag{55}$$

It is perhaps worth mentioning that apart from the time-dependent solutions (i)–(iv), Eq. (22) possesses a number of trivial, time- and/or space-independent solutions which have been presented in conjunction with the earlier models. These are the following.

(v) The solution corresponding to the disordered phase (stable for $T\geq T_c^*$),

$$\eta(x,t)=0 . \tag{56}$$

Here

$$\delta_c=v_c=\delta_e=v_e=\eta_0=0 .$$

(iv) The solution corresponding to the homogeneously ordered phase

$$\eta(x,t)=\pm\left[\frac{-(n+2)A_{n+2}+[(n+2)^2A_{n+2}^2-8(2n+2)A_2A_{2n+2}]^{1/2}}{2A_{2n+2}}\right]^{1/n} . \tag{57}$$

This solution exists only when $T<T_c^*$. Here $\delta_c=v_c=v_e=0$; $\delta_e=\infty$ and $\eta_0\neq 0$.

(vii) Provided $T<T_c^*$ and $D>0$, there exist solutions describing a stationary boundary wall between the solutions (vi) with opposite signs,

$$\eta(x,t)=\eta_0\tanh\frac{x}{\sqrt{2}\xi(T)} . \tag{58}$$

Here $\delta_c=v_c=v_e=0$; $\delta_e=[\sqrt{2}\xi(T)]^{-1}$. In the next section we proceed to analyze in detail the properties and existence ranges of the time-dependent solutions (i)–(iv).

IV. DISCUSSION OF THE SOLUTIONS

We now discuss the constraints imposed on the parameters c_1, c_2, and c_3 and through them on the coefficients A_2, A_4, A_6, and D in order for the time-dependent solutions to exist. From the requirements on the signs of c_1 and Δ stated for each of the solutions we easily deduce the following.

(1) Solution (i) requires that $D>0$ (dissipative systems) and the temperature range must be restrained to

$$T>T_c\left[1-\frac{v^2}{4aD}+\frac{A_{n+2}^2}{2A_{n+2}^2}\right]\equiv T_{c_1} . \tag{59}$$

However, T_{c_1} may be made arbitrarily small by the appropriate choice of parameters.

(2) Solution (ii) requires that $D<0$ and $T>T_{c_1}$.

(3) Solution (iii) exists only if $D>0$.

(4) Solution (iv) may exist both if $D<0$ and if $D>0$. In the former case one needs

$$T<T_c\left[1-\frac{v^2}{4aD}\right]\equiv T_{c_2} , \tag{60}$$

and in the latter case one needs $T > T_{c_2}$. From the form of these solutions we note that f contained in Eq. (54) is comprised of a function raised to the $(-1/n)$th power. Therefore, additional restrictions arise if n is even ($n=2$ is the most common case). In this case we require that in the entire range of $x-vt$, the function whose root is taken should be positive, otherwise unphysical divergences appear.

Upon analyzing this condition in all the four cases we find the following additional restrictions that have to be imposed in order for the solutions to attain physical meaning.

(1) Solution (i) requires that $c_2 < 0$ or else there will be at least one singular point. This combined with the previous requirement that $D > 0$ results in $A_{n+2} < 0$ which means that only systems exhibiting first-order transitions may possess this solution.

(2) Similarly, solution (ii) may only exist if $c_2\sqrt{-\Delta} > 1$ which implies that $c_2 > 0$ and $(c_2 - 4c_3c_1)^{1/2}$. However, c_3 is positive and c_1 is negative, and therefore the latter conditions can never be realized and consequently solution (ii) is unphysical.

(3) Solution (iii) exists only if $c_2 < 0$ which is equivalent to $A_{n+2} < 0$. The latter condition is satisfied only by systems undergoing first-order transitions.

(4) Solution (iv) can only be admitted if $c_2 < -2\sqrt{c_1 c_3}$, which in terms of the Hamiltonian constants, is written as

$$\frac{A_{n+2}}{D} < -\frac{1}{|D|}\left[2A_{2n+2}\left[2A_2 + \frac{v^2}{2D}\right]\right]^{1/2}. \quad (61)$$

This inequality is satisfied irrespective of the sign of A_{n+2} and therefore solution (iv) may exist in system exhibiting both first- and second-order transitions. The assumption that $D > 0$ is followed by $A_{n+2} < 0$, and conversely if $D < 0$; then it is required that $A_{n+2} > 0$. We conclude that solution (iv) may exist either in systems exhibiting first-order transitions with $D > 0$ or in systems exhibiting second-order transitions with $D < 0$. The final analysis we make is with respect to the form of the traveling solutions. Using Eq. (54) and Eqs. (46), (48), (50), and (52), we notice the following common features.

(1) The envelope velocity $v_e = v$ is given in Eq. (33) where we adopt

$$\langle H \rangle = A_2\bar{\eta}^2 + A_{n+2}\bar{\eta}^{n+2} + A_{2n+2}\bar{\eta}^{2n+2} \quad (62)$$

along with Eq. (57) for $\bar{\eta}$. Therefore we find that $\bar{\eta} \to 0$ as $T \to T_c^*$ and $\bar{\eta} = 0$ when $T > T_c^*$, $v \to 0$ as $T \to T_c^*$, and $v = 0$ when $T > T_c^*$. The envelope velocity v decreases continuously to zero with temperature if the transition is of second order and has an abrupt discontinuity at T_c^* in the case of a first-order transition. We conclude that all time-dependent solutions become stationary (or vanish altogether) above the transition temperature T_c^*.

(2) In all four cases the envelope width is $\delta_e = n\sqrt{|c_2|}$ and thus $\delta_e \to 0$ as $T \to T_c^*$.

(3) The profile of the time-dependent solutions is preserved throughout their propagation and can be desired as follows. Solution (i) is a kink-antikink couple, solution (ii) is a periodic function, solution (iii) is a kink, and solution (iv) is of an intermediate form between (i) and (iii). Solution (iv) becomes (i) when $\Delta = 1$ and (iii) when $\Delta = 0$. We have depicted these four profiles in Figs. 1–4.

(4) The amplitude for each solution can be written as

$$\eta_0 = (1/2c_1)^{-1/n} \text{ and } \eta_0 \to 0 \text{ as } T \to T_c^*.$$

The properties of solutions (i)–(iv) are summarized in Table I.

Finally, by comparison with the work of Parliński and Zieliński[7] we note that solution (iii) corresponds to their kinklike solution which has been interpreted as an interface between two allowed phases and solution (ii) corresponds to their kink-antikink couple which has been identified with the nucleation center. We emphasize here that we have found that these solutions exist only for first-order phase transitions in a limited temperature range and they require that $D > 0$ which characterizes a dissipative medium. The other two solutions which we include in Table I have not been demonstrated previously. The periodic solution, however, may only exist if n is odd (the order parameters must be invariant under time reversals

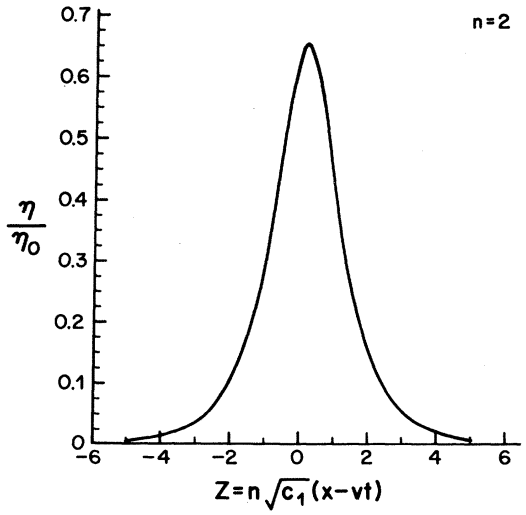

FIG. 1. Profile of solution (i).

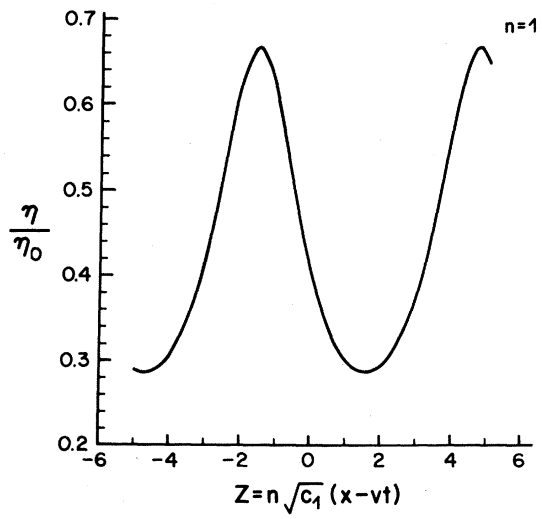

FIG. 2. Profile of solution (ii).

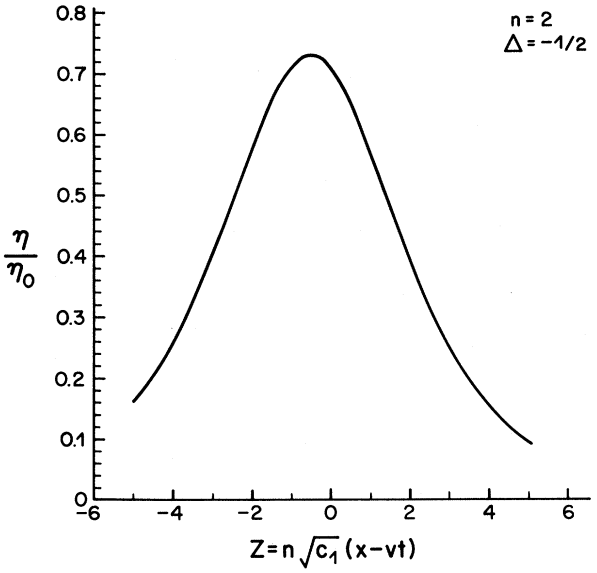

FIG. 3. Profile of solution (iii).

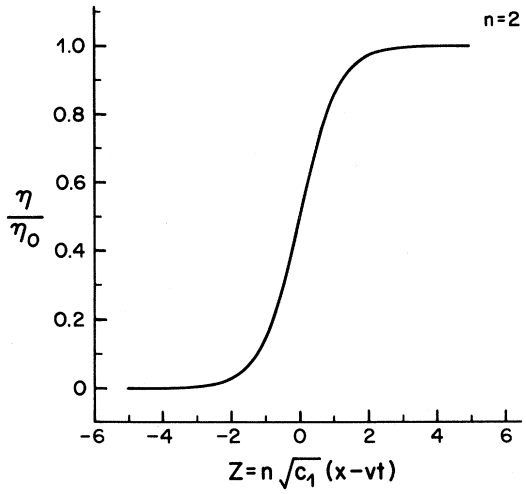

FIG. 4. Profile of solution (iv).

or space inversions). Furthermore, solution (iv) exists both in systems undergoing first- and second-order transitions. Both these new solutions appear if only the appropriate temperature ranges are ensured to coincide with the prescribed sign of the dissipation constant D. We may identify solution (ii) with elementary excitations[11] around the extremal value $\bar{\eta}$ and solution (iv) with local regions of order within the correlation length. Also notice that all the time-dependent solutions can propagate in both directions along the x axis and can have both positive and negative values of the amplitude as long as no external field breaking this symmetry is applied.

The physical meaning of the solutions with $D<0$ is, however, uncertain to the authors, as for the order parameter to be stable against fluctuations it is required that $D>0$. The opposite case can only be taken if a higher-order term proportional to $|\nabla^2\eta|$ is present to ascertain the stability. We intend to examine this question and also investigate the role of external fields in a future paper.

ACKNOWLEDGMENTS

The authors express their gratitude to Dr. S. R. Sreenivasan for many valuable discussions on the subject. The financial support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged by two of us (R.P. and R. C.).

APPENDIX

From the table of integrals[12] we find that the value of the following elliptic integral,

$$I=\int dx(c_3+c_2x+c_1x^2)^{-1/2}\,, \tag{A1}$$

depends on the sign of c_1 and $\Delta=4c_1c_3-c_2^2$, namely the following four possibilities exist.

(i) If $c_1>0$, then

$$I=(1/\sqrt{c_1})\ln\{2[c_1(c_3+c_2x+c_1x^2)]^{1/2}+2c_1x+c_2\}\,. \tag{A2}$$

TABLE I. Properties of solutions (i)—(iv).

Solution	Profile	Dissipation constant	Temperature	If $n=2$
(i)	Kink-antikink couple	$D>0$	$T_c^*\geq T>T_{c_1}$	First order
(ii)	Periodic function	$D<0$	$T_c^*\geq T>T_{c_1}$	Disappears
(iii)	Kink	$D>0$	$T_c^*\geq T$	First order
(iv)	Kink-antikink couple or kink depending on Δ	$D<0$	$T<T_{c_2}$, $T\leq T_c^*$	Second order
		$D>0$	$T_c^*\geq T>T_{c_2}$	First order

(ii) If $c_1 > 0$ and $\Delta > 0$, then

$$I = (1/\sqrt{c_1})\sinh^{-1}[(2c_1x + c_2)/\sqrt{\Delta}] . \quad \text{(A3)}$$

(iii) If $c_1 < 0$ and $\Delta < 0$, then

$$I = (-1/\sqrt{-c_1})\sin^{-1}[(2c_1x + c_2)/\sqrt{-\Delta}] . \quad \text{(A4)}$$

(iv) If $c_1 > 0$ and $\Delta = 0$, then

$$I = (1/\sqrt{c_1})\ln(2c_1x + c_2) . \quad \text{(A5)}$$

Abstract

Microtubules, which are thought to be the primary organizers of the cytoskeleton, are electrical polar structures with extraordinary elastic deformability at low stress and with energy supply from hydrolysis of guanosine triphosphate (GTP) to guanosine diphosphate (GDP). At least a part of the energy supplied from hydrolysis can excite vibrations. Energy is mainly lost by viscous damping of the surrounding cytosol. Viscous damping is diminished by a slip layer which is formed by an attracted ionic charge layer and by a thin surface layer of the microtubule. Relaxation time caused by viscous damping may be several orders of magnitude greater than period of vibrations at 10 MHz. Energy supplied to the microtubule is of the order of magnitude of 10^{-14} W cm^{-1} (per unit length of the microtubule).

1. Introduction

Physical processes in living matter participating in its organization are still not adequately understood. Frauenfelder et al. [1] claim than physical mechanisms of organization are of electromagnetic nature. Fröhlich pointed out that biological systems exhibit relative stability in a way in which some modes of behaviour remain very far from thermal equilibrium, postulated the existence of long range quantum mechanical phase correlations, and very strong excitation of a few modes of motion. Strong polar character of biological objects suggests longitudinal oscillations as stabilising modes [2–4]. The postulated rate equation for the *i*-th vibration mode may be written in a symbolic form

$$\dot{n}_i = s_i - [\dot{n}_i]_\phi - [\dot{n}_i(n_i, n_j)]_\chi$$

where $\dot{n}_i$ is the total rate of change of occupation number n_i (in 1 s), and s_i, $[\dot{n}_i]_\phi$, $[\dot{n}_i(n_i, n_j)]_\chi$ is the rate of change of n_i by energy supply, and by the linear and by the nonlinear interaction with the heat bath, respectively. The linear and the nonlinear term of the interaction with the heat bath describes transfer of one energy quantum between a vibration mode and the heat bath and energy transfer between two vibration modes with participation of the heat bath, respectively. The steady state solution to the rate equation shows that due to nonlinear term the supplied energy is not thermalized but condensed in a vibration mode. Excitation depends on the amount of the energy supplied to the system but not on the manner of its supply [5].

Eucaryotic cells are structurally and dynamically organized by a protein polymer network called the cytoskeleton [6]. The cytoskeleton exerts forces and generates movements without any major chemical changes. The cytoskeleton is a highly dynamic structure which reorganizes continually as the cell changes its shape, divides, and responds to its environment. The fundamental structure of the cytoskeleton formed by the microtubules satisfies the basic requirements for excitation of vibrations and generation of endogenous oscillating electric field [7]. Viscous damping by surrounding cytosol may quench excitation of vibrations. Viscosity effects on vibrations were examined using a model with longitudinal vibrations parallel to the planar interface between the microtubular medium below and the cytosol medium above the interface [8]. Slip boundary conditions make possible excitation of vibrations. Foster and Baish [9] used a cylindrical model of a microtubule but without slip boundary conditions and claimed that damping is so strong that excitation of vibrations is not possible. A cylindrical model of microtubule with the slip boundary conditions used in Refs. [10,11] confirmed the possibility of excitation. We present assessment of excitation in microtubules including viscous damping.

2. Subunits of the microtubule—electric dipoles

The microtubule is a hollow cylindrical polymer of tubulin heterodimers (Fig. 1a). The outer and the inner diameter is about 25 and 17 nm, respectively. Tubulin heterodimer—composed of α- and β-tubulins—may exist in two conformation states (Fig. 1b): the α state and the β state where the electron negative charge is placed toward the α-tubulin and the β-tubulin, respectively. In the β state, the heterodimer is tilted 29° with respect to the microtubule axis. In the interphase microtubules are organized in a radial structure extending from the centrosome to the periphery of the cell (Fig. 2a). In the M phase, microtubules assemble from the two separated centrosomes to form a mitotic spindle (Fig. 2b).

Each heterodimer binds 18 calcium ions [12–14]. The electric dipole moment is about 1000 Debye (10^{-26} Cm). The induced dipole moment per dimer arising only from the motion of mobile electrons or protons was estimated to be 200–400 Debye [15]. Ionic concentration inside a cell is of about 150 mM of cations and the same concentration of anions [6]. The ions from the cytosol form a charge layer—a cylindrical envelope around the microtubule [15]. Similar situation may be inside the microtubule (Fig. 3) as the liquid medium in the inner circular cavity is very likely to be cytosol. The ionic charge layer, which is schematically shown in Figs. 1 and 3, screens electrical potential generated by the charges in the microtubule [15]. Within a distance of about 2 Debye lengths the static potential is considerably screened. The Debye length is of about 0.8 nm [16]. Due to hydration, the ions are surrounded by bound water molecules up to a distance of 0.4–0.5 nm. Charged proteins of considerably greater size than ionized atoms may be in the ionic layer too. The majority of water molecules in the charge layer are not free and its viscous properties are dependent on hydrated ions. Some ions can penetrate inside the tubulin structure and behave like a part

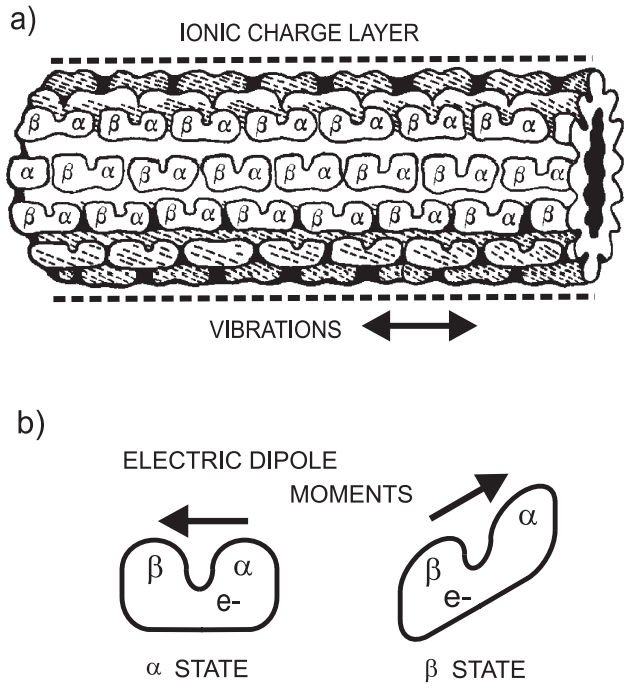

Fig. 1. (a) A schematic picture of a microtubule with tubulin heterodimers in parallel protofilaments and (b) conformation change of a heterodimer from the α to the β state after hydrolysis of GTP (guanosine triphosphate) to GDP (guanosine diphosphate) in the β-tubulin (b). The lines with arrows indicate the dipole moment vectors.

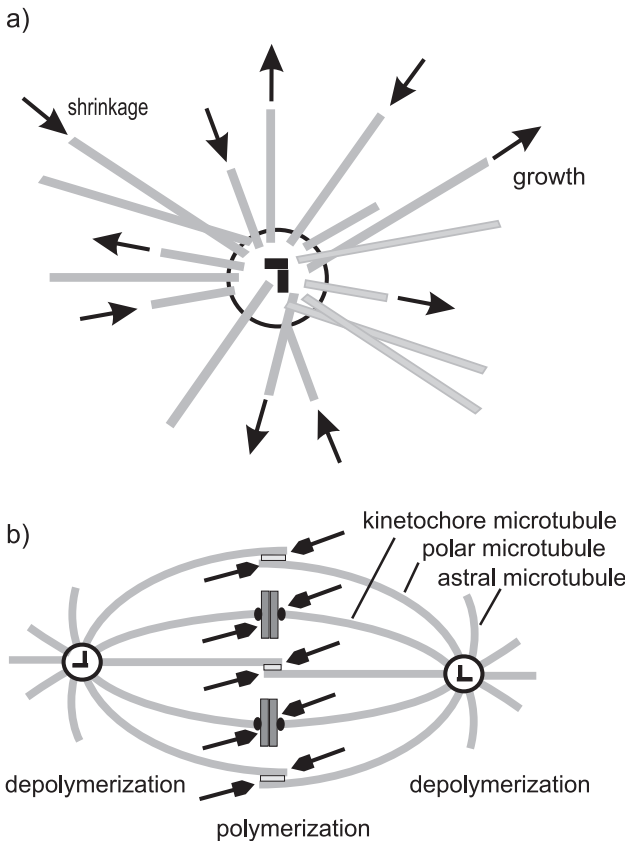

Fig. 2. (a) A centrosome with attached microtubules in the interphase. (b) The mitotic spindle in the M phase. The heterodimers with exhausted energy are exchanged for energy rich ones by the dynamic instability—the growth and shrinkage are indicated by arrows (a) and by the treadmilling—polymerization (indicated by arrows) and depolymerization take place at the center and at the poles of the mitotic spindle, respectively (b).

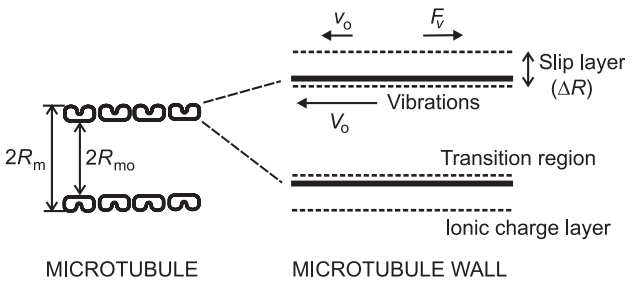

Fig. 3. A schematic picture of the microtubule wall with the slip layers. Each slip layer includes the ionic charge layer and the transition layer in the microtubule.

of the tubulin (as well as water molecules). Ions in the cytosol have small mobility and, therefore, there is slip between the charge layer and the microtubule surface.

We have to mention here that the cytoskeleton is a complicated structure with associated proteins cross-linking its parts, changing elastic properties of the structures and the viscosity effects. There are e.g. microtubule-associated proteins (MAP-1, MAP-2 forming sidearms), tau proteins and motor proteins. Phosphorylation of tau proteins plays very likely a role in microtubule binding and function [17]. Skeletor reticular matrix, spring like lattice around kinetochore microtubules, and protein cross-linked lattice around the spindle poles [18], are formed in the M phase. These structures might diminish viscosity damping but their description and analysis of their effects on excitation of microtubules is outside the scope of this paper.

3. The microtubule—a highly deformable structure

In contrast with actin and intermediate filaments the microtubules can be easily deformed and begin to flow without limit when the strain exceeds 50% (Fig. 4, [6,19]). Dynamic shear modulus G is of 5 N m^{-2} [19,20]. The dynamic shear modulus was measured in medium with ionic concentration similar to that in cytosol [19]. As the thickness of the ionic charge layer at the inner and at the outer surface of a microtubule are comparable with the thickness of the microtubule wall the measured dynamic shear modulus is an average value representing shear properties of the microtubule together with the charge layer. Therefore, as a rough approximation we will use the measured G value of the shear modulus for slip conditions inside the slip layer which consists of the microtubule surface layer (transition layer) and of the charge layer (Fig. 3). Fig. 3 shows similar slip layers on the outer and on the inner side of the microtubule wall. Large deformability is an important property for slip boundary conditions at the microtubule surface.

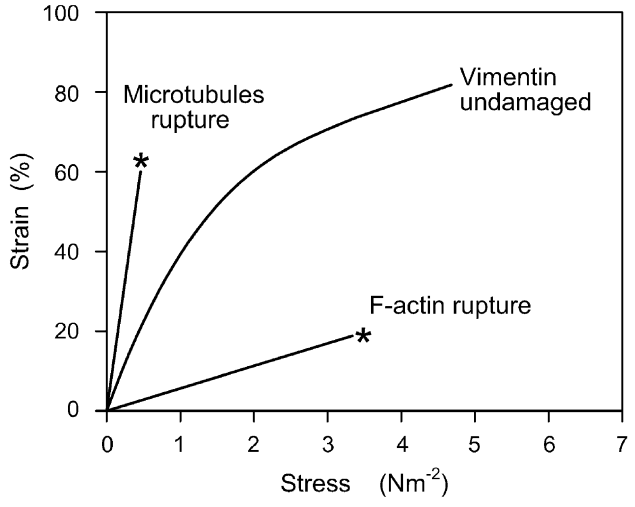

Fig. 4. Strain versus stress of actin, vimentin, and tubulin filaments. The microtubules are capable of large elastic deformation at low stress. After Refs. [6,19].

4. Energy excitation of the microtubular structure

The microtubule is a highly dynamic polymer that continuously exchange subunits (heterodimers) by the mechanism of dynamic instability (growth and shrinkage of the microtubules) and by treadmilling (heterodimers are continually added to one end and lost from the other one) [6,21,22]. After polymerization, guanosine triphosphate (GTP) bound to the β-tubulin in the heterodimer is hydrolyzed to guanosine diphosphate (GDP) and considerable amount of energy is stored in the microtubule [23,24]. Dynamic instability and treadmilling are important processes for energy supply to the microtubule structure.

The average rate of growth of a microtubule may be determined from histograms of lengths published e.g. in Refs. [25,26]. The mean microtubule length in histogram reported by Melki et al. [25] is about 0.5 μm and, therefore, the rate of growth is about 0.5 μm per 20 s. Five percent of heterodimers is incorporated into a microtubule in 1 s. For simplicity, we will assume microtubular structure where microtubules have the total length of 1 cm, and that 5% of it is exchanged in 1 s, i.e. $n = 8 \times 10^5$ of heterodimers may be replaced. From the energy released by hydrolysis of GTP to GDP, the amount $\epsilon = 7.1$ kJ mol^{-1} [23,24] is stored in the microtubule. Energy supplied within 1 s (i.e. power) $P_m = \epsilon n/L \approx \times 10^{-14}$ W cm^{-1} (where L is Avogadro's number). In the M phase of the cell cycle, the rate of exchange of heterodimers is more than one order of magnitude greater than that in the interphase and energy supply corresponds to this rate.

It is known that energy produced during GTP hydrolysis is delivered to microtubules and may be used for increase of tension in the microtubule, may excite solitons, may be transformed into vibrations and excite coherent states of the Fröhlich's type. In the last case, longitudinal polar vibrations (polarization waves) in the direction of the microtubule axis are of particular interest. These vibrations can generate electromagnetic field with dominant electric component around microtubules. Intensity of the electric field in the near vicinity of the outer surface and inside the circular cavity may be high.

Hydrolysis of GTP to GDP takes place at the fast growing end (plus end) below the cap with nonhydrolyzed GTP. The released energy may relax inside a microtubule which is from 1 to 10 μm long within about 1–10 ns for the velocity of vibration modes about 10^3 ms^{-1}. We cannot exclude energy transfer to the whole microtubule structure by this mechanism in a very short time of the order of magnitude of 10^{-8} s.

5. Viscous force at the upper surface of the slip layer

The microtubule may be approximated by a cylindrical layer with circular cross section and with rotation symmetry with respect to the microtubule axis. We will assume longitudinal harmonic vibrations along the axis of the cylinder (but independent of the distance along the axis). Due to viscosity oscillations in the microtubule excite oscillations in the liquid medium (in the cytosol) around the microtubule. The viscous force exerted by Newtonian liquid per unit area of the slip layer is given by

$$F'_v = \eta\left(\frac{\partial v}{\partial r}\right)_{r=R}, \tag{1}$$

where $\eta = \rho\kappa$ is the dynamic viscosity of the cytosol (ρ is the density of mass and κ is the kinematic viscosity), and $v = v_0\exp(i\omega t)$ is the velocity of vibrations in the direction of the microtubule axis (v_0 is the amplitude). In this case, the momentum equation is given by the diffusion equation $\partial v/\partial t = \kappa\nabla v$ [27]. Solution to the momentum equation in cylindrical coordinates can be found using Kelvin's functions [28,29] which can be expressed by Macdonald's functions (K_0, K_1). We get for the viscous force per unit length (shown in Fig. 3) [11]

$$F_v = -\beta v_0\exp(i\omega t) \quad \text{where}$$

$$\beta = \exp\left(i\frac{\pi}{4}\right)\sqrt{\omega\rho\eta}\,\frac{K_1\left(R\sqrt{i\frac{\omega}{\kappa}}\right)}{K_0\left(R\sqrt{i\frac{\omega}{\kappa}}\right)}S_i, \tag{2}$$

where R is the radius of the outer cylindrical surface and $S_i = 2\pi R$ is the area of the cylindrical surface of unit length.

6. Transfer of vibrations across the slip layer

As a first order approximation, we assume that the oscillations in a microtubule act on the damped upper surface of the slip layer by the force [11]

$$F_i = f\,Y_0\exp[i(\omega t + \phi)] \quad \text{where} \quad f = \frac{GS_i}{\Delta R}, \tag{3}$$

Y_0 is the amplitude of oscillations below the transition region in the microtubule, f is the elastic force constant, and ΔR is the thickness of the slip layer. The force F_i acts in the direction of the microtubule axis. Equation of motion for forced vibrations at the upper surface of the slip layer has the form

$$\frac{d^2y}{dt^2} + \frac{\beta}{m}\frac{dy}{dt} + \omega_0^2 y = \frac{F_i}{m} \tag{4}$$

(where ω_0 is the characteristic angular frequency, y is the displacement along the microtubule axis, and m is the mass of the slip layer). Under steady state conditions we get from Eqs. (2)–(4) for $\omega = \omega_0$ [11]

$$\frac{y_0}{Y_0} = \frac{f}{|\beta|\omega} \tag{5}$$

where y_0 is the amplitude of the displacement and $|\beta| = \sqrt{\Re(\beta^2) + \Im(\beta^2)}$. The same relation is valid for v_0/V_0 where V_0 is amplitude of velocity in the microtubule (shown in Fig. 3).

7. Relaxation time and energy losses

The average kinetic energy stored in the microtubule per unit length and the average rate of energy loss per unit length caused by viscous damping (as follows from Eq. (2)) are given by [11]

$$E = \frac{1}{4}\pi(R_m^2 - R_{m0}^2)\,\rho V_0^2 \quad \text{and} \quad E' = -\frac{1}{2}|\beta|v_0^2, \tag{6}$$

respectively. R_m and R_{m0} in Eq. (6) are the outer and the inner radius of the microtubule (Fig. 3). Using Eq. (6) the relaxation time τ and its relative value τ_{rel} (in the number of periods of oscillations) may be evaluated from

$$\tau = \frac{E}{|E'|} = \frac{1}{2}\pi(R_m^2 - R_{m0}^2)\rho\,|\beta|\,\frac{\omega^2}{f^2} \quad \text{and} \quad \tau_{rel} = \frac{\omega\tau}{2\pi}. \tag{7}$$

Fig. 5 shows the relative relaxation time as a function of frequency for $\eta = 5\times10^{-4}$ (the dashed lines) and 10^{-3} Pa s (the full lines). The range of magnitude from 5×10^{-4} to

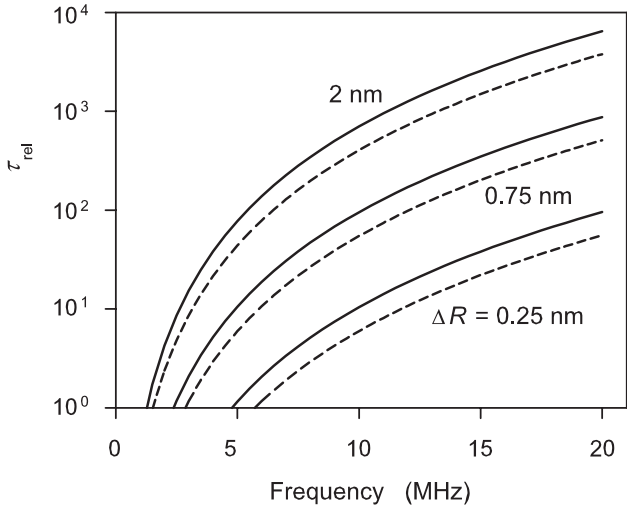

Fig. 5. Relative relaxation time τ_{rel} caused by viscous damping in a microtubule versus frequency. Parameter is the thickness of the slip layer ΔR (0.25, 0.75, and 2 nm). Dynamic viscosity η of the liquid medium is 5×10^{-4} (the dashed lines) and 1×10^{-3} Pa s (the full lines). The shear modulus G is 5 N m^{-2}.

10^{-3} Pa s corresponds to the viscosity of water for temperatures from 55 to 25 °C, respectively (more detailed information about viscosity of cytosol is in the discussion). $R_m = 12.5$ nm, $R_{m0} = 8.5$ nm [6], $R = R_m + \Delta R$, and the shear modulus $G = 5$ N m^{-2} [19]. The relative relaxation time τ_{rel} for $\Delta R = 2$ nm is about 10^3 at 10 MHz. The curves for $\Delta R = 0.25$ nm in Fig. 5 may correspond to the relaxation time for a slip in the transition surface layer of the microtubule. τ_{rel} is greater than 10 at 10 MHz. Assessment of damping for the magnitude of viscosity from 10^{-4} to 10^{-2} Pa s is in Ref. [11].

The average rate of energy loss is given by Eq. (6). We determine v_0 from Eq. (5) for amplitude of oscillations in the microtubule 0.5 nm. At 10 MHz power lost per 1 cm length is about 3.3×10^{-14} W cm^{-1} ($\eta = 5 \times 10^{-4}$ Pa s). This power is of the same order of magnitude as the power P_m supplied by hydrolysis of GTP to GDP.

8. Discussion

Fröhlich postulated that excitation of vibrations, condensation of energy in a vibration mode, and creation of the state far from thermodynamic equilibrium are fundamental physical properties of the living system [2–4]. This paper is a contribution to Ref. [7] in which we concluded that microtubules may satisfy the requirements for the Fröhlich's structure. Theoretical treatment describes a real biological mechanism of energy supply and possibility of energy excitation of a polar structure. Polar structures generate an electromagnetic field with dominant near zone electrical component which can participate for instance in the directional transport of reaction component [30], in orientation of macromolecules and polymer structures, and in polymerization processes.

We will make remarks on energy supply and energy losses conditioning excitation of the Fröhlich's system. The energy supply by hydrolysis of GTP to GDP seems to be sufficient for excitation even if we take into account losses at the outer and at the inner surface of the microtubule. Vibrations in bodies immersed in liquids are strongly damped by viscosity. Description of the properties of cytoplasm, especially of its viscosity, is contained in Ref. [31]. Cytoplasmic viscosity was measured as high as 0.011 Pa s—the value more than 10 times greater than that of water. (About 30% of mass in a mammalian cell is in the solid state form but due to compartmentalization its concentration is not uniform [6].) Other measurements revealed that apparent viscosity did not significantly differ from the viscosity of bulk water. Water is the major part of cytosol (a typical cell contains about 70% of water). Nevertheless, surface associated layers of ordered water up to the thickness of 200 nm may exist. Therefore, properties of water in living cells do not appear to be greatly altered in comparison with pure water but layers of ordered water may exist. Consequently, properties of cytosol around microtubules may differ from those of pure water and low damping of vibrations by viscosity may exist. Viscous losses from the inner surface might be very small as all the liquid medium in the cavity may be in an ordered state. We may conclude that even for viscosity of water excitation of vibrations is possible on account of the slip boundary conditions.

Experimental proof of the postulated theory is rather difficult as we have to measure living cells or subcellular structures of micrometer or submicrometer dimensions. Measurement method of electromagnetic emission from individual cells using special microelectronic sensors is described e.g. in Ref. [32]. Each detection structure in a microelectronic sensor has two electrodes 10 μm wide with a small gap between them. The electromagnetic emission of a sedimented cell at the gap is measured. The measurement results are promising. Nonetheless, the microtubular structures organized inside a cell need not be a source of electromagnetic emission from the cell. Two needle electrodes pricked inside a cell may be more convenient for measurement of the oscillating electric field generated by microtubules.

9. Conclusions

Microtubules satisfy conditions for excitation of vibrations and energy condensation. The damping effects of cytosol viscosity are minimized by slip layer at the boundary between the microtubule and cytosol. Formation of the slip layer depends on large deformability of microtubules at low stress and on the ionic layer at their surface. Energy supplied to the microtubule from the hydrolysis of GTP to GDP may be sufficient for excitation.

Abstract

Microtubules, which are thought to be the primary organizers of the cytoskeleton, are electrical polar structures with extraordinary elastic deformability at low stress and with energy supply from hydrolysis of guanosine triphosphate (GTP) to guanosine diphosphate (GDP). At least a part of the energy supplied from hydrolysis can excite vibrations. Energy is mainly lost by viscous damping of the surrounding cytosol. Viscous damping is diminished by a slip layer which is formed by an attracted ionic charge layer and by a thin surface layer of the microtubule. Relaxation time caused by viscous damping may be several orders of magnitude greater than period of vibrations at 10 MHz. Energy supplied to the microtubule is of the order of magnitude of 10^{-14} W cm^{-1} (per unit length of the microtubule).

1. Introduction

Physical processes in living matter participating in its organization are still not adequately understood. Frauenfelder et al. [1] claim than physical mechanisms of organization are of electromagnetic nature. Fröhlich pointed out that biological systems exhibit relative stability in a way in which some modes of behaviour remain very far from thermal equilibrium, postulated the existence of long range quantum mechanical phase correlations, and very strong excitation of a few modes of motion. Strong polar character of biological objects suggests longitudinal oscillations as stabilising modes [2–4]. The postulated rate equation for the *i*-th vibration mode may be written in a symbolic form

$$\dot{n}_i = s_i - [\dot{n}_i]_\phi - [\dot{n}_i(n_i, n_j)]_\chi$$

where $\dot{n}_i$ is the total rate of change of occupation number n_i (in 1 s), and s_i, $[\dot{n}_i]_\phi$, $[\dot{n}_i(n_i, n_j)]_\chi$ is the rate of change of n_i by energy supply, and by the linear and by the nonlinear interaction with the heat bath, respectively. The linear and the nonlinear term of the interaction with the heat bath describes transfer of one energy quantum between a vibration mode and the heat bath and energy transfer between two vibration modes with participation of the heat bath, respectively. The steady state solution to the rate equation shows that due to nonlinear term the supplied energy is not thermalized but condensed in a vibration mode. Excitation depends on the amount of the energy supplied to the system but not on the manner of its supply [5].

Eucaryotic cells are structurally and dynamically organized by a protein polymer network called the cytoskeleton [6]. The cytoskeleton exerts forces and generates movements without any major chemical changes. The cytoskeleton is a highly dynamic structure which reorganizes continually as the cell changes its shape, divides, and responds to its environment. The fundamental structure of the cytoskeleton formed by the microtubules satisfies the basic requirements for excitation of vibrations and generation of endogenous oscillating electric field [7]. Viscous damping by surrounding cytosol may quench excitation of vibrations. Viscosity effects on vibrations were examined using a model with longitudinal vibrations parallel to the planar interface between the microtubular medium below and the cytosol medium above the interface [8]. Slip boundary conditions make possible excitation of vibrations. Foster and Baish [9] used a cylindrical model of a microtubule but without slip boundary conditions and claimed that damping is so strong that excitation of vibrations is not possible. A cylindrical model of microtubule with the slip boundary conditions used in Refs. [10,11] confirmed the possibility of excitation. We present assessment of excitation in microtubules including viscous damping.

2. Subunits of the microtubule—electric dipoles

The microtubule is a hollow cylindrical polymer of tubulin heterodimers (Fig. 1a). The outer and the inner diameter is about 25 and 17 nm, respectively. Tubulin heterodimer—composed of α- and β-tubulins—may exist in two conformation states (Fig. 1b): the α state and the β state where the electron negative charge is placed toward the α-tubulin and the β-tubulin, respectively. In the β state, the heterodimer is tilted 29° with respect to the microtubule axis. In the interphase microtubules are organized in a radial structure extending from the centrosome to the periphery of the cell (Fig. 2a). In the M phase, microtubules assemble from the two separated centrosomes to form a mitotic spindle (Fig. 2b).

Each heterodimer binds 18 calcium ions [12–14]. The electric dipole moment is about 1000 Debye (10^{-26} Cm). The induced dipole moment per dimer arising only from the motion of mobile electrons or protons was estimated to be 200–400 Debye [15]. Ionic concentration inside a cell is of about 150 mM of cations and the same concentration of anions [6]. The ions from the cytosol form a charge layer—a cylindrical envelope around the microtubule [15]. Similar situation may be inside the microtubule (Fig. 3) as the liquid medium in the inner circular cavity is very likely to be cytosol. The ionic charge layer, which is schematically shown in Figs. 1 and 3, screens electrical potential generated by the charges in the microtubule [15]. Within a distance of about 2 Debye lengths the static potential is considerably screened. The Debye length is of about 0.8 nm [16]. Due to hydration, the ions are surrounded by bound water molecules up to a distance of 0.4–0.5 nm. Charged proteins of considerably greater size than ionized atoms may be in the ionic layer too. The majority of water molecules in the charge layer are not free and its viscous properties are dependent on hydrated ions. Some ions can penetrate inside the tubulin structure and behave like a part

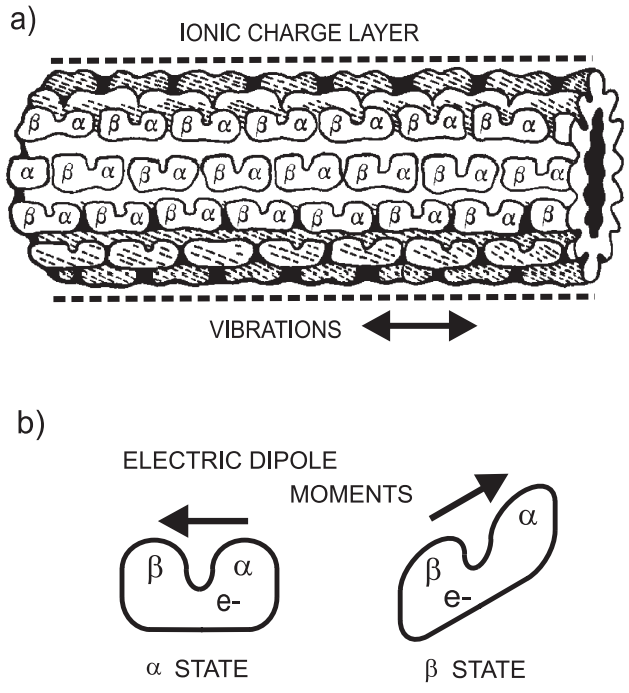

Fig. 1. (a) A schematic picture of a microtubule with tubulin heterodimers in parallel protofilaments and (b) conformation change of a heterodimer from the α to the β state after hydrolysis of GTP (guanosine triphosphate) to GDP (guanosine diphosphate) in the β-tubulin (b). The lines with arrows indicate the dipole moment vectors.

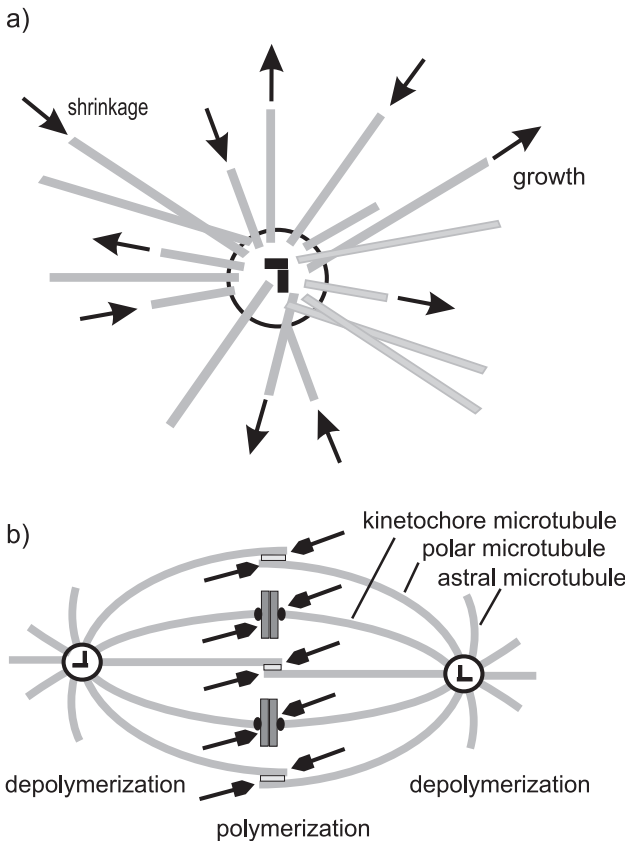

Fig. 2. (a) A centrosome with attached microtubules in the interphase. (b) The mitotic spindle in the M phase. The heterodimers with exhausted energy are exchanged for energy rich ones by the dynamic instability—the growth and shrinkage are indicated by arrows (a) and by the treadmilling—polymerization (indicated by arrows) and depolymerization take place at the center and at the poles of the mitotic spindle, respectively (b).

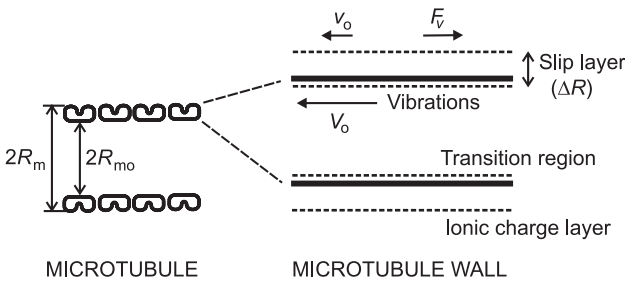

Fig. 3. A schematic picture of the microtubule wall with the slip layers. Each slip layer includes the ionic charge layer and the transition layer in the microtubule.

of the tubulin (as well as water molecules). Ions in the cytosol have small mobility and, therefore, there is slip between the charge layer and the microtubule surface.

We have to mention here that the cytoskeleton is a complicated structure with associated proteins cross-linking its parts, changing elastic properties of the structures and the viscosity effects. There are e.g. microtubule-associated proteins (MAP-1, MAP-2 forming sidearms), tau proteins and motor proteins. Phosphorylation of tau proteins plays very likely a role in microtubule binding and function [17]. Skeletor reticular matrix, spring like lattice around kinetochore microtubules, and protein cross-linked lattice around the spindle poles [18], are formed in the M phase. These structures might diminish viscosity damping but their description and analysis of their effects on excitation of microtubules is outside the scope of this paper.

3. The microtubule—a highly deformable structure

In contrast with actin and intermediate filaments the microtubules can be easily deformed and begin to flow without limit when the strain exceeds 50% (Fig. 4, [6,19]). Dynamic shear modulus G is of 5 N m^{-2} [19,20]. The dynamic shear modulus was measured in medium with ionic concentration similar to that in cytosol [19]. As the thickness of the ionic charge layer at the inner and at the outer surface of a microtubule are comparable with the thickness of the microtubule wall the measured dynamic shear modulus is an average value representing shear properties of the microtubule together with the charge layer. Therefore, as a rough approximation we will use the measured G value of the shear modulus for slip conditions inside the slip layer which consists of the microtubule surface layer (transition layer) and of the charge layer (Fig. 3). Fig. 3 shows similar slip layers on the outer and on the inner side of the microtubule wall. Large deformability is an important property for slip boundary conditions at the microtubule surface.

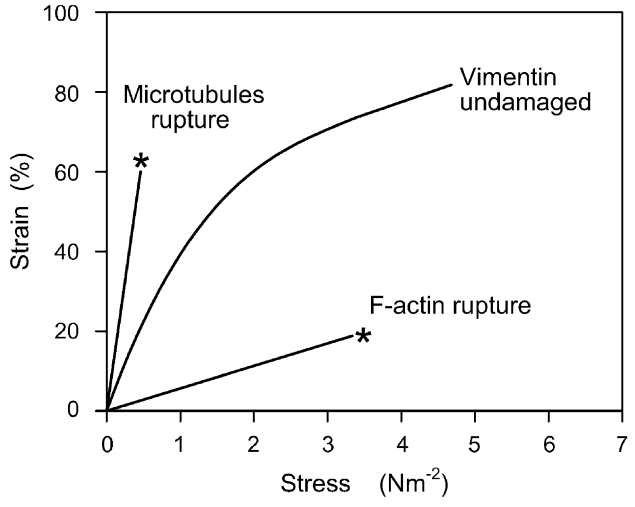

Fig. 4. Strain versus stress of actin, vimentin, and tubulin filaments. The microtubules are capable of large elastic deformation at low stress. After Refs. [6,19].

4. Energy excitation of the microtubular structure

The microtubule is a highly dynamic polymer that continuously exchange subunits (heterodimers) by the mechanism of dynamic instability (growth and shrinkage of the microtubules) and by treadmilling (heterodimers are continually added to one end and lost from the other one) [6,21,22]. After polymerization, guanosine triphosphate (GTP) bound to the β-tubulin in the heterodimer is hydrolyzed to guanosine diphosphate (GDP) and considerable amount of energy is stored in the microtubule [23,24]. Dynamic instability and treadmilling are important processes for energy supply to the microtubule structure.

The average rate of growth of a microtubule may be determined from histograms of lengths published e.g. in Refs. [25,26]. The mean microtubule length in histogram reported by Melki et al. [25] is about 0.5 μm and, therefore, the rate of growth is about 0.5 μm per 20 s. Five percent of heterodimers is incorporated into a microtubule in 1 s. For simplicity, we will assume microtubular structure where microtubules have the total length of 1 cm, and that 5% of it is exchanged in 1 s, i.e. $n = 8 \times 10^5$ of heterodimers may be replaced. From the energy released by hydrolysis of GTP to GDP, the amount $\epsilon = 7.1$ kJ mol^{-1} [23,24] is stored in the microtubule. Energy supplied within 1 s (i.e. power) $P_m = \epsilon n/L \approx \times 10^{-14}$ W cm^{-1} (where L is Avogadro's number). In the M phase of the cell cycle, the rate of exchange of heterodimers is more than one order of magnitude greater than that in the interphase and energy supply corresponds to this rate.

It is known that energy produced during GTP hydrolysis is delivered to microtubules and may be used for increase of tension in the microtubule, may excite solitons, may be transformed into vibrations and excite coherent states of the Fröhlich's type. In the last case, longitudinal polar vibrations (polarization waves) in the direction of the microtubule axis are of particular interest. These vibrations can generate electromagnetic field with dominant electric component around microtubules. Intensity of the electric field in the near vicinity of the outer surface and inside the circular cavity may be high.

Hydrolysis of GTP to GDP takes place at the fast growing end (plus end) below the cap with nonhydrolyzed GTP. The released energy may relax inside a microtubule which is from 1 to 10 μm long within about 1–10 ns for the velocity of vibration modes about 10^3 ms^{-1}. We cannot exclude energy transfer to the whole microtubule structure by this mechanism in a very short time of the order of magnitude of 10^{-8} s.

5. Viscous force at the upper surface of the slip layer

The microtubule may be approximated by a cylindrical layer with circular cross section and with rotation symmetry with respect to the microtubule axis. We will assume longitudinal harmonic vibrations along the axis of the cylinder (but independent of the distance along the axis). Due to viscosity oscillations in the microtubule excite oscillations in the liquid medium (in the cytosol) around the microtubule. The viscous force exerted by Newtonian liquid per unit area of the slip layer is given by

$$F'_v = \eta\left(\frac{\partial v}{\partial r}\right)_{r=R}, \tag{1}$$

where $\eta = \rho\kappa$ is the dynamic viscosity of the cytosol (ρ is the density of mass and κ is the kinematic viscosity), and $v = v_0\exp(i\omega t)$ is the velocity of vibrations in the direction of the microtubule axis (v_0 is the amplitude). In this case, the momentum equation is given by the diffusion equation $\partial v/\partial t = \kappa\nabla v$ [27]. Solution to the momentum equation in cylindrical coordinates can be found using Kelvin's functions [28,29] which can be expressed by Macdonald's functions (K_0, K_1). We get for the viscous force per unit length (shown in Fig. 3) [11]

$$F_v = -\beta v_0\exp(i\omega t) \quad \text{where}$$

$$\beta = \exp\left(i\frac{\pi}{4}\right)\sqrt{\omega\rho\eta}\,\frac{K_1\left(R\sqrt{i\frac{\omega}{\kappa}}\right)}{K_0\left(R\sqrt{i\frac{\omega}{\kappa}}\right)}S_i, \tag{2}$$

where R is the radius of the outer cylindrical surface and $S_i = 2\pi R$ is the area of the cylindrical surface of unit length.

6. Transfer of vibrations across the slip layer

As a first order approximation, we assume that the oscillations in a microtubule act on the damped upper surface of the slip layer by the force [11]

$$F_i = f\,Y_0\exp[i(\omega t + \phi)] \quad \text{where} \quad f = \frac{GS_i}{\Delta R}, \tag{3}$$

Y_0 is the amplitude of oscillations below the transition region in the microtubule, f is the elastic force constant, and ΔR is the thickness of the slip layer. The force F_i acts in the direction of the microtubule axis. Equation of motion for forced vibrations at the upper surface of the slip layer has the form

$$\frac{d^2y}{dt^2} + \frac{\beta}{m}\frac{dy}{dt} + \omega_0^2 y = \frac{F_i}{m} \tag{4}$$

(where ω_0 is the characteristic angular frequency, y is the displacement along the microtubule axis, and m is the mass of the slip layer). Under steady state conditions we get from Eqs. (2)–(4) for $\omega = \omega_0$ [11]

$$\frac{y_0}{Y_0} = \frac{f}{|\beta|\omega} \tag{5}$$

where y_0 is the amplitude of the displacement and $|\beta| = \sqrt{\Re(\beta^2) + \Im(\beta^2)}$. The same relation is valid for v_0/V_0 where V_0 is amplitude of velocity in the microtubule (shown in Fig. 3).

7. Relaxation time and energy losses

The average kinetic energy stored in the microtubule per unit length and the average rate of energy loss per unit length caused by viscous damping (as follows from Eq. (2)) are given by [11]

$$E = \frac{1}{4}\pi(R_m^2 - R_{m0}^2)\,\rho V_0^2 \quad \text{and} \quad E' = -\frac{1}{2}|\beta|v_0^2, \tag{6}$$

respectively. R_m and R_{m0} in Eq. (6) are the outer and the inner radius of the microtubule (Fig. 3). Using Eq. (6) the relaxation time τ and its relative value τ_{rel} (in the number of periods of oscillations) may be evaluated from

$$\tau = \frac{E}{|E'|} = \frac{1}{2}\pi(R_m^2 - R_{m0}^2)\rho\,|\beta|\,\frac{\omega^2}{f^2} \quad \text{and} \quad \tau_{rel} = \frac{\omega\tau}{2\pi}. \tag{7}$$

Fig. 5 shows the relative relaxation time as a function of frequency for $\eta = 5\times10^{-4}$ (the dashed lines) and 10^{-3} Pa s (the full lines). The range of magnitude from 5×10^{-4} to

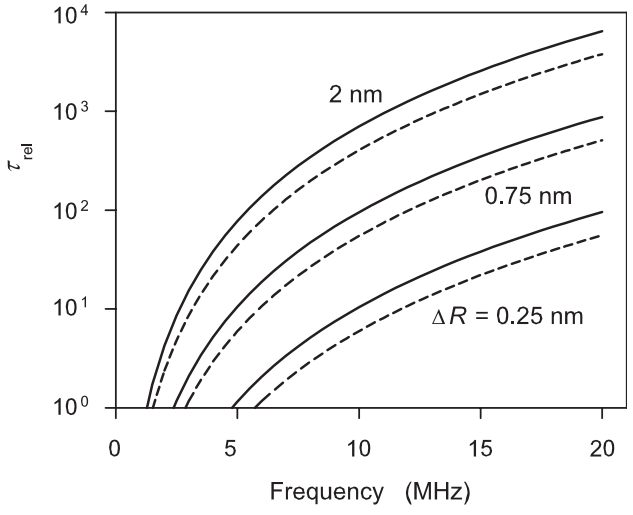

Fig. 5. Relative relaxation time τ_{rel} caused by viscous damping in a microtubule versus frequency. Parameter is the thickness of the slip layer ΔR (0.25, 0.75, and 2 nm). Dynamic viscosity η of the liquid medium is 5×10^{-4} (the dashed lines) and 1×10^{-3} Pa s (the full lines). The shear modulus G is 5 N m^{-2}.

10^{-3} Pa s corresponds to the viscosity of water for temperatures from 55 to 25 °C, respectively (more detailed information about viscosity of cytosol is in the discussion). $R_m = 12.5$ nm, $R_{m0} = 8.5$ nm [6], $R = R_m + \Delta R$, and the shear modulus $G = 5$ N m^{-2} [19]. The relative relaxation time τ_{rel} for $\Delta R = 2$ nm is about 10^3 at 10 MHz. The curves for $\Delta R = 0.25$ nm in Fig. 5 may correspond to the relaxation time for a slip in the transition surface layer of the microtubule. τ_{rel} is greater than 10 at 10 MHz. Assessment of damping for the magnitude of viscosity from 10^{-4} to 10^{-2} Pa s is in Ref. [11].

The average rate of energy loss is given by Eq. (6). We determine v_0 from Eq. (5) for amplitude of oscillations in the microtubule 0.5 nm. At 10 MHz power lost per 1 cm length is about 3.3×10^{-14} W cm^{-1} ($\eta = 5 \times 10^{-4}$ Pa s). This power is of the same order of magnitude as the power P_m supplied by hydrolysis of GTP to GDP.

8. Discussion

Fröhlich postulated that excitation of vibrations, condensation of energy in a vibration mode, and creation of the state far from thermodynamic equilibrium are fundamental physical properties of the living system [2–4]. This paper is a contribution to Ref. [7] in which we concluded that microtubules may satisfy the requirements for the Fröhlich's structure. Theoretical treatment describes a real biological mechanism of energy supply and possibility of energy excitation of a polar structure. Polar structures generate an electromagnetic field with dominant near zone electrical component which can participate for instance in the directional transport of reaction component [30], in orientation of macromolecules and polymer structures, and in polymerization processes.

We will make remarks on energy supply and energy losses conditioning excitation of the Fröhlich's system. The energy supply by hydrolysis of GTP to GDP seems to be sufficient for excitation even if we take into account losses at the outer and at the inner surface of the microtubule. Vibrations in bodies immersed in liquids are strongly damped by viscosity. Description of the properties of cytoplasm, especially of its viscosity, is contained in Ref. [31]. Cytoplasmic viscosity was measured as high as 0.011 Pa s—the value more than 10 times greater than that of water. (About 30% of mass in a mammalian cell is in the solid state form but due to compartmentalization its concentration is not uniform [6].) Other measurements revealed that apparent viscosity did not significantly differ from the viscosity of bulk water. Water is the major part of cytosol (a typical cell contains about 70% of water). Nevertheless, surface associated layers of ordered water up to the thickness of 200 nm may exist. Therefore, properties of water in living cells do not appear to be greatly altered in comparison with pure water but layers of ordered water may exist. Consequently, properties of cytosol around microtubules may differ from those of pure water and low damping of vibrations by viscosity may exist. Viscous losses from the inner surface might be very small as all the liquid medium in the cavity may be in an ordered state. We may conclude that even for viscosity of water excitation of vibrations is possible on account of the slip boundary conditions.
